Barilla thus referred to, kelp contains iodide of potassium, bromide of potassium, and sulphuret of potassiam; all of which probably exert considerable influence on vegetation. It is well known that seeds sown in pure sand, and watered with a solution of iodine, germinate very rapidly.

The residuum, when all the soda and common salt are extracted from the barilla, is principally earthy matters, which are of a very inert nature, and need not be regarded by the cultivator as possessing any peculiar fertilizing properties different from marl, which they much resemble in composition.

100 parts of these insoluble matters of kelp are composed of—

From the quantity of kelp produced on the shores of Scotland, and its reduced price since the peace, which again allowed the unrestricted import of Spanish barilla, and more especially since the discovery of a cheap mode of extracting soda from common salt, the application of kelp as a manure has engaged the serious attention of the farmers of that part of the island; and a committee was some time since appointed by the Highland Society of Scotland to report upon its pretensions; in much of that report, from which the following extracts are made, I cordially agree:—

"Your committee are unwilling to offer any theoretical opinion as to the way in which kelp may operate as a manure. From the quantity of alkali which it contains, it may naturally be expected to operate by rendering the animal and vegetable matter soluble, and a fit food for plants; but, from the series of facts to be noticed, kelp would seem to possess other qualities as a manure. Although it may be beneficially applied as a dressing by itself, yet the committee are at present inclined to think that, with a view to raising of green crops, it would be better to mix it in compost with other substances. The selection of these must depend upon what is in the ground, but the committee think that good earth or moss will form a good compost, and if to this mixture can be added a little vegetable or animal manure, a beneficial result can be relied on. In this way, a few tons of kelp would enable a farmer to extend his farm dung over at least four times the quantity of land."

The relative value of kelp as a manure may be estimated from the following experiments, made in the neighbourhood of Edinburgh:—

A field upon the estate of Inverleith, possessed by Mr. Hutchinson, was selected, which had been in wheat the year 1828, hence it was in some measure in an exhausted state: upon one ridge of this field there was sown at the rate of 12 cwt. of kelp per acre; on a second, at the rate of 10 cwt. per acre; and on a third at the rate of 4 cwt. per acre. Two other ridges were manured with the best cow and horse dung, at the rate of 20 tons per acre; and the whole was sown with wheat late in the spring of 1829. The two ridges which had got the greatest quantity of kelp were equal to that which had the ridge which had got the smallest quantity was decidedly superior to the others. Similar experiments were made upon the same field, by sowing barley after the previous crop of wheat; the result was, that the barley manured with the kelp was, according to the estimate of the tenant and his steward, a much heavier crop than after an application of horse and cow dung, and that the ridge with the smallest quantity of kelp appeared the heaviest crop.

A portion of the lands of Bangholm were manured with kelp of inferior quality, at the rate of one ton per acre, and the land sown with yellow turnip; the crop, upon examination, is considered to be fully equal to that part of the field which has been manured with dung. (Baxter's Lib. of Agr. Knowl. p. 406.)

Mr. Kerr, of Henfield, has given the result of his experiments on kelp, from which he is of opinion that "5 cwt. of kelp per Scotch acre will produce a manifest improvement on any crop." (Trans. High. Soc. i. p. 326.) Care must, however, be taken not to apply too copious a dressing of kelp. Mr. Mackinnon, of Corry, draws the following conclusion from his experiments; he used the ashes of sea-weed burnt in a heap: "of the ashes thus manufactured, 20 bushels were allowed to the acre, and distributed in the drills. When the turnips sprouted, they had an unhealthy green or rather yellowish appearance, but after some time several patches in the field seemed to be growing luxuriantly, while others seemed to retain their sickly hue. Upon a careful investigation, it was discovered that wherever the ground was deepest, and the ashes of the sea-weed had been most thrown upon the soil, the turnips were best; and, on the other hand, that where the ashes, not being mixed up with the soil, came in contact with the seed, the turnips did not at all thrive. In clearing the ground the weeds were collected into heaps, and burnt upon the spot; and it was observed that on
KELP.

the side of these heaps the turnips were very nearly as good as those on an adjoining piece of ground manured solely with dung.” (Ibid. vol. iv. p. 246.) There is a good paper on the manufacture of kelp in Quart. Journ. of Agr. vol. ii. p. 927; and on mixing kelp with compost, ibid. vol. iv. p. 556.

Every farmer has it in his power, even in the most inland situations, to procure soda for the use of his farm, by means of a mixture of two parts of lime and one part of common salt, and suffering the mixture to remain incorporated in a shady place, or covered with sods, in a dry state, for two or three months; a plan which I suggested some years since (Johnson on Salt, p. 32, 3d edit.), and which has been recently successfully adopted by Mr. Bennet, in Wiltshire. By this process a gradual decomposition takes place, chloride of calcium and soda are formed, the whole mass speedily becoming encrusted with this alkali. There is another advantage to be derived from the adoption of this process, besides the formation of the soda, viz. that the chloride of calcium is one of the most deliquescent or moisture-absorbing substances with which we are acquainted; and, in consequence, wherever it exists in a soil, the warmth of the sun has, in summer, much less influence upon it than it would otherwise have.

Mr. G. Irwin, of Taunton, bears testimony to the value of common soap-suds. “The portion of the garden invigorated by the soap-suds, only annually exhibits a luxuriance almost equal to anything this fertile neighbourhood can produce.” The Rev. J. Falconer, when commenting upon this experiment, says, “This mixture of an oil and an alkali has been more generally known than adopted, as a remedy against the insects which infest wall fruit trees. It will dislodge and destroy the insects which have already formed their nests and bred amongst the leaves. When used in the early part of the year, it seems to prevent the insects from settling upon them. Mr. Speechly, the author of a treatise upon the Cultivation of the Vine, published in 1796, used this mixture with great success, although, from not having employed a garden engine, he applied the soap-suds awkwardly and wastefully. He directs it to be poured from a ladder, out of a watering-pot, over both trees and wall, beginning at the top of the wall, and bringing it on in courses from the top to the bottom.”

Mr. Martin, of Warbleton, has recently used soda for turnips, half a cwt. per acre, previously to the last ploughing, thinking, as he observed, that it would destroy such insects as lie in the ground in an embryo state, or prevent their arriving at maturity so as to injure his crop. In respect to the use of soda on corn lands, he said he used it rather extensively last season, and that he had tried several experiments with it, both upon grass and arable land. To turn in aild of wheat, a very thin, poor, gravelly soil, he sewed one warp without any manure at all; on another warp adjoining, he used one cwt. per acre; and on a third warp he put ½ cwt. per acre. The produce of eight rods on each warp was as follows: this was in a land of a very bad description:—

KIDNEY-VETCH.

8 rods without manure, 7 gallops, or 17½ bushels.
8 rods with 1 cwt. soda per acre, 10½ gallops, or 26 bushels, 2 gallons.
8 rods with 11 cwt. soda per acre, 13½ gallops, or 32 bushels, 6 gallons.

KENNEL (Fr. chenil, from chien, a dog). The hole of a fox or other wild beast. In rural economy, a habitation for dogs, especially those of the hound kind: it should be situated a good distance from the house. Large kennels require to be kept clean, well aired, and strewed with fresh straw to prevent the mange or other infectious distempers. Those readers who wish to acquire information on the management of the kennel will do well to consult Blain’s Encyclopedia of Rural Sports.

KERN-BABY (a corruption of corn-baby) was an image formerly dressed up with corn, carried before the reapers to their harvest-home.

KERNEL (Sax. cynel, a gland). In general this word signifies the substance within a shell; but it has different meanings, sometimes implying anything included in a husk or integument, as the seed of pulpy fruits, the grain of oats, &c. In horticulture the Hardy fruits are generally arranged under the heads of kernel fruits, or pomes, including the apple, pear, quince, medlar, and service; stone fruits, as the peach, nectarine, almond, apricot, plum, and cherry; berries, as the mulberry, barberry, elderberry, gooseberry, currant, raspberry, cranberry, and strawberry; and nuts, as the walnut, chestnut, and filbert.

KIDNEY-BEAN, the kind of bean most cultivated in the United States, whereas the variety mostly cultivated in Europe is the horse-bean. See Beans.

KIDNEY-VETCH (Anthyllis; derived from α̃θυλλίς, a flower, and ἴκνος, down, in reference to the flowers being usually covered with a soft or silky pubescence). The species are, for the most part, elegant and free-flowering, plants proper for ornamenting rock-work. The hardy perennial and annual kinds thrive well in a warm situation and light soil. The greenhouse and frame kinds succeed best in sandy loam and peat; and increase plentifully from seeds, and sometimes from cuttings. (Paxton’s Bot. Dict.)

The common kidney-vetch, or ladies’ finger (A. vulgneraria), is the only species indigenous to the British Islands. It is found growing wild in chalky or limestone countries, where the soil is dry and rather barren, and the herbage affords good pasturage for sheep. The root of this species is woody, the stems annual, round, hairy, leafy, mostly simple, ascending, about a foot high. The radical leaves are simple, elliptical, on long stalks, soon disappearing; the rest alternate, pinnate, with a terminal elliptical leaflet, and several pairs of opposite, small, lanceolate ones; all entire, smooth, and a little glaucous above, hairy, or rather silky, underneath and at the margin. The flowers, which are numerous, in a pair of crowded terminal heads, accompanied by figured bracteas, are usually yellow, rarely of a fine red. In Germany, according to Haller, the flowers are most frequently white. This plant formerly had the reputation of possessing some vulne-
KITCHEN GARDEN.

A piece of ground laid out for the cultivation of fruit, herbs, pulses, and other culinary vegetables.

The kitchen garden is the most important object of the horticulturist's care, inasmuch as its productions, next to those of agriculture, tend most to the support of mankind. It often affords the chief support of the cottager, and ought to be the constant attendant of his dwelling. Of more exalted mansions it is always an accompaniment, but it is much to be regretted that a more plentiful use of its products is not adopted in preference to grosser aliment.

The kitchen garden also has for its inmates many plants chiefly valuable as rendering other kinds of food more palatable, or as possessing sanitary qualities. These last formerly far exceeded in number the edible plants. The subsequent more general employment of mineral medicines has reversed this state of our kitchen garder. The culture of aromatic herbs is also much less attended to since the introduction of spices. In selecting the site, and in erecting the enclosures, as well as in the after-preparation of the soil, the ingenuity and science of the horticulturist are essentially requisite. He will be called upon to rectify the defects, and to improve the advantages which nature affords; for it is very seldom that the natural situation of a mansion, or the plan of its grounds, allows him to construct it in the most appropriate spot.

The garden is best situated at a moderate elevation; the summit of a hill, or the bottom of a valley, is equally to be avoided. It is a fact, not very difficult of explanation, that low-lying ones are the most liable to suffer from blights and severe frosts; those much above the level of the sea are obviously most exposed to inclement winds. To determine the appropriate size of a kitchen garden is impossible. It ought to be proportionate to the number of the family, their partiality for vegetables, and the fertility of the soil. It may serve as some criterion to state, that the management of a kitchen garden occupying the space of a foot by a foot, is ample employment for a gardener, who will also require an assistant at the busiest periods of the year. In general, a family of four persons, exclusive of servants, requires a full roof of open kitchen garden. It ought not to be larger than can be conveniently cultivated; and it is too large if its proprietor is induced to bring into it the culture of the field, for that neatness and fertility which is essential to the garden can be obtained by the use of the spade only.

A wall of brick or stone is the best fence; one of paling may be placed next in order. It ought to be set close, and kept in good repair, and not lower than 6 feet, that poultry may be effectually excluded. The form of the walls or divisions must depend upon local circumstances, but to some extent the following recommendations of Bridgeman (Gardener's Assistant, p. 7), may be carried out: "Form a border round the whole garden, from 5 to 10 feet wide, according to the size of the piece of land; next to this border, a walk may be made from 3 to 6 feet wide; the centre of the garden may be divided into squares, on the sides of which a border may be laid out 3 or 4 feet wide, in which the various kinds of herbs may be raised, and also gooseberries, currants, raspberries, strawberries, &c. The centre beds may be planted with all the various kinds of vegetables. The outside borders facing the east, south, and west, will be well filled for raising the earlier fruits and vegetables; and the north border, being shady and cool, will serve for raising and prickling out such young plants, herbs, and cuttings, as require to be screened from the intense heat of the sun." The walks ought to be drained in some cases, and in all well gravelled. The edging or border may be of brick, which for a kitchen garden is preferable to all others, as it affords no shelter for slugs and vermin, is durable, and requires little labour to keep it in repair.

The order in which successive crops are grown on the same compartment has very considerable influence in prolonging the continuance of the soil in fertility. Some vegetables, as onions and carrots, are extremely impoverishing to the soil, whilst lettuces are but in a small degree prejudicial. It is, therefore, obvious, that a succession of exhausting crops should never be grown on the same bed, however plentiful manure may be, not merely because abundance is no excuse for a want of economy, but that fresh applied dung is not so immediately beneficial as those remains of organized matters, which, by long continuance in the soil, have become impalpably divided into its texture, and of which each succeeding crop consumes a portion. Those plants in general are the least exhausting which have the largest surface of leaves, and vice versa, because the first are not only possessed of a larger proportion of aqueous than solid matter than the latter, but also are enabled to obtain a greater quantity of their food from the atmosphere. It may be objected to many crops included by this rule, and especially to turnips, that they require a soil of extreme fertility; but this is only an apparent anomaly, for, although the turnip, for example, requires a rich soil, if it be wet it requires a regular supply of moisture; neither will a tenacious soil therefore be beneficial;
on the contrary, a superfluity or deficiency, according to the season, being then afforded, decay or immaturity is induced.

There are many other contingencies which should regulate the rotation of crops. The roots of different plants strike in different directions, and the size of the root systems varies, absorb different matters. Deep-rooted plants, therefore, should be succeeded by such as spread but a little below the surface; perennials always by annuals; crops left for seed, or those that are of a dry, solid texture, by such as are succulent and juicy; but, above all, the same species of plant should never be grown in successive crops upon the same ground. This is not even palliated by the excuse that manure is abundant, for, as Sir H. Davy observes, "though the general composition of plants is very analogous, yet the specific difference in the products of many of them prove that they must derive different materials from the soil; and though the vegetables having the smallest systems of leaves will proportionably most exhaust a soil of common nutritive matter, yet particular vegetables, when their produce is carried off, will require peculiar principles to be supplied to the land which produces them." (Leet. on Agr. Chem. p. 358.) It is known to every cultivator of soil, that land soon becomes tired of the same crop; in many instances, peculiar diseases are induced by the repetition. The most beneficial plan of rotation appears to be that where an exhausting and non-exhausting crop alternately succeed each other, for example,

Mr. Kelly, of Airthrey Castle, Scotland, says, that on poor ground the rotation he finds best is, 1st, celery; 2d season, cauliflowers, and red beet; 3d, cabbage, 4th, German beans or peas. By digging deep, and manuring abundantly for celery, the ground is brought into such fine tilth, that the whole rotation is often gone through without any further addition, and without failing in any of the crops.

A Hotbed will be found useful for forwarding several kinds of vegetables early in spring. In it tomatoes, egg-plants, peppers, early bush squashes, and cucumber plants may be raised, and planted out as soon as the danger of frost is over. The best material for a hotbed is fermenting stable manure, which may be mixed with a portion of cow manure or leaves, and turned over two or three times, at intervals of 5 or 6 days, before using. If dry, give it a little water at each turning. The frame may be made of strong boards or two-inch plank, about 1 foot high at front, and 1 foot at back. The width from back to front may be about 6 feet, and the length of any number of sashes that may be required. The sashes may be glazed with small glass from 5 to 10 inches. The smaller sizes will answer every purpose, are cheaper, and not so liable to break. Having the size of the frame, and a sheltered situation in which to make the bed, place a stake at each corner of it, allowing a few inches larger each way than the frame. The manure must be well shaken up and thoroughly mixed, and, in building, the bed regularly beaten down with the fork or lightly trodden, and if at all dry, well sprinkled with water. If wanted for early forcing, the bed should be at least 14 feet high; if for starting vegetables 2 feet, covering the seed with the same. The frame and sashes may then be put on, and in three or four days 8 or 10 inches of good light earth may be put in, and the seed sown. Squashes and cucumbers will do best in pots. A pot of 4 to 6 inches in diameter will be large enough for three plants. Tomatoes, egg-plants, and peppers may be sown over the bed, and afterwards thinned to regular distances. Early cabbages, cauliflowers, celery, and lettuce may be raised in the same way, and afterwards planted where wanted. But should the management of the hotbed be attended with too much trouble or expense.

The Frame can be used with much advantage, as in it plants can be raised and kept safe from frosts long before they would bear exposure in the open air. The frame may be set on the ground on the south side of the fence, and if the earth is rich and light, or made so, the seeds may be sown broadcast over a space allotted to each kind, and afterwards thinned out to proper distances. Lima beans may be started in this way, and transplanted before they attain to any great size. The frame is also useful for preserving cabbage, cauliflower, and lettuce plants during winter, for planting in the spring; as well as cabbages, lettuce, and celery for family use. A few leavés or litter put among the vegetables will aid materially in excluding the frost, and a shutter and mat must be put over the sashes in severe weather. Our object in this article is to give a condensed view of the common operations in the kitchen garden, as adapted to the United States, with a list of such varieties of the different species as are grown in this country, and can be had from the principal seedsmen in Boston, New York, and Philadelphia. Several articles are omitted, which obtain a place in some gardens, but these are either thought not to deserve a place, or to belong more properly to field culture. Fuller information on any particular subject can always be found under the proper head in the alphabetical arrangement.

Asparagus (Asparagus officinalis). Sow early in the spring; having previously soaked the seed in warm water for 24 hours, then drill it thinly, in rows sufficiently wide apart to admit the hoe; when two years old, transplant into permanent beds, which should be so situate as to cast off an excess of moisture, and having the soil prepared to the depth of two feet with plenty of manure under. A convenient width for the beds is four feet. The plants should be placed 12 inches apart in each direction; planted at least 4 inches beneath the surface; well manured at the time, and annually thereafter. If planted in rows, they should be 2½ feet apart. Common salt scattered over the bed in the winter operates favourably in-

* In compiling this article, we would here acknowledge our obligations to the excellent catalogue of D. Landreth & Co. of Philadelphia.
proving the growth of asparagus. Meat pickle or brine is still better.

Beans, English (Vicia faba). Plant very early in the spring, in rows. Broad Windsor and Mazagan are the best varieties.

Bush Beans (Phaseolus vulgaris). The Early Six weeks, China red-eye, and Red speckled Valentine, are among the earlier; the Valentine, Mohawk, and Marrow are very superior varieties. They may be planted for the first and succession crops from the middle of spring till the close of summer; the usual mode of culture is in rows, two or three in a clump, at intervals of 18 inches.

Pole or Climbing Beans (P. multiflora). The best varieties are the Lima, Carolina, White Dutch, Red and White Cranberry, and London Horticultural. The Limas are tender, and should not be planted till the close of spring. They may be forwarded by sowing them in a hotbed, and transplanting them into hills 4 feet distant from each other. Poles 8 or 10 feet long should be put into the ground before planting, and (if of seed) 6 or 8 planted round each pole, as the seed is apt to rot in cold or damp weather. Thin them afterwards, leaving three or four good plants in each hill.

The London Horticultural is an excellent variety, and may be used for the Lima in those districts where the Lima frequently fails to ripen. See Beans.

Beet (Beta vulgaris). The Turnip-rooted and Long Blood-red are generally esteemed the best for table use. The turnip-rooted is somewhat earlier than the long, and is equally good for winter use. Sow in drills from early in the spring till the commencement of summer. The plants should stand 6 or 8 inches apart in the drills, but the seed should be put in thick, to secure a full crop. A good plan is to drop several seeds together at proper distances, and when up remove all but the strongest.

Swiss Chard (Beta cicla), is much grown in Germany and Switzerland, and used as chard or asparagus. The laminne or thin parts of the leaves, are eaten as spinach or put in soups; and the stalk or midrib is boiled, and eaten with melted butter or gravy like asparagus. The culture is the same as for the blood beet, but the leaves are much larger, and a greater space should be left between the plants on that account. See Beet.

Cabbage (Brassica oleracea var. capitata). The earliest variety is the Early York; next the Early Sugarloaf, and Landreth's large York; Early Batterslea is late in the summer. The flat Dutch and Drumhead are for winter use, and red Dutch for pickling. Early and summer varieties are usually sown in seedbeds early in summer, protected therein or in cold frames, during winter, and transplanted early in the spring. Where the climate is mild, and the land light and dry, they are planted in the autumn, in which case they head earlier than those put out in spring.

Should a supply of plants not have been obtained in autumn, sow in a hotbed very early in spring, or somewhat later, on a warm border in the open air. But let it be borne in mind that in no case can fine cabbage (especially the earlier kinds) be had, unless on heavily manured and well-tilled land—heavy or strong loamy soil is best adapted to this crop.

For winter sorts, sow in a seedbed in the middle or latter end of spring, and transplant early in summer. To have these kinds to head early in autumn, sow at the same time as the early sorts. To preserve from the cabbage-fly, sow in boxes elevated two or three feet above the surface, and as soon as the plants are established, place them on the ground, lest the plants burn up. To keep them during winter, bury the stalk and part of the head with earth, over which, if the cold be severe, sprinkle straw, or put in a cold frame.

Savoy and Brussels Sprouts (B. oleracea var. bulata), are good for winter use, and become very tender after being touched by frost. Cultivate as winter cabbage.

Broccoli, Kale, &c. (B. oleracea var. acephala), may be treated as winter cabbages. They are said by Bridgeman to be delicious when rendered tender by smart frosts; and to be valuable plants to cultivate, particularly in the Southern States, as they will there be in the greatest perfection in the winter months; they will also, if planted in a gravelly soil, and in a sheltered, warm situation, bear the winter of the Western States; and may be kept in great perfection in the Eastern States, if taken up before the frost sets in with much severity, and placed in trenches up to their lower leaves, and then covered with straw or other light covering. See Cabbage.

Broccoli and Cauliflower (B. oleracea var. botrytis). Purple Cape broccoli is decidedly the best of many varieties. Sow in seedbeds in the middle of spring, and transplant and manage generally as winter cabbage. Early Asiatic cauliflower is sown in seedbeds in the beginning of autumn, kept in a cold frame during winter, and transplanted to very rich ground as soon as the frost ceases. Hand glasses or boxes put over them at night, when they are first put out, are useful. The late variety matures in autumn, and is sown at the same time, and managed like Cape broccoli. It is, however, not so sure to succeed as the broccoli, nor is it a better vegetable when obtained. See Broccoli.

Carrot (Daucus carota var. hortensis). The Early Horn is best for table use. The Long Orange is more productive. The Altrinham produces great crops, and is suitable to raise for horses and cattle. Sow the seeds in the middle of spring, in a rich, sandy loam, well pulverized, in rows a foot apart, cover about half an inch deep, and thin the plants to 4 inches distance. Gather the crop soon after the first hard frost, and keep them in a cave or warm cellar. See Carrot.

Celery (Apium graveolens). Sow the seed early in spring, in rich, mellow ground, and in a situation where the plants can be protected from the parching heat of the sun. It can either be sown broadcast or in drills, if in drills, they may be 18 inches apart. If an inch deep and 6 inches apart, that a small hoe may be worked between them. Plant out in July, in a piece of rich ground, in an open exposure, in trenches 8 or 10 inches wide, and allow the space of 4 feet between them. Dig each trench a spade deep, laying the earth equally on each side, and
put 4 inches of good rotten dung into the bottom; tread it firmly, and cover with an inch of soil from the sides, then plant a single row in the middle of each trench, leaving 7 or 8 inches between the plants. Give a plentiful watering, and shade with a board till they strike root. It may be grown also in beds, 4 feet wide, with alleys 4 feet between, prepared as above. Plant 4 rows in each bed, at from 6 to 8 inches apart, and water and shade as before. To blanch, earth up gradually in dry weather, as the plants progress in growth, repeating the earthing up every 2 weeks, at which time care should be taken to gather up all the leaves neatly, and not to bury the heart of the plants. The earthing up may begin in September. See Celery.

**Corn, Indian (Zea Maya).** There are several varieties used at table, but none are better than the common Sweet Corn.

**Cucumber (Cucumis sativus).** The Early Frame and Early Green Cluster are good varieties. The Long Green is chiefly used for pickling. As soon as the ground becomes warm in spring, plant in hills 6 feet asunder each way, putting a dozen seeds in a hill, and covering half an inch deep. Leave finally but three of the strongest plants. The ground must be rich and well manured. For very early use, sow in small pots in a hotbed; turn them into the open ground in May, taking care to protect them from the sun and late frosts. For pickling, plant in the end of June. See Cucumber.

**Egg-Plant (Solanum melongena).** Sow in hotbed, or other protected place, very early in the spring, and late in the spring transplant into very rich ground, keeping the plants about two feet asunder. The seed requires much warmth to cause it to vegetate. See Egg-Plant.

**Endive (Chichorum endivia).** Sow at close of spring to middle of summer in shallow drills; when up an inch or two, thin out to stand a foot apart. In dry weather tie up to blanch, as soon as seedled. See Cabbage and Endive.

**Leek (Allium porrum).** Sow in seed-bed middle of spring; when the plants are 4 or 5 inches high transplant into rows, setting them loosely and deeply into the soil, and leaving space to admit the hoe between them. See Leek.

**Lettuce (Lactuca sativa).** The Early Cabbage, brown Dutch, Royal Cabbage, Curled India and Tennisball are good, and stand the climate. Of the Cos varieties, which are very crisp and tender, but when sown to seed, the Egyptian Green Cos can be recommended. Sow in seed-bed from commencement to middle of autumn, protect the plants by a cold frame or with litter as they stand on the ground; early in the spring transplant them into rich ground. For a later supply, sow in drills from time to time during spring and summer; when up a few inches, thin out, leaving plants at proper distances. See Lettuce.

**Melon (Cucumis melo).** The Citron, Persian, Nutmeg, and Murray's Fine-apple are good varieties of the canteelop or musk-melon. Plant from light soil, at the distance of 6 feet asunder, in the latter end of spring, putting 6 or 8 seeds into each hill, 2 inches distant from one another, and half an inch deep. Thin out to 3 in each hill; draw the earth from time to time about the hills as high as the seed leaves. Pinch off the top at the first or second joint, as this will strengthen the plants, and cause them to fruit early. Grow no pumpkins or squashes near them.

**Melon, Water (Cucurbita citrullus).** The Spanish and Mountain Squash are good varieties. The Citron is cultivated for preserves. Cultivate as for canteelups, but let the hills be 7 or 8 feet distant.

**Okra (Hibiscus esculentus).** Plant in good, rich ground late in spring, as it is a very tender vegetable. Make drills an inch deep, and 3 or 4 feet asunder, into which drop 2 or 3 seeds together, at intervals of about 8 inches, and cover them nearly an inch deep. Thin them out to 8 or 10 inches as the plants advance, and earth up 2 or 3 times. See Onions. See that head.

**Parsley (Apium petroselinum).** Sow in rows early in the spring. By soaking the seed in warm water some hours immediately before sowing, it will vegetate more speedily. It sometimes lies in the ground 2 or 3 weeks before vegetating.

**Parsnip (Pastinaca sativa).** Sow early in spring, in good soil, deeply dug, making drills 18 inches apart. When the plants are 2 or 3 inches high, thin out to 6 or 8 inches apart.

**Pea (Pisum sativum).** Landreth's Extra Early, and Bishop and Russell's Early Dwarfs are the earliest varieties, and good of their kind. Dwarf Blue Imperial, and Dwarf Scimtar are much esteemed. Knight's Dwarf and Tall Marrowfats are late kinds, but superior to all others for flavour and productiveness. Tall and Dwarf Sugar or string peas are sweet, and productive; they are boiled without shelling, and served up as kidney beans. The dwarfs require sticks from 2 to 3 feet long, the others from 4 to 6, and a greater width between the drills.

**Pepper (Capsicum).** Grossum or bell-shaped, Large sweet, and Squash or tomato-shaped, are used for pickling; the last variety is the best. The Sweet has a delicate taste, and is used as a salad. Sow in hotbed in March, and transplant; or in the open ground, late in spring, in drills 2 feet apart. When the plants are an inch or two high, thin them out to about 15 inches apart in the rows, and hoe them repeatedly.

**Porto.** See that head.

**Radish (Raphanus sativus).** Short-top Scarlet, Salmon, Red and White turnip-rooted, may be sown in the spring, as early as the ground can be worked. Yellow turnip-rooted and Summer White are best for summer use. White and Black Spanish for winter. Sow these at close of summer, or early in autumn, and when ripe store them in a cellar. For a succession in spring and summer, sow every two weeks. The ground should be light, rich, and well worked.

**Rubarba (Rheum).** Tobolisk, Mammoth, and Giant, are the best varieties, and may be raised by dividing the roots early in spring, and planting them in rich, deep soil, in rows 4 feet asunder and 3 feet distant in the rows.
KNAPWEED.

To raise from seed, sow late in autumn or early in spring. Young seedling plants require to be protected the first winter by soil. To force very early, cover with boxes or barrels surrounded and covered with horse manure. Gather before the leaves are fully expanded. Salsify, or Vegetable Oyster (Tragopogon porrifolius). Cultivate as directed for carrot. Sea-Kale. See Kale, Sea.

Spinach (Spinacia oleracea). Round Savoy-leaved, and Prickly seeded. May be grown either broadcast or in drills. For spring and early summer use, sow as early as the ground can be worked and earthers at short intervals. For the autumn supply, sow at close of summer. For winter and early spring use, sow middle of autumn. The latter sowing will need a sprinkling of straw or long manure on the arrival of cold weather. Spinach is one of those vegetables for which the ground cannot be too rich; the stronger it is the more succulent will be the leaves, and of course the more delicate and tender. Squash (Cucurbita maxima). Early Bush, Early Crook-neck, Early Orange, Valparaiso, Winter and Canada Crook-necks. The three first are early varieties. The bush occupies but little room, and is best adapted for small gardens. Cultivate as directed for cucumber. The three last are winter varieties, and require more room.

Tomato (Solanum lycopersicum). Sow in hotbed in March or April, or in a warm border early in spring, and transplant, after settled warm weather, in rows 4 feet apart and about 3 feet distant in the row. They may be supported with brushwood, or trained to a trellis or fence.

Turnip (Brassica rapa). Early White Dutch, Early Stone, Early Red-topped, are best for early garden culture. For winter use the Rutabaga, Yellow Stone, Yellow Aberdeen, and Dale's Hybrid, are excellent. There is also a variety of aromatic and medicinal herbs cultivated in the kitchen garden, which are useful for many purposes. Of these, the Bene Plant, Sweet Basil, Caraway, Coriander, Sweet Marjoram, and Summer Savory are the seeds of which may be sown in the middle of spring, and thinned out to convenient distances.

Balm, Chamomile, Horehound, Hyssop, Fennel, Lavender, Mint, Pennyroyal, Rosemary, Rue, Sage, and Thyme, are perennials, and may be propagated by offsets or parting of the roots, and from seed sown in drills, and afterwards transplanted. These are the most useful productions of the kitchen garden. The varieties named are believed to be the best, and such as are most certain, in the United States, to repay their culture. Those who desire to go extensively into the cultivation of vegetables, can consult the works of M'Mahon, Bridgeman, and Fessenden, for more minute details of the modes of culture and more extensive lists of varieties.

Much success in cultivating vegetables will depend on the rotation of crops. The same kinds should not be grown on the ground successively. The ground must also be kept rich, by the application of manure, well-worked, and above all kept clear of weeds. I ought always to be remembered that what will nourish a crop of weeds will produce a crop of useful vegetables; and no operation will tend more to produce luxuriant vegetation, and prevent the ill effects of drought, than the frequent use of the hoe.

For the compilation of the preceding article we are indebted to Mr. William Sinton, gardener to General Patterson, Philadelphia.

KNAPPIA, EARLY (Knappia agrostidea). It was named by Sir J. Smith in compliment to Mr. M. Knapp, a writer on British grasses. Of this, one of the least of the British grasses, only one species is known; although common on the coasts of France, it is very rare in England, but is found in maritime pastures, sometimes in Wales. It is an annual; root of many long, slender fibres; stems 1 to 3 inches high, erect, simple, slender, smooth, triangular, naked, except at the very bottom, where they are invested with the membranous sheaths of a few short, obtuse, channelled leaves. Stipules membranous, bluntish, cloven, but not deeply divided. Spikes solitary, simple, erect, of from 6 to 10 flowers, mostly sessile, alternate, erect; two or three of the lowermost only or less stalked; their common stalks zigzag, slender, smooth, angular, but not excavaed, as in the truly spikcd grasses. Flow- ers, like the top of the stem, purplish. (Eng. Flor. vol. i. p. 84.)

KNAPWEED (Centanarea). This is a large herbaceous genus of plants, which Jussieu, after Tournefort, has divided into several, by the structure or termination of the calyx scales. Linnaeus has kept entire, and Decandolle has not disturbed it. Smith (Eng. Flora), also, makes one family of them. The following are the indigenous species known under the common name of knapweed. I have treated of other species under the heads Blue Bottle and Star Thistle.

1. Brown radiant knapweed (C. Jacea). This grows in meadows where the soil is tenacious and moist. It is a perennial, flowering in Aug-est and September. The root is rather woody, with many long fibres. Stem solid, erect; a foot high, branched, angular, furrowed and roughish, leafy. Leaves, light green, rough, with short hairs; radical ones largest, stalked, toothed or pinnatifid; the rest scattered, sessile, oblanceolat, entire, or toothed near the base. Flowers large, numerous, radiant, light crimson, solitary at the gumid end of each branch, accompanied by a few leaves close to the calyx, which is brown; the calyx scales are membranous, torn. Linnaeus says, the herb steeped in water, with alum, before the flowers expand, dyes silk of a fine yellow.

2. Black knapweed (C. nigra). This grows in pastures and by roadsides; very common, flowering from June to August. In habit it is like the last, but the stem is taller, more bushy, more deeply furrowed, and rather less rough. The lower leaves are somewhat lyrate, with angular lobes; upper ones ovate; their colour always darker than that of C. Jacea. The flowers are also of a deeper crimson, commonly without any radiant or abortive florets. The flowers are occasionally white.

\[3 \times 2\]
3. Greater knapweed (C. segetum). This is also a very common species, growing in the borders and ridges of corn-fields, and by waysides. The root is somewhat woody; stem about two feet high, erect, branched, angular, furrowed, leafy, smooth to the touch. Leaves dark green, slightly hairy on both sides, pinnatifid. The flowers, which blow in July and August, are terminal, stalked, solitary, large, and of a handsome crimson colour, rarely white; their radiant florets are large, each with five deep, long, and narrow segments. Calyx-scales ovate, green, somewhat downy, fringed with fine parallel teeth. The seeds are crowned with many reddish bristles; and after they are blown away, the calyx becomes reflex, and displays the silvery shining hue of its inside. (Eng. Flor. vol. iii. p. 463.)

KNAWEL. (Sedananthus, from σαγρά, hard, and σάβα, a flower; in allusion to the dry, juiceless calyx). These are dry, rigid herbs, which can only be considered as useless weeds.

The genus is European. There are several species, one of which, called S. annus, is so abundantly naturalized in sandy, arable fields, as to appear native to some of the United States. (Nuttall.)

1. The annual knawel, or German knot-grass (S. annus), which grows commonly in dry, sandy soils and corn-fields, flowering in July. The root is small and tapering. The stems numerous, widely spreading, and partly decumbent; round, leafy, a little downy, branched, and many-flowered at the upper part. Leaves linear, acute, pale green, combined at the base by a membranous fringed border. Flowers small, green, nearly sessile, partly collected into dense forked tufts. Calyx of the fruit spreading, with taper, acute segments. The Swedes and Germans introduce occasionally the steam arising from a decoction of the knawel into their mouths, with a view to cure the toothache. Its leaves are astringent. Goats and sheep eat this plant, but cows totally refuse it.

2. Perennial knawel (S. perennis). This species is less common; it flowers from August to October, while the annual knawel blows in July. The root is woody, branched, with many decumbent or prostrate stems, 3 or 4 inches long. The whole herb is of a glaucous, glistening appearance, turning red with age, especially the stems. The leaves are more tapering, crowded, and curved, than in the foregoing. Segments of the calyx more obtuse, concave, and finally converging. In several parts of Europe the roots of this species are attacked by the insect called Coccopolvus (Linn., Syst. vol. i. p. 741), which yields a fine crimson dye: it is said likewise to live on S. annus and on some Potentilla. A good account of its economy is given in the Ussel Transactions for 1742, i. t. p. 51.

KNOT-GRASS. A name sometimes given to the rough panic grass.

KNIGHT, THOMAS ANDREW, President of the Horticultural Society of London, F.R.S., &c., a distinguished vegetable physiologist and horticulturist, was born at Wormsley Grange, in Herefordshire, August 12, 1783. "My father," says Mr. Knight, in a late communica-
KNOT-GRASS. out like a large orange-coloured ball, which makes it very difficult for them to move about. I have found these insects on the knot-grass in every month from April to September inclusive. The larvae eat the leaves of the same plant. (Harris.)

**KNOT-GRASS, COMMON** (*Polygonum aviculare*; from *πολυγονός*, many, and *αὐκήλα*, a knee; referring to the numerous joints of the stem). This common annual grass is in England found almost everywhere, in waste as well as cultivated ground, streets, paths, and barren sandy places. The root is fibrous, long, very tough, and somewhat woody, branched below, simple at the crown. Stems several, spreading in every direction, generally prostrate, much branched, round, striated, leafy at the numerous knots or joints. Leaves alternate, stalked, hardly an inch long, elliptic or lanceolate, entire, obtuse, single ribbed, smooth except at the margin; tapering at the base, very variable in width; their substance rather coriaceous; their colour greyish or glaucous, stipules membranous, acute, often red, with a few remote, brownish ribs. The flowers which appear from April to October are axillary, 2 or 3 together, stalked, small, seeds acute, finely triangular, of a shining black, the food of many small birds. It is common in the United States.

**KNOT-GRASS, VALENTIA.** A name by which the powdery sea-heath (*Frankenia pulverulenta*), is known in some districts.

**KNOT-GRASS, WHORLED** (*Pileaenum verticillatum*). This is an interesting dwarf perennial plant, which is not uncommon in marshy, boggy ground in Cornwall and Devonshire, flowering in July. The different species are pretty, may be grown in any soil, and increase from seed without difficulty. The root is creeping; herb smooth, branched, procumbent. Leaves small, ovate, acute, or sometimes spatulate, scarcely stalked, rather fleshy. Stipules intra-foliaceous, small, white, jagged. The flowers are small, white, or reddish, whorled, without bractes. (Eng. Flor. vol. i. p. 335.)

**KNOT-WEED.** See *Persicaria.*

**KOHL-RABI.** Brown-stalked cabbage (*Brassica oleracea*, var. *cauda-rapa*). This curious variety of cabbage is a native of Germany, where it is much cultivated, and whence it was first introduced into England by Sir Thomas Tyrwhitt. The stem is swollen like a tuber, and, when divested of the leaves, may readily be mistaken for one. The produce is nearly the same as that of Swedish turnips, and the soil that suits the one is equally good for the other. It may either be sown in drills, or raised in beds, and transplanted like cabbages; in this case the beds require to be made and sown the preceding autumn. Two pounds of the seed will produce a sufficiency of plants for one acre of ground. Hares are so fond of it, that, on farms where these animals abound, the culture of this plant is found to be impracticable. 3840 grains of the tubes of kohl-rabi afford 105 grains of nutritious matter (Sinclair's Hort. Gram. p. 411). See *Cabbage*, p. 247.

LABOUR. I.

**LABELLUM** (Lat.). In botany, the front segment of an orchidaceous or other flower; also the lower petal or lip.

**LABOUR** (Fr. *labeur*; Lat. *labor*). In a general sense, labour implies the exertion of human strength in the performance of any kind of work. Without entering into an abstruse treatise on the science of political economy, it may not be out of place to examine shortly the subject, for labour is the only source of wealth to the farmer; and having done this, I shall next inquire into the means by which labour may be rendered most efficient. Nature spontaneously furnishes the matter of which all commodities are made; but until labour has been applied to appropriate that matter, or to adapt it to our use, it is wholly destitute of value, and is not, nor ever has been, considered as forming wealth. Were we placed on the banks of a river, or in an orchard, we should infallibly perish of thirst or hunger, unless by an effort of industry we raised the water to our lips, or plucked the fruit from its parent tree. But this illustration is an extreme case; and it is more to our purpose to remark, that the mere appropriation of matter is seldom sufficient. In the vast majority of cases, labour is required not only to appropriate matter, but to convey it from place to place, and to give it that peculiar shape without which it may be totally useless, and incapable of administering either to our necessities or our comforts. The coal used in our fires is buried deep in the bowels of the earth, and is absolutely worthless, until by the labour of the miner it has been extracted from the mine, and brought into a situation where it may be made use of. The stones and mortar used in building our houses, and the rugged and shapeless materials that have been fashioned into the various articles of convenience and ornament with which they are furnished, were in their original state destitute alike of value and utility. And of the innumerable variety of animal, vegetable, and mineral products which form the materials of our food and clothes, none were originally serviceable, while many were extremely noxious to man. The labour that has sublued their bad qualities, that has given them utility, and fitted them to satisfy our wants, and to minister to our comforts and enjoyments, is plainly therefore the only source of wealth. "Labour," to use the words of Adam Smith, "was the first price, the original purchase-money, that was paid for all things. It was not by gold or by silver, but by labour, that all the wealth of the world was purchased." (Wealth of Nations, p. 14.) Those who observe the progress and trace the history of the human race in different countries and states of society, will find that their comfort and happiness have in all cases been principally dependent on their ability to appropriate the raw products of nature, and to adapt them to their use. The savage whose labour is confined, like that of the Australian, to the gathering of wild fruits, or of shell-fish on the sea-
LABOUR.

coast, is placed at the very bottom of the scale of civilization, and is in point of comfort decidedly inferior to many of the lower animals. The first step in the progress of society is made when man learns to hunt wild animals, to feed himself with their flesh, and clothe himself with their skins. But labour, when confined to the chase, is extremely barren and unproductive. Tribes of hunters, like beasts of prey, whom they closely resemble in their habits and modes of subsistence, are but thinly scattered over the countries which they occupy; and, notwithstanding the farness of their numbers, any unusual deficiency in the supply of game never fails to reduce them to the extremity of want. The second step in the progress of society is made when the tribes of hunters and fishers devote themselves, like the ancient Scythians and modern Tartars, to the domestication of wild animals and the rearing of flocks. The subsistence of herdsmen is much less precarious than that of hunters; but they are almost entirely destitute of the various comforts and elegancies that give to civilized life its chief value. The third and most decisive step in the progress of civilization, in the great art of producing the necessaries and conveniences of life, is made when the wandering tribes of hunters and shepherds renounce their migratory habits and become agriculturists and manufacturers. It is then that man begins fully to avail himself of his productive powers. He then becomes laborious, and by a necessary consequence his wants are then, for the first time, fully supplied, and he acquires an extensive command over the articles necessary for his comfort as well as his subsistence. The importance of labour in the production of wealth was very clearly perceived by Locke. In his Essay on Civil Government, published in 1689, he has entered into a lengthened, discriminating, and able analysis, to show that it is from labour that the products of the earth derive almost all their value. "Let us at one time draw a parallel between the four different kinds of labour and the four elements, and observe what the difference is between an acre of land planted with tobacco or sugar, sown with wheat or barley, and an acre of the same land lying in common, without any husbandry upon it, and he will find that the improvement of labour makes the far greater part of the value. I think it will be but a very modest computation to say, that of the products of the earth useful to the life of man, ninety-nine hundredths are the effects of labour; nay, if we rightly estimate things as they come to our use, and cast up the several expenses about them, what in them is purely owing to nature, and what to labour, we shall find that in most of them ninety-nine hundredths are wholly to be put on the account of labour.

There cannot be a clearer demonstration of any thing than several nations of the Americans are of this, who are rich in land and poor in all the comforts of life; whom nature having furnished as liberally as any other people with the materials of plenty, i. e. a fruitful soil apt to produce in abundance what might serve for food, raiment, and delight, yet for want of improving it by labour have not one hundredth part, of the conveniences which might be enjoyed. 692

LABOUR.

"To make this a little clearer, let us but trace some of the ordinary provisions of life through their several progressions before they come to our use, and see how much they receive of their value from human industry. Bread, wine, and cloth are things of daily use and great abundance; yet, notwithstanding, acorns, water, and leaves or skins must be our bread, drink, and clothing, did not labour furnish us with these more useful commodities. For whatever bread is more worth than acorns, wine than water, and cloth or silk than leaves, skins, or moss, that is solely owing to labour and industry; the one of these being the food and raiment which unassisted nature furnishes us with; the other provisions which our industry and pains prepare for us; which how much they exceed the other in value, when any one hath computed, he will then see how much labour makes the far greatest part of the value of things we enjoy in this world. And the ground which produces the material is scarcely to be reckoned in as any, or, at most, but a very small part of it; so little that even amongst us, land that is wholly left to nature, that hath no improvement of pasturage, tillage or planting, is called as indeed it is, waste; and we shall find the benefit of it amount to little more than nothing.

"An acre of land that bears here twenty bushels of wheat, and another in America, which, with the same husbandry, would do the like, are, without doubt, of the same natural intrinsic value (utility). But yet the benefit mankind receives from the one in a year is worth five pounds, and from the other possibly not worth a penny, if all the profit an Indian received from it were to be valued and sold here; at least, I may truly say, not one thousandth. It is labour, then, which puts the greatest part of value upon land, without which it would scarce be worth anything. It is to that we owe the greatest part of all its useful products; for all that the straw, bran, bread, of that worth of wheat, is mere worth in addition to the product of an acre of good land which like waste, is all the effect of labour.

"For it is not barely the ploughman's pains, the reaper's and thresher's toil, and the baker's sweat is to be accounted into the bread we eat; the labour of those who sell the oxen, who dined and wrought the iron and stones, who felled and framed the timber employed about the plough, mill, oven, or any other utensils, which are a vast number, requisite to this corn; from its being seed to be sown to its being made bread, must all be charged on the account of labour, and received as an effect of that; nature and the earth furnished only the almost worthless materials as in themselves. It would be a strange catalogue of things that industry provided and made use of about every loaf of bread before it came to our use, if we could trace them; iron, wood, leather, bark, timber, stone, bricks, coals, lime, cloth, dyeing drugs, pitch, tar, masts, ropes, and all the materials made use of in the ships that brought away the commodities made use of by any of the workmen to any part of the work; all which it would be least impossible, at least too long, to reckon up."
LABOUR.

Labour is the sole source of exchangeable value, and, consequently, of wealth. It is the talisman that has raised man from the condition of the savage; that has changed the desert and the forest into cultivated fields; that has covered the earth with cities, and the ocean with ships; that has given us abundance, comfort, and elegance, instead of want, misery, and barbarism. Labour, according as it is applied to the raising of raw produce, to the fashioning of that raw produce, when raised into articles of utility, convenience, or ornament, or to the conveyance of raw and wrought produce from one country or place to another, is said to be agricultural, manufacturing, or commercial. An acquaintance with the particular process, and most advantageous methods of applying labour in each of these grand departments of industry, forms the peculiar and appropriate study of agriculturists, manufacturers, and merchants.

In the endeavouring to exhibit the importance of labour, and the advantages which its successful prosecution confers on man, it must not be supposed that reference is made to the labour of the hand only. This species, indeed, comes most under our observation; it is that, too, without which we could not exist, and which principally determines the value of commodities. It is questionable, however, whether it is really more productive than the labour of the mind. The hand is not more necessary to execute than the head to contrive. All the means by which labour may be facilitated and wealth increased resolve themselves, 1st, into the better division and combination of employment among individuals and nations; and 2d, into the more extensive or more judicious application of capital or stock in industrious undertakings.

The division of employments can only be imperfectly established in rude societies and thinly-peopled countries; but in every state of society—in the rudest as well as the most improved—we may trace its operation and effects. Even in the simplest business this co-operation and subdivision is required; neither hunting nor fishing, any more than agriculture or manufacture, can be advantageously carried on by solitary individuals. As society advances, this division of labour extends itself on all sides; one man becomes a tailor or dresser of skins, another a weaver, a third a smith, and so on. The wealth and comforts of all classes, in consequence, prodigiously augment. In countries where the division of labour is carried on to a considerable extent, agriculturists are not obliged to spend their time in clumsy attempts to manufacture their own produce, and manufacturers cease to interest themselves about the raising of corn, and the fattening of cattle. The facility of exchanging is the vivifying principle of industry; it stimulates agriculturists to adopt the best system of cultivation, and to raise the largest crops, because it enables them to exchange whatever portion of the produce of the land exceeds their own wants for other commodities contributing to their comforts and enjoyments, and it stimulates manufacturers and merchants to increase and improve the quantity, variety, and quality of their goods, that they may thereby obtain greater supplies of raw produce. A spirit of industry is thus universally diffused; and that apathy and languor which characterize a rude state of society entirely disappear.

Besides that sort of division of labour which enables each individual in a united society to confine himself to a particular employment, there is another and most important branch of the division of labour, which not only enables particular individuals, but the inhabitants of entire districts, and even nations, to addict themselves in preference to certain branches of industry. It is on this territorial division of labour, as it has been appropriately termed, that the commerce carried on between different districts of the same country, and between different countries, is founded. The variations in the situation, soil, climate, mineral products, &c. of the different districts of an extensive country, render them more suitable for some than for other species of industry. A district where coal is abundant, which has an easy access to the ocean, and a considerable command of internal navigation, is the natural seat of manufactures. Wheat and other species of grain are the proper products of rich arable soils; and cattle, after having reared in mountainous districts, are most advantageously fattened in meadows and low grounds. Nothing can be more obvious than that the inhabitants of these different districts will be able, by confining themselves to those employments, for the prosecution of which they have some peculiar capability, to produce a much greater quantity of useful and desirable articles than they could do were they to engage indiscriminately in every possible employment.

Providence, by giving different soils, climates and natural productions to different countries, has evidently provided for their mutual intercourse and mutual civilization. By permitting the people of each to employ their capital and labour in those departments in which their geographical situation, the physical capacities of the soil, their national character and habits fit them to excel, foreign commerce, or the territorial division of labour, has a wonderful influence in multiplying the products of arts and industry.

Having been led thus far into this fertile subject, I will conclude with some apposite and excellent observations by Dr. Paley:—"Every man has his work. The kind of work varies, and that is all the difference there is. A great deal of labour exists besides that of the hands; many species of industry besides bodily operation, equally necessary, requiring equal assiduity, more attention, more anxiety. It is not true, therefore, that men of elevated stations are exempted from work; it is only true that there is assigned to them work of a different kind; whether more easy or more pleasant may be questioned; but certainly not less important, nor less essential to the common good." *(Breward's Dict. of Lit. and Art.)*

LABOURER. One who is employed in coarse and toilsome work. But, in agriculture, the term is applied to a person who performs the manual or most laborious part of
the business of a farm. The price of labour has at all times varied; and, as the poorer classes feel, with additional rigour, every evil arising from the pressure of the times, different expedients have been devised, with a view to alleviate their burdens, supply their wants, and render them more comfortable. From these investigations, it appears that, in the middle of the 14th century, the usual price of labour was 2d. per day, and wheat was sold at from 3s. 4d. to 4s. per quarter. In the middle of the 15th century the pay of a labourer per day was 3d., and wheat cost from 5s. to 5s. 6d. per quarter. In the earlier part of the 16th century the price of labour rose to 3½d., and that of a quarter of wheat to 7s. 6d. About the middle of the 17th century the pay of a labourer upon an average was (in Essex) 13d., and corn had risen to 40s. per quarter. Towards the latter end of the 18th century the daily pay of a labourer was from 14d. to 18d. in the country, and from 2s. to 2s. 6d. in the metropolis, while the price of wheat was 48s. per quarter. The payment of daily wages, however, serves but imperfectly to ascertain the real price of labour, as a considerable portion of work is performed by the piece, so that a labourer in general earns from 3d. to 6d. per day more than by the common pay. The curious and philanthropic reader, who feels an interest in this popular inquiry, will be fully gratified by a perusal of Mr. Davies’s Case of Labours in Husbandry Stated and Considered, &c. 4to, 1795, p. 200; and Sir F. M. Eden’s State of the Poor, &c., 3 vols. 4to, 1797. Mrs. Davies Gilbert of Eastbourne, a lady whose active interest for the prosperity of agriculture, and the improvement of the condition of the labouring poor, may fairly (as has been justly observed) be set as an example for many country gentlemen to follow, urges most strenuously, in many publications (but particularly in the Quart. Journ. of Agr. vol. xii. p. 252), the advantages to be derived from manual labour, in preference to horse labour. In England, very prevalent persons of distinguished rank have also recently taken up the cause of the labourer, and formed themselves into a society, very appropriately named “the Labourer’s Friend Society.” They advocate strongly, and endeavour to promote more generally the system of home colonies for the cultivation of waste land. See Allotment and Spade Husbandry, Farm Servants, Workmen, &c.

Concerning the most valuable class of men that a populous country possesses, should have every comfort provided for them that is compatible with their situation, and conformable to the general interest of the community. Their wages ought to be everywhere and at all times sufficient for the maintenance of themselves and families while in health, with a surplus to provide against the day of sickness, without their being under the debasing necessity of making application to their neighbours for relief. Persons so essential to society should not merely support existence, but have the comforts of wholesome habitations, with sufficient spaces of ground to furnish them and their families with changes of proper vegetable food without much expense.

LACTARY. A milk-house, dairy, or place where milk is kept. The term has been made to designate the whole establishment of a dairy. See Dairy.

LACTIC ACID. This substance, in the opinion of Berzelius and some other chemists, exists in milk, and in larger proportion when it has become sour; but others imagine that it is the product of its decomposition. It was first recognised as a peculiar acid by Scheele, but he did not obtain it perfectly pure. It was afterwards observed by Berzelius in many animal fluids; and by Braconnet to exist with acetic acid in fermented rice-meal, wheat-paste, the juice of the beet-root, and other vegetable substances: he named it nancecid. It is formed, also, during the putrefactive process in some animal bodies. Lactic acid is a colourless, inodorous, syrupy liquid, and very sour. It may be so concentrated as to have a specific gravity of 1·215: it attracts moisture from the atmosphere, and dissolves in water and alcohol in all proportions. At 48° Fahrenheit, it is decomposed. When added to boiling milk, it is capable of immediately coagulating about 700 times its weight; but, when cold, it produces comparative little effect upon it: it also coagulates albumen. It has the property of dissolving fresh precipitated phosphate of lime; a property which is of great advantage in the animal economy, and might even be rendered useful in manures. The constituents of the lactic acid are, 6 parts of carbon, 5 of hydrogen, and 5 of oxygen. (Penry Cyclopaedia, vol. xiii. p. 268.)

LACTOMETER. (Lat. lac, milk, and metrum, a measure). A term applied to a glass tube for ascertaining the proportion which the cream bears to the milk of any particular cow, or the produce of a whole dairy. Lactometers of different kinds have been invented; the best is called "the four or five glass lactometer."

The principle of the instrument is, that if new milk is poured into glass tubes and allowed to remain, the division between the cream, which floats upon the surface of the milk, will be so evident that its depth may be easily measured; and should the milk from any cow produce more cream than that of another, the difference will be seen by the divisions or
LADIES' FINGER.

marks on the glass tubes. The lactometer consists of 4 or 5 glass tubes, about half an inch diameter, and 11 inches long, fitted into an upright mahogany frame; each tube having a fine line drawn round it 10 inches from the bottom; 3 inches from the line downwards, it is graduated into inches and tenths of inches. At milking time each tube is to be filled up to the line with new milk. After standing 12 hours, the quantity of cream which floats upon the surface is shown by the scale of inches and tenths; each division will therefore represent one per cent. of the whole.

The milk given by a cow at one meal is 1 gallon, or 8 pints, and the thickness or depth of the cream which floats upon it measures 14 divisions, multiply the number of pints, 8, by the depth of the cream, 14; the result will be that the produce of the cream of that meal is 112, or 1 pint \( \frac{1}{14} \). Care must be taken to fill these tubes as soon as the pail is taken from under the cow, for if any delay takes place, some of the cream will have ascended towards the top. The milk should be taken from the middle of the pail, and if desired by drawing a cream-pot below the froth. (Journ. Roy. Inst. vol. iv. p. 157; Recs Cyclo. vol. xx.)

LADIES' FINGER. A name given to the common kidney-velvet (Anthyllis vulneraria), which, from its soft and downy nature, was supposed to possess vulnerary properties in stanching the blood of slight wounds. See KIDNEY-VELVET.

LADIES' MANTLE (Alchemilla). The species of this genus of plants are all astringent in their root, and somewhat mucilaginous. A. vulgaris is slightly tonic. Many of them are ornamental, and well adapted for planting in gardens near the front of borders, or for adornning rockwork. They succeed well in any common soil, if not over wet, and may be increased from seeds or divisions. The species indigenous to Britain are—

1. Common ladies' mantle (A. vulgaris). A perennial, growing in dry, rather mountainous pastures. The root is woody, with long fibres: stems from 4 to 8 inches high, more or less procumbent, alternately branched, round, hairy, leafy, terminating in numerous little corybaceous clusters of green flowers, or smooth, almost capillary stalks. The radical leaves are numerous, on long footstalks, large, roundish, kidney-shaped, bluntly-lobed, pinnate, serrated, of a fine green above; soft and hairy beneath. The stem-leaves are of the same form, but a great deal smaller; alternate, on short stalks, with a pair of large notched stipules to each. Horses, sheep, and goats, eat this vegetable; but it is not relished by cattle, and hogs totally refuse it.

2. Alpine ladies' mantle (A. alpina). A perennial plant growing on alpine rocks, especially in a macaceous soil. It is rather smaller in habit than the last species, and especially different, not only in the silvery pubescence of the stalks, flowers, and backs of the leaves, but in the latter being separated to the base into 5 or 6 obovate lobes, closely serrated towards the extremity. Nothing can be more beautiful than the silvery splendour of their under sides, especially in exposed and barren spots, when the leaves are agitated by the wind. No figure can do them justice. The upper surface is smooth and virescent, of a fine green. This species is found on the mountains of New Hampshire.

3. Field ladies' mantle, or parsley piert (A. arvensis). This annual species will generally be found in England growing in sandy or gravelly fields, especially when fallow, as well as on heathy banks. The root is small and fibrous; stems numerous, about a finger's length, spreading or prostrate, round, leafy, hairy; leaves flat, three-lobed, variously cut on short stalks. The whole plant is more or less hairy, and in flavour and scent approaches its natural ally, burnet. (Smith's Eng. Flor. vol. i. p. 229.)

LADIES' SLIPPER (Cypripedium, from Cyprius, one of Venus's names, and podion, a slipper; hence the name Venus's or ladies' slipper). The species of this genus are remarkably handsome when in flower, and on that account deserve a place in every collection. They are all of the herbaceous type. The Hardy species succeed very well in peat soil, either kept in a frame, or planted out in a shady border. The species, natives of America, require to be protected from severe frost and rain. The only indigenous species is the common ladies' slipper (C. calceolus), which is very rare, growing only in mountainous woods and thickets in the north of England. It is perennial, blooming large yellow, solitary, terminal flowers, without scent, in June. The stems are solid, 12 or 18 inches high, downy, bearing 2 or 4 large alternate, ovate, rather pointed leaves, clasping or sheathing at their base.—(Eng. Flor. iv. 51; Paxton's Bot. Dict.; see Darwin's Flora. Cest. 513.)

LADIES' SMOCK (Cardamine). An interesting genus of the simplest culture and propagation, natives of various countries, generally preferring watery situations. The native species are five in number:—

1. Daisy-leaved ladies' smock (C. bellidifolia). This perennial species grows in moist, grassy, lowly, alpine, pastures. The root is rather woody, divided at the crown. Herb 2 or 3 inches high, unbranched, erect, bright green, smooth leaves, sometimes a little wavy or angular, the uppermost nearly sessile. Flowers few, corymbose, white, appearing in August. Style short, conical.

2. Impatient ladies' smock (C. impatiens). This annual species grows in shady, rather moist, rocky situations in the north of England; it is rarely met with in Scotland. The root is small and tapering; the herbage pale green; stem 1½ to 2 feet high; leaves pinnate; leaflets lanceolate, mostly cut; stipules fringed. The flowers, which are numerous, and small, and white, appear in May and June. Pods erect, very slender, composing long clusters, and discharging their seeds with a crackling noise and great force on the slightest touch or concussion, by means of the revolute valves. The whole plant is disagreeably bitterish and pungent.

3. Hairy ladies' smock (C. hirsuta). Also annual in habit. This species is found very frequent in waste or cultivated ground, especially in moist, shady places; flowering from

695
March to June. The root consists of many
white fibres. The herb is variable in size and
luxuriance, deep green, more or less hairy,
rarely quite smooth; stem from 3 to 12 inches
or more in height; leaves pinnate, without
stipules; leaflets stalked, roundish, oblong,
notched.

4. Meadow ladies' smock (C. pratensis). See
Cuckoo Flower.

5. Bitter ladies' smock (C. amara). This is not
a common species, but is found occasionally in
watery places, by the sides of rivers and brooks.
It is perennial, and before it flowers greatly
resembles water-cress, but the taste is bitter
and nauseous. The root is toothed, somewhat
creeping; stems 1 to 2 feet high, more or less
hairy, creeping at the base, with several radi-
cles, and sometimes a few slender scions.
Leaves pinnate, without stipules; leaflets of
the lowermost roundish; of the rest, toothed
or angular. Style obliquely elongated. Flow-
er, which appear in April or May, always
white or cream-coloured, with violet anthers.

(Smith's Eng. Fl. vol. iii. pp. 186—91.)

LADIES' TRACES (Neotia, a bird's nest, in
allusion to the interwoven fibres of the roots).
This is a pretty genus of orchideaceous plants.
The hardy species will succeed well in chalky
soil, or a mixture of loam, peat, and sand; they
are all increased by divisions. (Paxton's Bot.
Dict.)

There are in Britain only two indigenous species:

1. Sweet ladies' traces (N. spiralis), which
grows in open pastures, on a chalky or gravelly
soil, or in meadows in various parts of Eng-
land, flowering in August and September. The
leaves are awned, all radical, on broad stalks,
spreading, ovate, acute, ribbed, rather glauc-
ous. Stalk a finger's length or more, viscid,
and downy upwards, clothed with several
sheathing, upright, pointed bractes. Spike
spiral, of many crowded small white and
highly fragrant flowers, in a single row, each
with an ovate, tumid, pointed, downy, close
bracte.

2. Proliferous ladies' traces (N. gemmipara).
This species grows in marshes on the west
coast of Ireland, and flowers in July. The
root consists of two thick, fleshy, downy, an-
nual, perpendicular knobs, each about 3 inches
long, and one-fifth of an inch in diameter near
its origin, tapering downwards to a blunt point.
After flowering the root decays. Leaves 5 or 6,
upright, broadly lanceolate, acute, three-ribbed,
3 inches in length. Foot-stalks broad, sheath-
ing, near an inch long. Stalk erect, 2 inches
high, sheathed more than half way up by the
foot-stalks of the innermost leaves, and bear-
ing in the upper part 2 or 3 lanceolate, smooth,
upright bractes. Spike an inch long, ovate,
dense, erect, of about 18 white flowers in 3
rows, twisted round in a very remarkable way,
and each accompanied by a smooth, lanceolate
bracte, as tall as itself. The outside of the
flowers and capsule are downy; every other
part of the herb is smooth. Buds destined to
flower the following year are formed among
the leaves, at the bottom of the flower-stalk.
In the spring, each bud puts forth a pair of oblong
knobs and becomes a separate plant. (Smith's
Eng. Fl. vol. iv. p. 35.)

LADY BIRDS.

LADY BIRDS. A framework of steps between
two upright pieces. Ladders of various length
are essential requisites on a farm, whether for
use in the barns or in the barn-yard, for reaching
stacks, or in cases of fire.

"Garden ladders are of three kinds: the
common wall tree ladder, which differs from those
used in other arts in having two pieces of 10
or 12 inches in length, projecting at right an-
gles from the upper end, the use of which is to
avoid injuring the trees, by keeping the top of
the ladder at a small distance from the wall,
and thus admit of the operation of nailing. The
orchard ladder consists of a frame on low wheels,
as a basis for several ladders which fit into each
other, and are capable of being hoisted up by
machinery, so as a person near the extremity
of the ladder may have access to any part of a
tree with convenience, either to prune it or
gather the fruit.

The three-styled, forked, and double ladders
are also well adapted for the ordinary purposes
of gathering fruit or pruning. The rule joint
ladder is used for working on curvilinear roofs either
of glass, or domes of lead, stone, &c., which
require panes renewed or trees nailed. Such
ladders are particularly useful for repairing the
roofs of hothouses and greenhouses. The step-
ladder, instead of round rods on which to place
the feet, has steps or boards, an improvement
essentially necessary where much work is to be
done, because less fatiguing to the feet. Such
ladders have a back or fulcrum, by which they
stand independently of any other object, and
which is removable at pleasure by drawing out
an iron bolt. (London's Enc. of Gard. p. 290.)

LADY BIRDS, or LADY BUGS. Familiar
names applied to small hemispherical beetles,
scientifically denominated coccinella. These little
beetles are generally yellow or red, with black
spots, or black, with white, red, or yellow spots;
there are many kinds of them, and they are very
common and plentiful insects, and are gene-
 rally diffused among plants. They live, both
in the perfect and young state, upon plant-lice,
and hence they services are very considerable.
Their young are small flattened grubs of a
bluish or blue-black colour, spotted usually
with red or yellow, and furnished with six legs
near the forpart of the body. They are hatch-
ed from little yellow eggs, laid in clusters among
the plant-lice, so that they find themselves at
once within reach of their prey, which, from
their superior strength, they are enabled to seize
and slaughter in great numbers. There are
some of these lady-birds, of a very small size,
and blackish colour, sparingly clothed with
short hairs, and sometimes with a yellow spot
at the end of the wing-covers, whose young are
clad with short tufts or flakes of the most
delicate white down. These insects belong to
the genus Scymnus, which means a lion's whelp,
and they well merit such a name, for their
young, in proportion to their size, are as san-
guinary and ferocious as the most savage
beast of prey. I have often seen one of these.
LAIR.

little tufted animals preying upon the plant-lice, catching and devouring, with the greatest ease,lice nearly as large as its own body, one after another, in rapid succession, without apparently satiating its hunger or diminishing its activity. (Harris.) See ALBAT.

LAI R. Provincially, land in a state of grass or sward. (See LAY.) Also employed in some countries, to signify soil and dung. Lair is used sometimes to express the couch or resting-place of a boar or wild beast, or of cows in dairies.

LAMA, or LLAMA. See ALPACA.

LAMB'S LETTUCE. See CORN SALAD.

LAMB'S QUARTERS. A name given to wild or mountain spinach. (Chenopodium album.) See GOLDFRUIT.

LAMB SKINS (Germ. Lammsfelle). The value of lamb skins varies according to the fineness, brilliancy, and colour of the wool. Black lamb skins are more generally esteemed than those of any other colour. English lamb skins are seldom to be met with perfectly black; but since the introduction of merino sheep into England, many of the white fleeces have, in point of quality, arrived at a pitch of perfection which justly entitles them to be ranked with some of the best fleeces in Spain. The importation of lamb skins is immense, having amounted on an average in 1831, and 1832, to 2,363,635. Eight-tenths of the whole quantity are supplied by Italy. They are mostly used in the glove manufacture. (M'Culloch's Com. Dict.) See WOOL.

LAMENESS. In farriery, an affection in the feet or limbs in horses and other animals, by which motion is rendered less perfect. In the horse, it is brought on from various causes—sprains, over-exertion, diseases of the foot, &c. The muscles of the shoulder are occasionally sprained, and in this case the animal cannot lift his foot without great difficulty, indeed he will be observed to drag his toe along the ground. In this case few local measures can be adopted. The horse should be bled from the vein on the inside of the arm, fomentations applied, and a dose of physic given. In this, as in most other cases of lameness, quiet and rest are essential to the restoration of the animal. (The Horse, p. 229.)

LAMMAS DAY. In the English calendar, the 1st of August. Dr. Johnson supposes this term to be a corruption of laternmoth, which signifies a second mowing of grass. Others derive it from a custom which once prevailed in some parts of England, of bringing a lamb alive on this day into the church at high mass. Others again derive it from a Saxon term signifying loaf mass, so named as a feast of thanksgiving for the first-fruits of the corn. (Brande's Dict. of Lit. & Art.) See LAMPS.

LAMP BLACK. A colouring substance which is in very general use for several purposes. The finest lamp black is produced by collecting the smoke from a lamp with a long wick, which supplies more oil than can be perfectly consumed, or by suffering the flame to play against a metallic cover, which impedes the combustion, not only by carrying off part of the heat, but by obstructing the current of air. Lamp black is prepared, however, in

a much cheaper way for the demands of trade. The dregs which remain after the purification of pitch, or else small pieces of fir wood, are burned in furnaces of a peculiar construction, the smoke of which is made to pass through a long, horizontal flue, terminating in a close-boarded chamber. The roof of this chamber is made of coarse cloth, through which the current of air escapes, while the soot remains. (Ure's Dict.)

LANCEOLATE. In botany a term used to describe leaves which are oblong and gradually tapering towards each extremity, or shaped like a spear or lance.

LANCEWOOD (Guatteria, in honour of J. B. Guatteri, an Italian botanist, and once professor at Parma). This is a splendid genus of evergreen shrubs, succeeding in a mixture of loam, peat, and sand. They are natives of warm climates and require stave culture. Young plants are readily obtained by cuttings raised in sand under a glass in heat. (Paxton's Bot. Dict.)

LAND (Germ.), in the widest acceptance of the word, is used to denote the solid matter of which the globe is composed; in contradistinction to the liquid matter or water (see Grain): but in its most restricted significance it is commonly employed to mean the surface of the earth. The latter is the legal meaning of the term; and in this sense it is used in all original writs, and in all court and formal pleadings.

LAND-DITCHING, or hollow draining as it is sometimes termed, is chiefly practised in England in the counties of Essex and Hertford. It consists in digging both main and side drains, similar to those generally adopted in draining land: the former are usually made from 22 to 24 inches, the latter from 20 to 22 inches in depth. The soil is previously ploughed, and the length to which the main drains may be protracted without a vent, depends upon the situation of the land. When the land has a regular declivity, the most proper method will be to carry off as much water as possible, by means of side drains; but if the ground be irregular, it will be requisite to form additional main drains, so that every advantage may be derived from the valleys, into which the latter must often be conducted to a considerable extent. The length of the side drains varies according to the elevation of the soil; in general they need not be more than one rod apart from each other: though in very loose or porous grounds, they may be dug at a distance of one rod and a half. When the trenches are cut to a sufficient depth, they are filled up and covered in the usual manner with straw and bushes. The expense of this method of draining is computed in England to be nearly 3d. per acre. Land-ditching not only carries off the water from wet or marshy soils, but also mellorates stiff loamy clays, which being thus better enabled to resist the long continuance of moisture on their surface during the winter, promote vegetation very early in the spring, and the grass is rendered of a superior quality. The weeds, &c. change their colour, and are totally divested of their rankness; the corn also increases both in quantity and weight. Another important advantage arising from this practice is, that
it will admit of the soil being ploughed at an earlier period of the spring and later in autumn; while it may be tilled with greater facility, and kept clean from weeds at a very small expense.

LANDLORD. One who owns lands or houses, and has tenants under him. See Tenant, Customs of Counties, Lease, Agreement, &c.

LANDMARK, signifies in a general sense any thing by which the boundary of a property is defined. In ancient times the correct division of lands was an object of great importance; and monuments were adopted to give distinctness and permanency to the boundaries of every man's property. Stones and hillocks were the most usual landmarks. The importance of this subject among the Israelites particularly, may be judged of from the denunciation of Moses, "Cursed be he that removeth his neighbour's landmark."

LANDSCAPE GARDENING. The art of laying out grounds so as to produce the effect of a natural landscape. Larches are in the same as those upon which the landscape painter proceeds in composing a picture; and though it is an art of which, like many others, everybody thinks he is a judge, it requires to be properly practised, and the possession of powers of a much higher order than fall to the lot of most men. Mr. Brown, commonly called Capability Brown, was the first who practised the art in England, so as to render himself worthy of the name of artist. To lay down the principles of this art here would be quite impossible; but this general observation contains the sum of them; let selected and beautiful nature be constantly your model, and success must follow. London's Enc. of Gardening, and Downing's Landscape Gardening, recently published in New York, may be consulted with advantage by those desirous of practising the art.

LANDSLIP. A portion of land that has slid down in consequence of disturbance by an earthquake, or from being undermined by the action of water or other means.

LAND SPRINGS. Land springs are sources of water which only come into action after heavy rains; while constant springs which derive their supplies from a more abundant source, flow throughout the year. All springs owe their origin to rains. In the case of land springs, the water when it sinks through the surface, is speedily interrupted by a retentive stratum, and there accumulating soon bursts out into a spring, which ceases to flow a short period after the cause which gave it birth has ceased to operate; but the water which supplies constant springs sinks deeper into the earth, and accumulates in rocky or gravelly strata, which become saturated with the fluid.

LAND STEWARD. A person who has the care of a landed estate, and whose duties vary in different countries, according to the mode in which landed property is managed. In England, where the landlord very commonly undertakes to keep the buildings and fences of his tenants in repair, the duties of the land steward are constant and multifarious; while in Scotland, where the buildings and fences are kept in repair by the tenant, the duties of the steward are limited to receiving the rents, and seeing that the covenants of the leases are duly fulfilled. In many parts of the Continent, and particularly in Italy, where the landlord is a partner with his tenant, and shares the produce with him, the duties of the land steward or fattore, as he is there called, are much more onerous than in Britain. See Bailiff.

LAND TAX. In England, a branch of the public revenue, which was first raised in its present form in 1693. The rate at which this tax is charged is 4s. in the pound on the annual value. The amount which it yielded to the exchequer in 1837 was 1,192,685l. (Penny Cyclo. vol. xii. p. 300.)

LARCH TREE. (Lat. larix; It. and Span. larice). The larch is one of the most valuable exotics which has been introduced into Britain. In the north of Scotland it has been grown to a great extent, cultivated with particular attention; and found to be one of the most profitable of all trees to the planter, provided the land be well drained, but it will not succeed in damp, swampy situations. It grows with great rapidity, is subject to very few accidents, transplanting with but little risk, and produces timber of great excellence and value, not only for domestic but for naval purposes.

In bridges, dock-gates, mill work, and especially in mill axles (where oak only used formerly to be employed), larch has been substituted with the best effect. The small larch is useful for agricultural implements, gates, upright palings, rails, and hurdles. Boats built of larch have been found sound when the ribs made of oak 40 years old were decayed. A fine frigate of 36 guns, named the Atholl, was launched at Woolwich in 1820, built entirely of larch, the growth of the Atholl plantations. It is also very useful for staves for casks.

1. The common larch fir or white larch (Abies larix). The leaves of all the species are clustered, and deciduous. The cones vary: in the common larch they are ovate, oblong, blunt; and the flowers are pink. In mountainous districts in Scotland the Duke of Atholl planted this species in immense quantities, having had nearly 9000 acres in cultivation with the larch alone. We are told by Dr. Anderson that his grace planted 200,000 every year; and in the winter of 1819 and the following spring no less than 1,102,367 were planted on 556 acres, at 2000 per Scotch acre. The late Earl of Fife also planted 181,813 in Morayshire. Goodwood, the property of the Duke of Richmond, was probably the first place at which the larch was planted as a forest tree, and even there it was only in small numbers. A few years after, viz. in 1738, it was introduced into Scotland by a Mr. Menzies. About 1740, James, Duke of Atholl, commenced planting larches around Dunkeld House and Atholl House, the two residences of his grace; and great attention having been paid to these nurseries by his grace's successors, the plantations have amazingly increased. A very detailed account of the plantations on the Atholl estates, and experiments on the wood, will be found in the 3d vol. of the Prize Essays of the Highland Society, p. 165, drawn up from papers and documents communicated by his grace's trustees. In a communication to the
LARCH.

Board of Agriculture in February, 1812 (vol. vii. p. 273), the Duke of Atholl, speaking of the advantages and beauty derived from the general culture of the larch, says, "The lower range of the Grampian Hills, which extend to Dunkeld, are in altitude from 1000 to 1200 feet above the level of the sea; they are in general barren, and are composed of mountain schist, slate, and iron-stone. Up to the highest tops of these, larch grow luxuriantly, where the Scotch fir, formerly considered the hardest tree of the north, cannot rear its head. In considerable tracts, where fragments of shivered rocks are strewn so thick that vegetation scarcely meets the eye, the larch puts out as strong and vigorous shoots as are to be found in the valleys below, or in the most sheltered situation." And it further appears from a report of that nobleman to the Horticultural Society (Trans. vol. iv. p. 416), that in situations 1500 to 1600 feet above the level of the sea, he has felled trees 80 years old that have each yielded six loads of the finest timber. The growth of larch is not, however, confined to Scotland; but much land has been planted in the northern counties of England. The Society in London for the Encouragement of Arts and Manufactures, so long ago as 1783, offered premiums for the planting of larch. A gold medal was offered to those who should plant within any one year 5000 larches from two to four years old at a distance of 5 feet asunder; and a silver medal to any one who should plant 3000 larches at the same distance. This premium only contemplated making plantations solely of the larch. The first claimant for the premium was the Bishop of Llandaff, who had by that time planted 48,500 larches on 18 acres of the high grounds near Amble-side in Westmoreland, at a distance of 4 feet from one another. Immense numbers continued to be planted annually up to the year 1805, from which year to 1816, no candidates appeared to claim the premium, in consequence of the severe blight which affected the larch trees in England for some years; and which preventing the formation of the cones, deprived the growers of larch plants of the usual supply of seed.

There is no account given of the height at which these larches were planted. Had they been placed at a considerable elevation above the level of the sea, they would have probably escaped the contagion of the blight. In the account of the Dunkeld larch plantations, the late Duke of Atholl conceived that he had introduced three great improvements in the planting of the larch, when it was to be raised for medicinal timber. These improvements were the planting it at a high elevation on the mountain side, in a region in which no other kind of timber tree would grow to perfection in this country; the inserting the tree in the soil at an early age, not exceeding two years old in the seed-bed; and the notching the small plants into the ground by a peculiar instrument at wide intervals, not nearer than 5½ feet to each other; for, if planted close, they exhaust the soil, and prevent its being nourished by the annual deposition of spines, on account of the closeness of the trees.

In 1820 the gold medal was awarded to the Duke of Devonshire for planting 1,981,065 trees within 90 acres of waste land with larch. Besides these instances of the planting of the larch alone, there are many others in England in which they were planted along with other trees; but as they would probably be so planted merely as nurses to the hard timber, such plantations cannot be considered as interesting experiments, in regard to the value of the larch as timber. From the foregoing details, however, we find that, mainly under the auspices of the Society for the encouragement of Arts and Manufactures, 1,407,036 larches were planted in England in 87 years. It is clear that so much elevated barren land in the counties of Hants, Sussex, and Kent should be suffered to remain barren with this and other timber, which would find a ready sale in the neighbouring government yards.

Plantations that are formed exclusively of larch destroy the heath and all other vegetables; but after a few years a fine grass springs up which is so valuable for grazing, that it has been let from 10s. to 5l. per acre for this purpose. If planted wisely, not only the soil, but the heath itself, would not bring as many pence. Three varieties of the common larch are mentioned by botanical writers; one remarkable for the young cones being pale green instead of crimson, and erect, not drooping. A second has a weeping habit, with pendulous branches, but is distinct in botanic characters from the black larch (Larix pallasii) of North America; both these varieties are natives of the Tyrol. The third sort is of a slow, stunted growth, and an inelegant appearance, leaving early, and very subject to injury from spring frosts. The bark is cinnereous, not yellowish brown. It was raised by the Duke of Atholl from seed, procured at Archangel in 1806. Both in its appearance as a tree, and its value as timber, this Russian larch is much inferior to the common larch. From the boiled inner bark, mixed with rye flour, and afterwards buried a few hours in the snow, the hardy Siberian hunters prepare a sort of leaven, with which they supply the place of common leaven when the latter is destroyed by the frost. It is supplied by the intense cold to which hunters are subject in the pursuit of game. The bark of the larch is nearly as valuable to the tanner as oak bark; this valuable property was first discovered by Mr. T. White in 1812. (Com. to Board of Agr. vol. vii. p. 278.) The larch also produces the substance called Venice turpentine, which is of considerable use in medicine, and flows in abundance when the lower part of the trunk of old trees is wounded or tapped between the months of March and September. When forests of larch in Russia take fire, which sometimes happens, a gum issues from the medullary part of the trunks, during the combustion, which is called Orchefour gum. A saccharine matter, also, resembling manna, and called manna of Briareon, exudes from the larch in June; and another sort of manna is exuded from its leaves in the form of a white, flocculent substance, which finally becomes concreted into small lumps. From the inner rind or bark of the larch the Russians manufacture

LARCH TREE.
LARCH, AMERICAN.

fine white gloves, not inferior to those made of the most delicate chamois, while they are stronger, cooler, and more pleasant for wearing in the summer.

The larch is propagated by seed, which is generally ripe in September and December, when the cones may be collected and carefully dried and stored till April, which is considered the best time for sowing. The most proper season for sowing the larch is July.

2. The red larch fir (A. microcarpa). In this species the cones are oblong, small, thin; scales erect, close pressed, the upper ones much smaller than the lower. It is a graceful tree, with much of the habit of the common larch, from which, however, its very small cones, of a bright purple, readily distinguish it. It is a native of North America. This is by no means so well adapted to the planter’s purposes as the common larch. According to the Duke of Atholl, trees when 50 years old do not contain one-third as many cubic feet as the common larch. The wood is so heavy that it will scarcely swim in water.

3. The black larch fir (A. pseuda). Cones oblong, with numerous spreading scales, which gradually diminish from the base to the apex of the cones. Branches weak and drooping. The larch seed will often begin to drop at the height of 15 or 20 feet from the ground, and after gradually acquiring a horizontal direction will bend towards the earth, so as to form a natural arch of great beauty. This species is also a native of North America, where it is found growing on a rich clay soil, mixed with sand, in cold, mountainous districts. When cultivated in Britain it is an elegant tree, having a good deal of resemblance to the common larch, but being of a brighter green colour, and much more graceful. The wood is less valuable than the common larch.

There is a report (Trans. High. Soc. vol. v. p. 391), by Mr. Lawson on larches raised by him from seed imported from the Tyrol, which being the native country of the larch, is supposed to mature the most perfect seed.

The larch is affected with many diseases in Britain. Some of these have been supposed to arise from a constitutional weakness engendered in the tree from the seed not having been perfectly ripened. The reader’s attention may be drawn to several valuable treatises on the diseases of the larch, distributed through the volumes of the Trans. of the High. Soc. of Scotland, &c. In the Quart. Journ. of Agr. there are also some able papers, “On the probable Cause of the Diseases of the Larch in Great Britain,” by the late M. Decandolle (vol. v. p. 403); “On the Diseases of the Larch in the South of Scotland,” by Mr. Webster (Ibid. p. 535); “On the Rot in Larch,” by Mr. Gorrie (Ibid. p. 537); and some papers on the foregoing papers dried, and put up in the former and latter.

LARD OIL.

In the United States, where swine are raised so abundantly, oil is now very extensively separated from lard. Its close connection with the question of disposing of the agricultural products of the Union, and especially of the Western States, forms a reason for giving it an extended consideration. Several large factories for the manufacture of this oil have been some time in operation in Cincinnati, and thousands of gallons are daily prepared for home consumption and exportation. It is also carried on at Cleveland, Ohio; Chicago, Illinois; Burlington, Iowa; Hannibal, Missouri; and other places both in the Western and the Atlantic States.

It is considered much superior to olive or sperm oil for machinery and for the manufacture of woolens, &c. It can be furnished also at half the price, and therefore it will doubtless supersede that article of import. As it contains less stearine than other oils, it is found much better for combing wool, for which purpose a single factory wished to contract for 10,000 gallons from one establishment. It is also undergoing trial in England; and, if it succeeds, of which there can scarcely be a doubt, large orders for it may be expected, or at least the American lard itself, which pays a less duty, will find a ready market.

Repeted experiments have shown that for
LARD OIL.

the purpose of combustion, no oil is superior.
It is important, in trying it with this view, to
obtain a good article, manufactured from good
lard, and not from the dark-burned, which
creates smoke and clogs the flame. For want
of sufficient care in this respect, some have no
doubt met with disappointment in their attempts
to substitute this oil for sperm oil in their
lamps.

The following are given as the relative con-
stituents of lard oil and sperm oil, in 100 parts
of either:—

<table>
<thead>
<tr>
<th></th>
<th>Carbon</th>
<th>Hydrogen</th>
<th>Oxygen</th>
</tr>
</thead>
<tbody>
<tr>
<td>Lard oil</td>
<td>79.07</td>
<td>4.62</td>
<td>16.31</td>
</tr>
<tr>
<td>Sperm oil</td>
<td>79.05</td>
<td>6.09</td>
<td>14.86</td>
</tr>
</tbody>
</table>

It will thus be seen that the difference in
carbon is only 3·00; about the same in hydro-
gen; while in oxygen it is about 4·10 in favour
of the lard oil. The large quantity of carbon
proves that it may be relied on as a material for
giving light, as it is well known that whenever
carbon predominates in an animal oil, the ar-
cicle is capable of a high degree of luminous
power. Experiments have been made which
have shown results in favour of lard oil.
About 60 lbs. in 100 of good lard, in tallow only
28 is oil; and the processes of manufacture
resorted to show that it may be made a profit-
able business. Large orders have already been
executed at the West for this oil, to be used in
the Eastern States. The heat of lard oil for
the blow-pipe has been found to be much
greater than that of sperm. Lard itself melts
at 82° to 87° of Fahrenheit; its specific gravity
at 60° is 0.935. Lard crystallizes in small
globules; sperm in flakes or scales. It is
soluble in boiling alcohol. The proportion is
80 gallons of lard to 1 of alcohol. The appli-
cation of stearine for candles promises greatly
to reduce the price of that article, so that can-
dles equal to spermaceti may eventually be
reduced to 283 cents per pound.

As the capillary attraction of the lard oil is
not so great as that of sperm, it is recommend-
ed that the form of the lamp should be such as
to bring the bulk of the oil as near to the point
of combustion as possible.

It is also recommended that the tube should
be filed thinner at the top where the wick is
inserted, to prevent the escape of heat. Various
lamps have been constructed for burning lard
as well as lard oil, which have been found to
answer very well. The burning of this oil has
been introduced with entire success into the
light-houses on Lake Erie. An objection has
been made against lard oil, that it is not capable
of being preserved in a liquid state in cold wea-
ther; but by a process similar to that by which
the winter sperm is prepared, lard oil can be
made which will not chill at 30° of Fahrenheit.

The importance of this application of lard
can scarcely yet be realized. Vast quantities
of the oil can be manufactured at the West.
Indeed, there is hardly any assignable limit to
the power of production of the article, so that,
while the demand continues, the business may
be conducted profitably. The immense herds
of swine which can be suffered to range over
the lands adapted to them, and gather their
food from mast as well as the surplus of corn,

wheat, potatoes, &c., on which they may be
sustained, admit of the manufacture being car-
rried on to almost any extent.

The proportion of lard to the whole hog is
about 60 per cent., after taking out the hams
and shoulders, or taking out the hams only;
the estimate for hogs of the best breeds, and so
ted as to produce the greatest quantity of fat,
is 70 per cent. As the object is not in this
case to make pork for food, the objection
against those species of nuts, and other modes
of feeding which render the animal more gross
and oily, is obviated; and it has been proposed
to feed out oil-cake to swine, to increase the propor-
tion of oil.

By a new process of steaming, a very sim-
ple method described by Mr. Stafford, it ap-
pears that the whole of the lard or oily matter
in the hog, or of tallow in cattle, may be ob-
tained; while the danger of burning (common
in other modes) is avoided, the consumption
of fuel lessened, and the degree of pressure
required not so great as otherwise. It will be
recollected that, while conducting the manu-
facture of lard, the other parts of the animal,
as the hams and shoulders, may be turned to
profit. Besides these, also, the hides may be
tanned by a cheap process: and the bones, which
are worth half a cent per pound, may be calci-
cined and made into animal carbon, for
which they are said to be worth, in this calci-
cined state, 22 cents per pound. (Ellsworth's
Report.)

LARKSPUR (Delphinium, from dolphin, a dol-
phin, in reference to the supposed resemblance
in the nectary of the plant to the imaginary
figures of the dolphin). All the species of
larkspur are showy, and valuable as border
dowers, especially D. ajacis and D. consolida,
both of which are universally grown among the
border annually. The herbaceous and pe-
rennial kinds are increased by divisions or
seeds, and the annual and biennial kinds mer-
ly require sowing in the open border, where
they will flower and seed freely. The field
larkspur (D. consolida), grows wild in sandy or
chaly corn-fields in England, and is regarded
as a simple astringent. In gardens this species
is sometimes called the branching larkspur, and
attains the height of 3 or 4 feet, blowing vivid blue
flowers.

D. Grandiflorum is a hardy and beautiful pe-
rennial, blowing dark blue flowers in July and
August. It loves a dry soil, and open situation.

The bee larkspur is a beautiful perennial,
blowing bright blue flowers in July and Au-
gust. Sheep and goats eat the wild larkspur,
horses do not relish it, while cows and swine
totally refuse it. Bees are remarkably attach-
ed to its flowers, which are likewise gathered
by the country people of Germany, cut small
and mixed with tobacco, to improve its flavour.

LARVA (Lat. a mask). A term applied to
that state, in which an insect exists, immedi-
ately after its exclusion from the egg, and
which precedes the pupa state. The animals
commonly called grubs, maggots, and cater-
pillars, are larvae. Grub appears to be a general
term analogous to larva; the term maggot is
most generally applied to the larva state of
dipterous insects; and caterpillar, in the most
common acceptance of the term, is used to de-

3 x 2
701
signate the larval state of lepidopterous insects. These terms, however, are used in a very vague manner. (Penny Cyclo. vol. xiii. p. 383.)

LAST. An uncertain quantity, varying in different countries, and with respect to various articles. The following quantities of different commodities generally make a last:—12 dozen of hides or skins; 12 barrels of meal; 1½ qr.s. of cole seed; 10 qr.s. of corn or rape seed (in some parts of England 21 qr.s. of corn go to a lasts); 12 sacks of wool, 1700 lbs. of feathers or flax. (McCallum's Com. Dict.)

LATHYRUS (from la, augmentative, and thoreus, anything exciting, in allusion to the medicinal qualities of the seeds). This genus belongs to the natural order Leguminosae. It consists for the most part of very handsome plants when in flower, well adapted for arbours or shrubberies, where they must be supplied with branches to support them, as they climb by means of tendrils terminating the footstalk, and sometimes without tendrils. Any common soil suits them; they are increased by seeds, and some of the perennial kinds by dividing the roots.

The yellow vetchling (L. aphanus) is an annual, flowering in June. The plant is glaucescent, without any true leaves or leaflets, except near the root. The flowers are solitary on long stalks, small, drooping, lemon-coloured. The pod is an inch in length, nearly cylindrical, smooth, and containing six seeds, which produce intense headache if eaten in any quantity, while the roots of L. tuberosus are said to be wholesome food. (Paxton's Bot. Dict.) See Vetchling.

Crimson vetch (L. missolus) is also an annual, flowering in May. It is destitute of tendrils, it has a grass-like form, and bears beautiful crimson flowers, variegated with purple and white. The pod is long and the seeds numerous.

There are five other species of lathyrus: namely, L. hirsutus, L. pratensis, L. sylvestris, L. palustris, and L. latifolius, which is the only one of importance as a garden flower.

Broad-leaved, everlasting pea (L. latifolius) is a perennial, flowering in July and August. The herb is glaucescent, the stem winged, the leaflets oblong by elliptical, bluntest, three or five ribbed, and the tendrils in five branches. The stipules are ovate in their upper part, and broader than the stem. The flowers are large, handsome, of a fine rose colour, and in tufts of five or ten. The legume is long, compressed, and narrow. It is one of the most showy of the herbaceous species of the pea tribe; and well adapted as an ornament to cottages.

Several American species of lathyrus are enumerated by Nuttall, among which are, L. nyctifolius found near Philadelphia. L. venosus, with about five pair of leaflets. This grows on the declivities of shady hills, and is common in the Alleghany mountains. L. polymorpus, with naked quadrangular stems, and four or five pair of leaflets. This is found on the grassy alluvial plains of the Missouri from its confluence to its sources. The flowers are as large as those of the Pisum maritimum, and of a fine purple, variable however in size. (Nuttall's Genera.) See Everlasting Pea.

LAUREL (from the Celtic word blaur the b is dropped, signifying green, in allusion to the foliage of the plants). This is a very handsome and interesting genus of plants: among the most interesting and valuable of the hardy kinds, is the bay tree (L. nobilis), which is injured by severe frost. (See Bay Tree.) L. benzoin, L. sassafras, and several others are deciduous, and in some situations attain a great size. They may be increased by layers or cuttings of the roots. The bark of L. benzoin or spice wood is stimulant and tonic, and in North America it is used in intermittent fevers. In the L. fatoes, an acrid red or violet juice is particularly abundant. All the species are most of less aromatic for stomachic.

The Portugal laurel (Prunus lusitanica), is a beautiful evergreen, which grows from 10 to 15 feet high, blowing handsome spikes of white flowers in June and July. It forms a round head, and is very ornamental upon lawns.

The Alexandrian laurel (Rhus racemosa) is a dwarf evergreen shrub, growing about two feet high, and blowing a yellow flower, succeeded by red berries. See Kalmia, Cherry Laurel, and Spurge Laurel.

LAURESTINE, Lauritisins, or Wild Bay (Fibnearum tines), said to be derived from rice, to tie; because of the pliability of some of the branches). All the species of Fibnearum are very elegant, rather early-flowering shrubs. The hardy kinds are well fitted for planting in ornamental shrubberies. They are increased by layers or by cuttings planted under a glass in a shady situation. The berries are violently purging, but become catable after fermentation, and are made into a sort of cake by the North American Indians. See Geelder Rose.

LAURUS (Sassafras, spice wood, &c.). This extensive genus of shrubs and small trees, which afford the cinnamon, the cassia, and the camphor of commerce, is for the most part confined to the tropical and temperate latitudes. One species (L. nobilis) is found in Europe; five in Japan; India affords three of the most important species, long celebrated as spices; in the Canary islands there are two, the tropical regions of America afford no less than 21, amongst the most remarkable of which is L. caulstica of Chili, being poisonous, and the L. Persea, called avocado, and alligator-pear, producing a large and very grateful fruit formed like a pear.

In the Southern States two species are found, one called L. cotesbaeri, and the other L. Carolinensis, or Red Bay. This last, which flowers in July, Mr. Nuttall says he has met with as far north as Sussex county, in the state of Delaware. The whole plant is aromatic. See Sassafras, Red Bay, Camphor Tree, Spice-wood, &c.

LAVA. The substances which flow in a melted state from a volcano. They vary considerably in texture and composition.

LAVENDER (Lavandula, from lavo, to wash, in allusion to the use formerly made of its distilled water in baths, on account of its fragrance). The hardy kinds are the only plants of this genus worth cultivating.

Common garden lavender (L. vera) is well
known and much esteemed for the fragrance of its flowers, and the volatile oil which they yield by distillation with water. It is cultivated in great abundance for the London market, at Mitcham in Surrey. A very poor and light gravelly soil is best suited to this plant, being in such more fragrant, longer lived, and more capable of enduring severe weather than in a rich soil. In rich or moist soils it grows luxuriantly, but is in general destroyed during the winter. The situation cannot be too open. It is propagated by slips and cuttings of the current year's shoots, which may be planted in May and June, as well as by cuttings of those which are a year old; these are to be planted in March, April, and early in May. Both slips and cuttings must be from five to seven inches in length, these, after being stripped to half their length of the lower leaves, are to be planted to that depth either in a shady border, or in any compartment, to have the shade of a mat during mid-day until they have taken root, in rows six inches apart each way. Water must be given in moderate quantity every evening until fully established.

Having attained sufficient strength, they may be moved to their final stations in September or October, which is the season to be preferred if the soil is not light and dry on which they have been raised; or they may be left until the succeeding spring. If it is grown in considerable quantity for medicinal purposes, which is the only claim it has to a place in the herbarv, it must be planted in rows two feet apart each way; otherwise, only detached plants are inserted along the borders. The only after-culture required is the occasional employment of the hoe, the decayed spikes and branches being removed in autumn, and the surface gently stirred with the spade in the spring.

The flowers are ready for gathering either to dry or for distillation, in July or the end of June. The flowers are used as excitanls and carminatives in medicine, in the form of tinctures. The oil is an agreeable perfume, and one or two drops rubbed up with sugar and mixed in water forms a useful draught in nervous headache and hystcrta.

LAVENDER, SEA. See Thrift.

LAWN. A space of ground covered with grass, kept short by mowing, and generally situated in front of a house or mansion, or within the view from such. Lawns, when once established, require only to be kept neat by the ordinary routine of rolling, mowing, and sweeping, except keeping the surface perfectly even, by making up small hollows with screened mould early in spring. When lawns become worn out, a top dressing of any finely divided manure will refresh them; malt dust applied in October is excellent for this purpose; and at the same time an additional quantity of grass seed may be sown.

LAY. A term applied to land in the state of grass or sward. This kind of ground is frequently distinguished into such as has been long in the state of sward, and such as is newly laid down to grass, or into old and new lays. The proper method of managing the latter is of great importance to the farmer, and which Young thought should be by keeping them perfectly free from stock for the following autumn and winter after their being laid down, when, in the spring, they will afford a growth of young grass highly valuable for sheep, with which they should only be well stocked, and kept down then, and during the following summer. Nothing, in his opinion, being more pernicious than mowing a new lay, as directed by certain authors. They may, he thinks, have succeeded in spite of such bad management, but never by it.

LAYERING. In gardening, an operation by which the propagation of plants is effected by laying down or bending the shoot, so that a portion of it may be covered with earth. A shoot so operated on is called a layer, and the point which furnishes the layers bears the name of stock. Some plants are so much disposed to emit roots that if their branches happen to come in contact with the earth they immediately begin to strike. Plants so situated as to render it impossible to bend their branches to the ground, may nevertheless be layered by having their shoots introduced into a pot or box of soil elevated to them, and supported in a convenient position. This is a common practice among the Chinese, who cause branches of trees to root in this manner by partially ringing them, and covering their parts so ringed with a ball of clay, which is kept moist. (Penny Cyclo.)

LEADWORT (Plumbago; from plumbum, lead). A genus of pretty free-flowering plants, growing in any common soil, and increased readily by cuttings. The root of P. europaea, it is said, when chewed, will cure the toothache.

LEAF (Sax.). The well-known fine membranous part of a tree or plant, which is put forth and unfolded in the spring, and which in some trees falls off in the autumn. "The leaf," says a writer in the Penny Cyclopedia, "is an expansion of the bark of a plant, from whose axil a leaf-bud is developed: but this opinion is hypothetical. The leaf is usually thin, and traversed with one or more veins, composed of woody and vascular tissue; sometimes it is fleshy, and occasionally cylinrdrical, or nearly so." The functions of the leaf being at once that of respiration, digestion, and nutrition, its surface is covered with stomata, or breathing pores, which communicate with minute hollow chambers in its interior. It is in the leaf that all the peculiar secretions of a plant are prepared out of the under sap which the roots obtain from the soil, and which, carried up to the leaves, is exposed to the air, and undergoes the action of the vital chemistry which converts it into the proper juice. It is then returned to the stem, and forms the different secretions of the plant, as resin, starch, sugar, gum, &c. A leaf is either united to the stem by means of a petiole, or stalk, or it is sessile—that is to say, seated on the branch without an intermediate stalk; the veins pass through the petiole before they can expand into the broad or green part forming the blade of the leaf. Some leaves are furnished with an appendage, which in grasses is a thin membranous body arising from the base of the lamina, and in palms is a coarse net, formed, it is said, of tissue belonging to the veins of the leaves. When leaves
LEAF.

have but one blade, they are simple, as in the apple; but when there is more than one blade, each seated on a ramification of the petiole, a leaf is called compound. Of these, and of the external form of the leaf, there are endless modifications. Between 200 and 300 are enumerated by Bischoff.

The distinction of leaves made by those who have written on botany are the following: a simple leaf is that which is not divided to the middle. A compound leaf is divided into several parts, each resembling a simple leaf, as in liquorice, &c. A digitate leaf is a leaf divided into several parts, all of which meet together at the base, as in hemp, black hellebore, &c. A trifoliate leaf is a compound leaf, consisting of three leaflets, as the trefoil, &c. A quinquefoliate leaf is a leaf consisting of five leaflets, as in Hedera quinquefolia. A pinnated leaf is a compound leaf divided into several parts, each of which is called a leaflet, placed along a middle axis, either alternately or by pairs. When the axis is terminated by an odd leaflet, it is said to be unequally pinnated; and equally pinnated when it is not terminated by an odd leaflet, as in the cassia; when the leaflets are all nearly of the same form and bigness, it is called an uniform pinnated leaf, as in the liquorice; when they are not so, it is said to be disform, as in the agrimony. A winged leaf is a pinnated leaf, with an intervening membrane. A toothed leaf is that which is still farther divided than the pinnated leaf, as in the osmund royal, female fern, &c. An entire leaf or lobe is that which has no division on its edges, as in the apple-tree, &c. A sinuated leaf is that which is cut about the edges into several long segments, as in common mallows. A serrated leaf is that which is cut about the edges into several acute segments, resembling the teeth of a saw, as in the nettle, &c. A crenate leaf is that which is cut on the edges into several obtuse segments, as in betony, &c. A lacerated or ragged leaf is that which is cut about the edges into several pretty deep portions in an irregular manner, as in the horned poppy, &c.

All the experiments which have been made, in order to show how serviceable the leaves of trees and plants are to their well-being, have proved that when the plants have been divested of their leaves, or their leaves have been eaten or cut during their growth, they have been remarkably weakened or destroyed. If the leaves of plants be the means by which their juices are prepared for their support, as has been just stated, it should teach us not to pull or cut off the leaves of trees or plants on any account, while they retain their verdure, and are in health, as they may be greatly injured thereby. Hence, probably, the error of the common practice of feeding down wheat in the winter and spring with sheep, as, by so doing, the stalks may in many cases be rendered weak, and the ears shorter, the grains of corn not being so plump and well nourished as when it is not fed down upon the ground. It is well known, too, that in grass which is often mowed, the blades are rendered finer in proportion to the frequency of mowing; so that, though this may be a desirable thing in lawns, &c., where regard is had to the produce, it should certainly be avoided.

The leaves of trees or plants, where they can be collected in large quantities, as in parks and woods, may be highly useful in augmenting the manure heaps of the farm.

Mr. Young, in his Calendar, recommends that, in wooded countries, all the leaves that can be had at little expense, should be raked up in October, and carted to the yards and standing folds, for littering and making them into dung: he did it, he said, at 3d. per one-horse cart load. They do not rot easily, but that is, he thinks, no objection to them; they are a spongeto be saturated with urine, and if not touched previously to carting on to the land, will convey to the field much of what might otherwise be lost; and they are extremely useful in aiding the main object of bedding the yards in the autumn and winter season.—See Botany.

LEAF-BUDS. Rudiments of young branches, made up of scales imbricated over each other, the outermost being the hardest and thickest, and surrounding a minute axis, which is in direct communication with the woods and cellular tissue of the stem. When stimulated by light and heat they extend into branches; or if artificially removed from the plant that bears them, they are capable of multiplying the individual from which they have been taken. In this case, however, the individual is not a progeny as from seed, but merely an extension of the parent.

LEAFLET. A part of a compound leaf, or a small leaf formed on the petiole of a leaf branchling out.

LEAGUE. A measure of length, principally used in reckoning distances at sea. The sea league is 3 nautical or geographical miles, or the 1-20th of a degree, and consequently about 3-45 English miles. The common landleague is a well-known itinerary measure on the continent of Europe, chiefly in France. The French, however, have two distinct leagues; the legal posting league, containing 2000 toises, and equal to 2-42 English miles, and a league of 25 to the degree, or equal to about 2-76 English miles.

The word is said to have been derived from the Celtic leach, stone; the distances having been marked by stones in the Roman provinces. See Mile.

LEOPARD’S BANE (Doronicum). An ornamental genus, and from the plants flowering early in spring, they are well deserving of cultivation; they grow in any garden soil, and may be increased with facility by dividing at the root.

The great leopard’s bane (D. pardalianchis), is a perennial, native of Great Britain, growing in mountainous pastures or meadows. The root is creeping, and consists of several knobs connected by long fibres; woody at the crown. The stem is 2 or 3 feet high, hollow, round, leafy, and hairy; branched, and glossy at the upper end. The leaves are rather soft and downy, heart-shaped, more or less regularly toothed, or wiry. The flowers, which appear in May, are solitary at the ends of the branches; 2 inches wide, of a uniform bright yellow; the

704
earliest overtopped by succeeding ones. The roots are aromatic, and used by sportsmen in Alpine countries against giddiness.

The connection between landlord and tenant has gradually improved from that of master and slave into a state of almost total independence and mutual interest in the soil.

The beneficial effects, both to the landlord and tenant, of leases of a sufficient duration to encourage men of capital and skill to properly cultivate the land need hardly be pointed out. And it will be very desirable to have as few restraining covenants introduced into these as possible. They merely retard and annoy the good farmer, and rarely improve the practice of the unskilful.

In the northern part of England, custom and expediency have very generally fixed the duration of the lease at about 20 years. Experience will evince that the time is not always more than enough to allow the possessor of the land to conduct and mature a profitable system of management, and to pay to the owner an adequate rent. All the great operations of the husbandman have a prospective result as regards the profit to be derived. The capital expended in such cases is only to be drawn back by periodical returns after the lapse of time. In the providing of extraneous manures, in the adoption of rotations of crops, which, to be effectual to the purposes intended, must be extended through many seasons, in the draining of the land, and the like, time is necessary, both to effect the operations, and to recover with a future profit the capital employed. When, indeed, land is of very rich quality, and at once productive, without other outlay than the ordinary expenses of tillage, or when it has the means of fertilization near to it, and abundant, as in the vicinity of cities, the duration of the term may be comparatively short. But in other and dissimilar cases, this cannot be without a sacrifice of present income; and a landlord will scarcely fail to experience, that if there be not a sufficient period of secure possession accorded to the occupier, the necessary expenditure on the cultivation of the ground will not be hazarded; but more than this, a person of good capital will, like every trader, regard as a benefit the power of carrying on his business undisturbed, and he will set a pecuniary value on security and independence. (Quart. Agr. vol. i. p. 795.)

With regard to a lease in general, and its covenants, see a good paper (ibid. vol. ii. p. 134). In speaking of rents, the author remarks, "As to the kind of rent to be paid, constant experience proves that the best and most satisfactory is a fixed rent in money, to rents payable in grain, or in money regulated by the prices of grain, there is this objection, that the tenant will generally be required to pay the higher rent, if he is least able to do so, that is, when prices rise from a deficiency in the produce of the crop." And when speaking of the lease and its precautionary covenants, he observes, "the greatest error consists in vain precautions and attempts to provide against every possible contingency, which, from the nature of the transaction, and the unforeseen events to which it may give rise, it is impossible to do. All that can be done is to make as precise as possible the conditions which experience shows to be necessary. The terms of the contract should be few and simple, and easily understood and complied with. Not only are hurtful covenants to be avoided, but such as are unnecessary, since to increase the number of them too much serves but to perplex the lessee, and give birth to future quarrels, and since all experience on the subject shows that the interests of either party may be sufficiently guarded without multiplying too much conditions, penalties, and restrictions."

LEASE. A term applied to game, &c., by sportsmen, and which implies three; as three hares, partridges, &c. It also signifies a line to hold a dog by.

LEATHER (Germ. Leder; Dan. Læder). The prepared skins of animals. The principal object of the art of converting skin into leather is to render it strong and tough, durable, and often water-proof, and to prevent its destruction by putrefaction. The skins are first cleansed of hair and cuticle, then impregnated either with vegetable tan and extract, as in the production of what is called tanned leather. In this process the tannic acid, which is the active principle of the astringent vegetables employed, combines with the gelatin of the skins, and forms an insoluble tannate of gelatin. It is this formation which renders the skins impermeable to water, and checks the tendency to decomposition which they, in common with all animal matter, possess. Instead of tan, some leather is prepared with alum and other salts, as for tawed leather. These processes are sometimes combined; and tanned leather often undergoes the further operation of currying, or impregnation with oil. As instances of these different results,—thick sole-leather is tanned; white kid for gloves is tawed; the upper-leather for boots and shoes is tanned and curried; and fine Turkey leather is tawed and afterwards slightly tanned. Morocco leather, as it is called, is chiefly prepared from sheep-skins. Shammoy leather is generally sheep or doe-skin, prepared by dressing, lining, &c., and dyed, if necessary, and then finished in oil. Russia leather acquires its peculiar odour from birch tan. There is an excellent abstract of the manufacture of different kinds of leather in Ure's Dictionary of Arts, &c., which those who wish to pursue the subject further may consult. The leather manufacture of Great Britain is of very great importance, being inferior, in point of value and extent, only to those of cotton, wool, and iron.

LEATHER-WOOD (Dirceu palustris). This
LEAVEN.

is a low shrub, and native of the United States, growing in moist, shady places, seldom rising more than four feet high, spreading into a head, with many small and very delicate leaves. It goes by the name of legume beans; when the leguminous plants are thoroughly dry, they are ground up and used as a substitute for flour. The flowers are produced at the extreme ends of all the stems of the plant, and are of a very delicate, pinkish color, and are the only ones that can be seen in the flower pot. The leaves are also very delicate, and are often used as a substitute for flour in the manufacture of bread. The flowers, which appear at the later part of March, before any perfect leaves are formed, are of a yellow color. The bark is uncommonly tough, yet the enclosed wood is very brittle. It was highly valued by the native Indians, and used in the place of cord. This plant, according to the information of Mr. W. Bartram, occupies an extensive range of territory, from Canada to Georgia. (Willich's Donn. Encyc.)

LEAVEN (Lat. levare, to raise). A piece of sour dough, used to ferment and render light dough or paste. It is a very imperfect substitute for yeast; and as it communicates to the bread an astringent taste, which few persons relish, it ought to be used only where yeast cannot be procured. As, however, the latter ferment cannot always be obtained, especially during winter, I shall state the most simple methods of preparing, as well as of preserving it under the name of leaven. This method is very useful, especially when we have no yeast or other leaven to hand.

By the law of Moses, leaven was strictly forbidden during the passover; and the Jews, who were taught to regard it from the vigil of the feast as unclean, with religious scrupulosity purified their houses from the contaminating influence. See Bread.

LEEK (Allium porrum). The leek is a hardy biennial; for, although it attains perfection in size and for culinary purposes the first year, it does not run to seed until the second, the perfecting of which it also often survives. The whole plant is eaten, being employed in soups, &c., and is by some persons boiled and eaten with meat. There are four varieties: the Musselburgh, and the large London leek, which are by far the best; the Scotch or flag, which is larger and harder; and the Flanders. It is raised solely from seed, which must be sown first in the end of February, a small crop for transplanting in June and July, as well as in part to remain where sown; again for the main crop in the course of March or early in April; and a third time as the close of April or beginning of May, for late transplanting. These sowings are in general performed broadcast, and raked in; though some gardeners employ drills, the plants to remain after thinning; the leek, however, is so much benefited by transplanting as obviously to point out the error of this practice. When the plants are three or four inches in height, in eight or ten weeks after sowing, they must be weeded, hoed, and thinned, where growing too close, to two or three inches apart; water also being given, in dry weather, will, with the above treatment, strengthen and forward them for transplanting in another month, or when six or eight inches high. They must be taken away regularly from the seed-bed, the ground being well watered previously, if not soft and easily yielding. When thinned out, they may be left to remain in the seed-bed six inches asunder, as they do not grow so large as the transplanted ones, which must be set by the dibble in rows ten inches apart, and eight in the lines, being inserted nearly down to the leaves, that the neck, by being covered with the earth, may be formed坚实的shortly. The flowers, which appear at the time of planting, and the long weak leaves shortened, but the roots left as uninjured as possible. The bed should be hoed over occasionally, as well to kill the weeds as to loosen the soil. By this treatment, and by cutting off the tops of the leaves about once a month, as new ones are produced, the neck swells to a much larger size. The several sowings above directed will yield a supply from August until the following May, when they may be used with the last plant. It is always taken up and laid in sand previous to the ground being locked up by continued frost, but they will not keep many days in this situation. To obtain seed, some of the finest roots of the previous year's growth, which have been left where raised, may be transplanted thence in February or the early part of March, eight inches asunder, in a row beneath a warm fence; and when seed-stems arise, they must be attached to stakes for support, or to the fencing: the closer and sooner they are drawn to this latter, the better it will enable the seed to ripen; for in cold summers, particularly in open exposures, it never comes to maturity, and by the first sharp autumnal frost it is entirely destroyed. Good varieties never flower before May or June, and ripen their seed in September. The heads should be cut when changed to a brownish colour, with a foot in length of the stalk left attached, for the convenience of tying in bundles, three or four together, to dry; when they are perfectly dry, they may be hung up and kept in the head until wanted, or immediately threshed out and stored. As the husk is very tough, it is usual, when small quantities have to be operated upon, to rub them against a tile, which breaks it more easily than any other mode that can be adopted. (G. W. Johnson's Kitchen Garden.)

LEES. The dregs or feculencies of liquors, which, after being separated by fermentation, fall to the bottom of the vessels. All the various kinds of lees, such as those of wine, beer, ale, oil, &c., may be made use of as manures when they can be had in sufficient quantities.

LEGS. The extremities that form the support of animals. Of the four legs of a horse, the two before have several parts, each of which has a peculiar name: thus, by the name of fore-leg, we commonly understand that part of the fore-quarters that extends from the hough to the pastern-joint, and which is frequently called the shank. The part that corresponds with it in the hinder quarters is called the instep. In the language of the manage, a horse is said to want the fifth leg when he is treading, and, bearing upon the bridle, lies heavy upon the rider's hand.

LEGUMINOUS PLANTS (from legumen, pulse) are those which bear legumes or pods, such as beans, peas, tares, &c. The Leguminosae are a very extensive natural order of plants, found in all parts of the world, forming large trees and huge twiners in the tropics; herbaceous plants or small bushes, rarely trees in colder countries. The order contains a very
LEICESTER SHEEP.

A great variety of useful and beautiful species, some of which, like clover, lucern, sainfoin, and vetches, are cultivated for cattle; others, as beans, peas, lentils, and various other kinds of pulse, form part of the food of man. Indigo, logwood, and many more, are well-known dyeing plants; several acids and certain "diamonts" yield tragacanth; the tamarind and others bear pods whose interior is filled with an agreeable pulp; Cassia acutifolia and other species of cassia yield senna; Glycyrrhiza, the liquorice-root; Ceratonia, the wild locust. Fruits of Scripture: finally, many are valuable tonics, and some are dangerous narcotics, among which the common laburnum is to be named.

Leguminous crops, according to the strict agricultural acceptance, include beans, peas, and other pulse. But the class is made to embrace a much more extensive range of plants, namely, all such as are considered as ameliorating or enriching crops, such as clover, potatoes, turnips, carrots, beets, cabbages, &c. These latter are far less exhausting than the culmiferous or grain plants, as few of them mature their seeds, and all, on account of their broad leaves, draw more or less nourishment from the atmosphere. They also ameliorate the condition of the soil, by dividing and loosening it with their tap and bulbous roots. As they generally receive manure and drill culture, they are peculiarly adapted to enrich and prepare the soil for the culmiferous crops.

LEICESTER SHEEP. See Sheep.

LENTICULAR. A botanical term, signifying lens or pea-shaped.

LENTIL. (Ervum Lens, from crew, tilled land in Celtic; some of the species are a pest in cultivated ground, being useless and too prolific weeds.) Pl. 7, s. An exotic plant of the vetch or tare kind, cultivated in some parts of England as fodder for cattle. The lentil is an annual, growing to the height of about eighteen inches, with stalks and leaves like those of vares, but smaller, and producing pale purple flowers, which are succeeded by small flat pods, containing two or three round, hard, smooth, and flat seeds. There are two sorts of lentil, the white and the yellow; but the latter affords the greater quantity of fodder. The seeds of this plant are generally sown in March or April, in the proportion of one and a half to two bushels per acre. Lentils also furnish good dry fodder for cattle, and particularly for cutting into chaff as rough-meal for sheep and horses.

LETTUCE (Lactuca, from loc, milk, on account of the milky juice which exudes from the plants when broken). There are in England three indigenous species of lettuce, all biennials.

1. Strong-scented lettuce (L. virosa), which grows about hedges, old walls, and the borders of fields on a chalky soil, not uncommon. The whole herb abounds with an acrid, fetid, milky juice, having the smell of opium, but only slightly narcotic, and little likely to produce the consequences attending the use of that drug. This juice springs out suddenly in large drops, on the slightest touch, from the calyx and tender leaves, when the plant is in flower, but not at other times; evincing a considerable degree of irritability in the plant. The root is tap-shaped. Stem solitary, two or three feet high, round, smooth, sparingly leafy, scarcely branch ed, panicked at the top, a little prickly below. Leaves horizontal, nearly smooth, finely toothed, radical ones numerous, obovate, undivided, depress ed. Flowers numerous, panicked, light-yellow.

2. Prickly lettuce (L. scariola). This species is found in waste ground, and dry, stony borders of fields. The whole herb is glaucous, milky, bitter, but less fetid than the preceding. Stem two or three feet high, leafy, panicked. Leaves numerous, vertical, not horizontal, variously pinnatifid and toothed; thu midrib furnished with a close row of prominent prickles, their base clasping the stem. Flowers small, pale lemon-coloured.

3. Least lettuce (L. saligna). This species grows in chalky waste ground, or about salt marshes. The whole plant is very slender. Stem about two feet high, wavy, pale-brown or whitish, somewhat branched, leafy throughout. Leaves glaucous, smooth except the midrib beneath, linear, hastate or pinnatifid, entire, sessile. Flowers in small alternate tufts composing long clusters, very small, pale-yellow, open in sunshine only, and soon fading. (Smith's Eng. Flor. vol. iii. p. 344.)

Of the well-known cultivated lettuce (L. sativa) there are many varieties, which are divided into families, the cos and the cabbage. The first are more grown in summer than winter; the second at all seasons, but more usually in winter, on account of their superior hardihood. The cos varieties are characterized by being of an upright growth, and, with the exception of the Brighton, require to have their leaves drawn together for bedding; the cabbage, as growing close to the ground, produces a blanched heart, in the manner of a cabbage, without any assistance. The ciccias are of a nature intermediate between the two. When young, the cabbage varieties are in general sweeter than those of the cos at the same age; but at full growth this is reversed: hence the latter are preferred for salads, and the former for soups.

The cabbage varieties succeed better in a hotbed than the cos.

The following varieties are recommended for cultivation in England; but as some of them have been found not to succeed well in this country, those enumerated in the article Kitchen Garden had better be depended on for the main crop.

CABBAGE VARIETIES. COS VARIETIES.

Drunkenhead. Brighten.
Tennisball. Early Egyptian.
Hardy green, or Capuchin. Green.
Prussian. White or Versilizes.
Prince's. Silver.
Common white. Red or leopard.
Large white. Green and brown Cilicia.
Imperial. Lop.
Grand admirable. Large Bumpson.

Lettuces thrive best in a light, rich soil, with a dry substratum. In a poor or tenacious one they never attain any considerable size, but run to seed prematurely. Like most other crops, that soil is to be preferred which is rich rather

707
LETTUCE.

from prior cultivation than the immediate application of manure. It is of advantage to trench it, and if manure is necessarily applied at the time of insertion, it should be in a state of forward decay. For the first and last crops of the year, a warm, sheltered situation is required; but for the midsummer ones, a border that is sheltered during the meridian, but far from being confined or under the shadow of trees, is to be preferred. Lettuce is propagated by seed: that for the first crop should be sown in a frame, on a warm border, or slender hotbed, at the end of January or early in February; at the close of this is being done, the second foot apart, those removed being pricked out at similar distances. Those from the sowings in January and February, in a similar situation to that in which they were raised; and thence until August in any open situation. Those of the August sowing must be divided into two portions; the largest being selected and planted in an open compartment for late autumn use, and the smaller on a warm border for winter and early spring.

When planted out finally, they must be set in rows of not apart each way, which is abundant for the largest variety, and not more than necessary for the smaller. At the time of every removal, whether of picking out or planting, water must be given moderately, and until the plants are rooted. It may be remarked, that transplanted lettuces never attain so fine a growth as those left where sown, nor become so soon fit for use; those which are planted out at once to remain, better in these respects than those which are pricked out previous to final planting. The difference in their time of becoming fit for harvest is generally in favor of the latter, as by these means a more perfect succession is obtained. Those which are planted to withstand the winter are best planted on the summit or south side of ridges, as this is a great protection from excessive wet, from which they always suffer. In every stage of growth they must be kept free from weeds, well watered, and the earth around them frequently stirred for the extirpation of slugs and snails, which are particularly injurious, and are very prevalent in moist seasons.

When the cos varieties have attained an advanced growth, they require their leaves to be drawn together with a shred of matting, to render the interior blanched, care being taken that it is not performed so tight as to bruise them. Under every favourable circumstance for a vigorous growth, the plants, especially of the cos varieties, and during dry seasons, will yet run up to seed before the heart is perfectly blanched: to retard this, it is an effectual practice, at the time of tying them up, to cut out the centre of each with a sharp knife. The plants raised from the September sowings may be divided as directed for those of August; but, in addition, some of the cos varieties may be planted on a warm border, to have the shelter of frames and hand-glasses.

To produce seed, some of the finest and most perfect plants of each variety that have survived the winter, or from the foremost sowing of the year, should be selected. The seed from any that have run up prematurely cannot be depended upon. All other plants must be removed from their neighbourhood, themselves being left at least a foot apart; neither is it allowable for two varieties to flower near each other, as only mongrel varieties will be obtained. Each stem is advantageously attached to a stake, as a support in tempestuous weather. It is to be observed, that the branches must be gathered as the seed ripens upon them, and not left until the whole is ready, as some will ripen two or three weeks before others, and consequently the first and best seed will be shed and lost. It must be well dried before it is beaten out and stored. Lettuce seed is considered to be best the second year; but when three years old it refuses to vegetate.

The juice of the lettuce inspissated is termed lactearius. It possesses slight narcotic properties, and is useful in coughs.

LETTUCE, LAMB'S. See CORN SALAD.

LEVELLING. In husbandry, implies rendering the ground even, and removing of impediments to the common operations of tillage. This is generally done by the plough, but sometimes machines are employed for the purpose.

LEVER. In mechanics, an inflexible rod or bar, movable upon a fulcrum or prop, and having forces applied to two or more points. The lever is one of the mechanical powers; and being the simplest of them all, was the first that was attempted to be explained.

Examples of the application of the lever are of constant occurrence in the mechanical arts. The crowbar, the handspike, nippers, pincers, &c., are levers of the first kind. The second kind includes the chopping knife, the common branch of the plow, the sheep-shear, &c. To levers of the third kind belong the sheep-shear, the trellis of the turning-lathe, tongs, &c. The bones of animals are generally levers. The socket of the bone is the fulcrum; a strong muscle, attached to it near the socket, is the power; and the weight of the limb, with whatever resistance is opposed to its motion, is the weight. A very moderate contraction of the muscle thus gives considerable motion to the limb. (Gregory's Mech. vol. ii.)

LEVERET. A young hare, in the first year of its age.

LEY, LEA, or LAY. Land in the state of swary or grassy surface.

LIBER (Lat. bark). In botany, the interior lining of the bark of exogenous plants. It consists of woody tissue in great quantity, and very thick-sided, intermixed with cellular tissue. It appears to be formed annually, at the same time as the concentric zones of wood, and is intended by nature to convey downwards the secretions elaborated in the bark and leaves.
LIBRARIES, FARMERS'.

The liber is the principal seat of laeticiferous vessels.

LIBRARIES, FARMERS'. Collections of books on agricultural and horticultural subjects are now becoming very general through-out the country, through the instrumentalty of farmers' clubs. They cannot fail of being eminently useful to the cause of agriculture, by diffusing among the cultivators of the soil the latest discoveries and improvements in husbandry, as well as the different opinions and theories entertained on matters having reference to agriculture and its collateral sciences of chemistry, botany, natural history, geology, meteorology, and vegetable physiology, &c.

LICE ON ANIMALS. There is not an animal that does not, under suitable circumstances, nourish in its hair, wool, feathers, or its skin, some kind of louse; and sometimes more than one kind of these parasites lodge and prey on the same animal. In ordinary cases, they do not produce much mischief, but when they increase so much as to produce the disease called mange (Pityriasis), they become truly formidable. The cause of animals being troubled with lice, may usually be traced to a want of cleanliness. When the dust and sweat accumulated on the hair, and in contact with the skin of the ox or horse, are allowed to remain undisturbed by the comb or brush; when the stables are kept filthy, unventilated, and unwholesome; when animals, reduced in autumn by want of pasture, or by living in unhealthy ones, are suffered to take their chance for the winter without extra care or attention; or when a beast loaded with pediculi is turned into the yards or the stables of those exempt from these parasites, it may be expected that they will multiply and infest animals. When we see horses rubbing their tails, biting their manes, and showing other signs of uneasiness and irritation; when cattle are observed to be rubbing their heads against posts or fences, and the hair coming off from the head and neck; or when sheep tear out tufts of wool with their teeth, and bite these places till blood appears, we may expect that lice are present. On most animals, these parasites have some favourite place of resort; on horses, the mane and tail; on horned cattle, around the nose, base of the horns, and the neck; on sheep, they run over every part; and on swine, they do not seem to be confined to any particular location.

Pure air, room for exercise, plenty of food, and above all, cleanliness, are the first things to be attended to in the cure of this evil. Currying, brushing, and washing should be resorted to, as, except in bad cases, this treatment will be usually sufficient to free the animal from these insects, without recourse to other remedies. Where these fail, it will be necessary to have recourse to such external or internal applications as shall operate directly on the vermin.

One of the most common remedies is the mercurial ointment, commonly called unguentum; but this, though effectual, cannot be used without some danger, as numerous instances have occurred in which valuable animals have been destroyed by its too free use. Care should be taken not to prevent the animal from biting itself where the ointment is applied, until it has had time to take effect. A decoction of tobacco leaves, in a strong lye, forms a very good wash; but this, too, owing to the narcotic poison of tobacco, has caused death. Various vegetable remedies have been resorted to, among which are the seeds of the larkspur (Delphinium stephanyagria); and the leaves and flowers of the ledum palustre, or marsh, or Labrador tea. The roots of the black hellebore, or a decoction made from them, have been used with success; and it is said that the water in which the skins or parings of potatoes have been boiled will effectually destroy lice by a few washings. The internal use of sulphur is an excellent remedy, and if given to animals occasionally, is one of the best preventives. It is more difficult to apply remedies for lice to sheep than to any other animals. The English shepherds make use of a salve compounded of white arsenic and corrosive sublimate, carefully parting the wool, and applying the ointment in small quantities directly to the skin, and rubbing it down with the finger. Tessier prefers tobacco smoke to this ointment, as attended with less danger in its use. The sheep is held in such a manner that tobacco smoke is forced from a bellows among the wool to the skin in all directions. After this fumigation, the sheep must be placed in the open air, that the vapor may have room to pass off without being inhaled by them. Perhaps the best remedy for lice in animals, where they have not become so numerous as to produce the disease Pityriasis, is to rub any oil, such as whale oil or melted lard, on such places as they most frequent, or on parts of the animal where they will be most likely to come in contact with it. All the pediculi breathe through what are termed spiracles or openings in their bodies, and the least particle of oil spread over their bodies, by causing suffocation, at once effects their destruction. This is also a perfectly harmless remedy. But prevention in this case is better than cure; and neatness, cleanliness, and good keeping, by insuring comfort and health, leaves no opportunity for the attacks of vermin. (Cultivator.)

LICE ON PLANTS. See Aphidians, American Blight, and Insects.

LICHENS. Plants of a very low organization, which grow on the bark of trees or rocks, when they form a kind of incrustation, or upon the ground, when they consist of irregular lobes, parallel with the earth's surface. Occasionally, in all situations, they are found in a branched state; but their subdivisions are generally irregular, and without order. Their fructification consists of hard nuclei, called shields, which break through the upper surface of the thallus, or main substance of the lichen, are of a peculiar odour and texture, and contain the reproductive particles. Lichens abound in the cold and temperate parts of the world. The greater number are of no use, some, as the reindeer-moss (Cenomyca rangiferinum), the Iceland moss (Cetraria Islandica), and various species of Gyrophora, are capable of sustaining life, either in animals or man. The Iceland moss, when deprived of its bitterness by soaking in an alkali and then boiling, be-
LICKS.

LIGHT.

comes, indeed, a diet recommended to invalids. Others are used as tonic medicines, as *Variaxia fagiana* and *Parnassia porchatia*. Their principal use is, however, that of furnishing the light with brilliant colours; orchid, callubear, and percelle, with many more, are thus employed. (Brodie's Dict. of Science.) See Moss.

LICKS. A term applied in the United States to places where salt springs escape from the earth and impregnate the soil, and sometimes give rise to an efflorescence of common salt. To such spots the deer, buffalo, and almost all graminivorous animals resort, for the purpose of licking the surface. See Salt.

This calyx, which falls off from the flower in a single piece.

LIFE EVERLASTING. See Cuswweed.

LIGHT, IT'S INFLUENCE ON VEGETATION. That light has a considerable influence upon the growth of plants, is an observation that must have been very early made by mankind. The inferior green colour of plants growing in the shade, as in woods, or when covered with earth, or inverted vessels, would clearly indicate to the most careless observer, that light ought to be considered in the colour of vegetation; every gardener, in truth, takes advantage of this fact, when he is bleaching his culinary vegetables. But it was not till after the days of Priestley, that the other chemical effects which light produces upon a growing plant were so much better understood.

It is probable that this influence commences at a very early period in the life of the plant, with even the germination of the seed. Ingenhouz, says Dr. Thomson, found that seed always germinate faster in the dark than in the light. (Exper. sur la Veg. 11.) And these experiments were repeated by Sennebier with equal success. (Mén. Physico-Chem. vol. iii. p. 41.) But the Abbé Bertholin, who distinguished himself so much by his labours to demonstrate the effect of electricity on vegetation, objected to the conclusions of these philosophers, and affirmed that the difference in the germination of seeds in the shade and in the light, was owing, not to the light itself, but to the difference in the moisture in the two situations, the moisture being much faster in the seeds in the light than from those in the shade; and he affirmed that when precautions were taken to keep the seeds equally moist then those in the sun germinated sooner than those in the shade. (Jouer. de Physique, 1789.) But when Sennebier repeated his former experiments, and employed every possible precaution to insure equality of moisture in both situations, he constantly found the seeds in the shade germinated sooner than those in the light. We may conclude, therefore, that light is injurious to germination; and hence one reason for covering seeds with the soil in which they are grown. But from the more recent experiments of Saussure, there is reason to believe that light is only injurious to vegetation in consequence of the heat it produces; for where the direct rays of the sun were intercepted, though light was admitted, the germination of the seeds was not sensibly retarded. (Rech. Chem. sur la Veg. p. 28; Thoms's Chem. vol. iv. p. 307.)

And with regard to the after-growth of plants, light exercises a very considerable influence. It is now clearly ascertained that plants vegetating in the light, absorb carbonic acid gas from the atmosphere, and emit oxygen gas; but when vegetating in the dark different effects are produced, for then carbonic acid gas is emitted, and oxygen gas absorbed. (See Gases.) This latter process is thus explained by Liebig:—"It is true that the decomposition of carbonic acid is arrested by the absence of light; but then, namely, at night, a true chemical process commences, in consequence of the action of the oxygen in the air upon the organic substance, composing the leaves, blossoms, and stamens of other acids. This process is then connected with the life of the vegetable organism, because it goes on in a dead plant exactly as in a living one. The substances composing the leaves of different plants being known, it is a matter of the greatest ease and certainty to calculate which of them during life should absorb most oxygen by chemical action where the influence of light is withdrawn. The leaves and green parts of all plants containing volatile oils, or volatile constituents in general, in proportion in which the absorption of oxygen, should absorb more than other parts which are free from such substances. Those leaves, also, which contain either the constituents of nutgalls, or compounds in which nitrogen is present, ought to absorb more oxygen than those which do not contain such matters. The correctness of these inferences has been distinctly proved by the observations of De Saussure; for whilst the tasteless leaves of the *Agave Americana* absorb only 0·3 of their volume of oxygen in the dark during 24 hours, the leaves of the *Pinus Abies* which contain volatile and resinous oils absorb 10 times, those of the *Quercus Robur* containing tannic acid 14 times, and the balmy leaves of the *Populus Alba* 21 times that quantity. This chemical action is shown very plainly also in the leaves of the *Cotyledon Calycina*, the *Caladium ficoides*, and others; for they are sour like sorrel in the morning, tasteless at noon, and bitter in the evening. The formation of acids is effected during the night by a true process of oxidation; these and similar acids are not resorbed during the day and evening, and are changed, by separation of a part of their oxygen, into compounds containing oxygen and hydrogen, either in the same proportions as in water or even with an excess of hydrogen, which is the composition of all tasteless and bitter substances. When the green leaves of the poplar, the beech, the oak, or the holly, are dried under the air-pump, with exclusion of light, then moistened with water, and placed under a glass globe filled with oxygen, they are found to absorb that gas in proportion as they change in colour. The chemical nature of this process is thus completely established. The diminution of the gas which occurs can only be owing to the union of a large proportion of oxygen with those substances which are already in the state of oxides, or to the oxidation of the hydrogen in those vegetable compounds which contain it in excess. The fallen brown or yellow leaves of the oak contain no longer tannin, and those of the poplar no balsamic constituents. (Org. Chem. p. 29.)
The action of light upon the growing plant is in every point of view full of interest to the cultivator: "If all the branches of a tree, exclusive of one," said Mr. T. M. Knight (and he was one of the ablest of modern vegetable physiologists), "be much shaded by contiguous objects, they all, in different situations, react upon each other; their tendrils might come into contact, and I was by these means afforded an opportunity of observing with accuracy the difference between the motions of these and those of the amelopsis under similar circumstances. The latter almost immediately receded from light, by whatever means that were made to operate upon them; and they did not subsequently show any disposition to approach the points from which they once receded. The tendrils of the vine, on the contrary, varied their positions in every period of the day, and afterwards returned again during the night to the situations they had occupied in the preceding morning, and they did not so immediately or so regularly bend towards the shade of contiguous objects. But as the tendrils of this plant, like those of the amelopsis, spring alternately from each side of the stem, and as one point only in three is without a tendril, and as each tendril separates into two divisions, they do not often fail to come into contact with the organs, and the effects of contact upon the tendrils are almost immediately visible. It is made to bend towards the body it touches, and, if that body be slender, to attach itself firmly by twining round it, in obedience to certain causes. The tendril of the vine, in its internal organization, is apparently similar to the young succulent shoot and leaf-stalk of the same plant; and it is abundantly provided with vessels or passages for the sap; and I have proved that it is alike capable of feeding a succulent shoot, or a leaf when grafted upon it. It appears, therefore, I conceive, not improbable that a considerable quantity of the moving fluid of the plant passes through its tendrils, and that there is a close connection between its vascular structure and its motions." (Ibid. p. 166.

"The stems of the potato," he adds in another place, "as of other plants, rise perpendicularly under the influence of their unerring guide, gravitation, so long as they continue to be concealed beneath the soil; but as soon as they rise above it they are, to a considerable extent, under the control of another agent, light. Each inclines in whatever direction it receives the greatest quantity of it, and consequently each avoids and appears to shun the shade of every contiguous plant; gravitation labouring to give a perpendicular, the other a horizontal direction to the leaves, and the comparative power of one agent increasing, as that of the other decreases." (Ibid. p. 306—306.)

The opinions of Liebig, as to the chemical changes produced in plants by the action of light, and its withdrawal, seem confirmed, in some degree, by those of Davy. "In the changes that take place in the composition of the organized parts," said that excellent philosopher, "it is probable that saccharine compounds are principally formed during the absence of light; gum, woody fibre, oils, and
resins, during its presence; and the evolution of carbonic acid gas, or its formation during the night, may be necessary to give greater solubility to certain compounds in the plant. (Agric. Chem. p. 223.) And after giving a variety of experiments to elucidate the action of vegetation on the atmosphere (see Gases, their Uses to Vegetation), he adds, "These facts confirm the popular opinion, and when the leaves of vegetables perform their healthy functions, they tend to purify the atmosphere in the common variations of weather, and change from life to life. It may occur, however, as an objection to these views, that if the leaves of plants purify the atmosphere towards the end of autumn, and through the winter and early spring, the air in our climates must become impure, the oxygen in it diminish, and the carbonic acid gas increase, which is not the case; but there is a very satisfactory answer to this objection. The different parts of the atmosphere are constantly mixed together by winds which, when they are strong, may travel the whole length of the earth. In our winter, the southwest gales convey air which has been purified by the vast forests and Savannas of South America, and which, passing over the ocean, arrives in an uncontaminated state. The storms and tempests which often occur at the beginning and towards the middle of our winter, and which generally blow from the same quarter of the globe, have a salutary influence. By constant agitation and motion, the equilibrium of the constituent parts of the atmosphere is preserved; it is fitted for the purposes of life; and those events which superstition formerly referred to the wrath of heaven, or the agency of evil spirits, and in which they saw only disorder and confusion, are demonstrated by science to be ministrations of Divine intelligence, and connected with the order and harmony of our system." (Ibid. p. 230.)

LIGHTNING. An electric phenomenon, produced by the passage of electricity between one cloud and another, or between a cloud and the earth. The identity of lightning with electricity, though it had been previously suspected, was first directly demonstrated by the celebrated Dr. Franklin, in the year 1749, by the experiment of drawing sparks by the electric kite. Since that time the science of electricity has been greatly advanced; nevertheless, the cause of some of the appearances connected with lightning is not well explained even at the present day.

There are three phenomena in particular for which, at least, a satisfactory account can be given. The first is the form of the flash, which is always zigzag, or in broken lines, making a greater or smaller angle with each other. The second is the frequent repetition of the flashes from the same cloud, which often follow one another in quick succession, contrary to what takes place in the case of electric conductors, which generally recover their natural state, or discharge the whole of their electricity at a single stroke. The third is the length of the flash, which sometimes appears to embrace a large portion of the sky. This phenomenon can be best observed from the tops of mountains, reaching above the clouds from which the lightning proceeds; and observers in such cases agree in stating that they have seen flashes certainly extending several miles in length.

The zigzag form of the flashes is common to lightning and the electric spark; the same explanation should consequently apply to both; but this the theory has not yet been able to give.

The theory of the electric fluid, and the well-ascertained differences in the conducting power of different substances, suggested the idea of protecting buildings from the destructive effects of lightning by metallic rods. Such rods are usually made of iron about half an inch in diameter. The lower portion should descend into the ground some 3 or 4 feet, and in all cases penetrate to the moist earth. It should be made rather larger than the rest of the rod, and have a slant from the foundation, or outwardly. Some recommend that the lower end should be pointed in the same manner as the upper extremity. The top of the rod should have one or more sharp points. As iron is so liable to rust, it is usual to have these either gilt or tipped with platinum, so as to be preserved from oxidation. The tops of the rods may be raised some 4, 6, or 8 feet above the chimneys or highest points of the buildings they are intended to protect. If the buildings be large, there should be more points than one elevated at the different parts. Indeed, some persons who have devoted attention to the subject, say that there should always be several projecting points raised to receive the lightning from different directions. Lightning rods cost but little, as the platinum points can be bought for $1.25, and the conductors may be easily made by any blacksmith. They should have as few joints as possible, and be inspected from time to time to see whether any separation exists, and whether the joint remains in its place. Where, from rust or other causes, any interruption to the course of the electric fluid occurs, a lightning rod, instead of furnishing protection, is an additional source of danger.

LIGHTS, by ORIALLIES, or AURORA BOREALIS. A luminous meteor, generally appearing in the northern part of the sky, and presenting a light somewhat resembling the dawn or break of day. The appearances which it exhibits, and the forms it assumes, are so provisorily unsteady, that it is not possible to comprehend them under any general description. In the Shetland Isles, and other countries in high latitudes, the northern lights are the constant attendants of clear and frosty evenings in winter. They are most frequent in autumn. A very interesting account of this meteor, and of the works treating on this subject, will be found under the head "Aurora Borealis," in Brande's Dict. of Science, &c.

LIGNEOUS (Lat. lignum, wood). In entomology, a part so called when it is composed of a hard, inelastic substance like wood.

LIGNIN (Lat. lignum). The woody fibre. This most important proximate principle of vegetables exhibits itself in a variety of forms, constituting the different textures of hard and soft wood, and various fibrous products, such as hemp, flax, cotton, &c. When by fine me-
chemical division it is reduced to a pulpy state, it is formed into paper. When by different reagents all the soluble matters are extracted from wood, the insoluble residue is lignin; its ultimate components are carbon, oxygen, and hydrogen, the two latter elements being in the same relative proportions as in water; so that woody fibre may be considered as a compound of carbon and water, and, according to Dr. Prout's experiments, almost exactly in equal weights. Lignin is very unperishable, but under certain circumstances it is attacked by dry rot, arising out of the growth of a parasitic fungus, which causes its rapid decay. Damp timber, in situations where air has not free access, is particularly subject to its attacks; and when once it has made its appearance, the well-seasoned timber in its neighbourhood becomes liable to the same disease. The dry rot may be prevented by impregnating the timber with certain saline solutions, and of these, solution of corrosive sublimate has been found most effectual; this (the bi-chloride of mercury) combines chemically with the albumen of the wood, and the compound is very indestructible. (See Dry Rot.) Lignin has also a strong attraction for alumina, and hence lignin, spread on the paper, and other forms of this fibre, may be aluminized by steeping them in hydrated alumina diffused through water, or more effectively by soaking them in certain alumina solutions, drying them, and afterwards washing out the excess of the salt. It is in this way that cotton goods are impregnated with alumina for the purpose of dyeing and calico printing. Other metallic oxides exhibit similar attractive powers, especially the oxide of iron. The analogy that exists between the composition of sugar, gum, starch, and even vinegar and lignin, suggests the possibility of the conversion of those substances, by an exchange of their proximate elements, into each other; and it has accordingly been found that by carefully roasting pure and fine sawdust, it is rendered partially soluble in water, and that a part of it is converted into a nutritious substance, probably intermediate between sugar and starch, and which, when mixed with a little flour, yields a palatable bread, not very unlike that made by some of the inhabitants of the northern parts of Europe of the bark of trees. Mixed with sulphuric acid, lignin passes into gum, and from this sugar may be obtained, by boiling it for some hours in a very dilute sulphuric acid; this sugar, when purified, much resembles grape or honey sugar. By this process, rags may be converted into nearly their own weight of this peculiar saccharine matter.

The production of vinegar by the destructive distillation of wood, was originally suggested about the middle of the 17th century, by Glau- ber, a celebrated German chemist of that time; it has lately become a very important branch of manufacture in England. Upon the whole, there are very few natural products equally important with lignin in their applications to the useful and ornamental arts. See PRO-
LILAC (Syringa, from syrinx, a pipe. The branches are long and straight, and are filled with medulla; hence the old name of the lilac, pipe-tree. The English name of the genus is from Blaer, for lilag, the Persian word for the flower). The species of lilac are well known elegant shrubs.

The common lilac (Syringa vulgaris) is a shrub originally from Constantinople, growing to the height of 18 or 20 feet. The elegant lilac-coloured bunches of flowers are very sweet and graceful to the eye. There is also the white lilac, still more delicate-looking, and equally sweet-scented. The most beautiful variety of the common purple lilac is that known by the title of the Scotch lilac.

The Chinese lilac (S. chinensis) is a native of China, and less in size than the common lilac; it was first brought to this country in 1795. Blooms violet-coloured flowers in May.

The Persian lilac (S. persica) is a native of Persia, and seldom exceeds five or six feet in height, blowing light purplish pink flowers in May. The lilacs love a good garden soil, and may be propagated by layers, shoots, and suckers from the roots.

LILY (Lilium, derived from the Celtic word li, signifying whiteness; on account of the beautiful white flowers of the original species). This is a fine ornamental and well-known genus of exotic plants, almost all of which are remarkable for the delicacy and beauty of their flowers. Most of the species succeed in a rich, light soil, but the American species should be grown in peat. (Paxton's Ed. Dict.)

Miller, in his Dictionary, mentions 13 species, with their varieties; but there are now more than 34 known species, besides innumerable varieties: the finest for garden ornament are as follows:

The superb martagon (L. superbum). A beautiful plant, blowing many bright orange flowers spotted with violet. It loves bog soil.

Purple martagon, which grows 3 or 4 feet high, blooming reddish or white flowers spotted with purple. It blows in July. It is sometimes called Turk's cap. It is a native of Germany.

Scarlet martagon (L. chalcedonicum). Native of the Levant, blowing a bright scarlet flower in June and July. It likes a good soil.

Turk's turban (L. pomponium), blows a pretty pendulous red flower in June, in the shape of a turban. In Kamschatka the bulb of this species is cultivated the same as the potato is in this country.

Orange or fire lily (L. bulbiferum). Large flower, of a deep orange colour, flowering in June and July. The Russians and Tungusians also eat the roots of this species, either boiled in milk or roasted. A German author informs us that these mealy roots might, in times of scarcity, be made into wholesome bread. The roots are cathartic, and the leaves cooling.

Tiger lily (L. tigrinum). A beautiful showy bulb, blooming an orange flower in June: it loves a sandy soil and open situation.

Philadelphia lily (L. philadelphicum). Native of North America, blooming a deep orange spotted or scarlet flower in July. This very elegant plant may be known from the other

LILAC.
LILY OF THE VALLEY.

species by the claws of the petals. The colour of the flower is orange-red. Protect it in winter by spreading coal ashes over it.

The American or Canadian lily (L. Canadense), has flowers of a yellowish orange. It is a fine plant, growing 2 or 3 feet high, and found in abundance on the marshy shores of the Delaware below Philadelphia. It is perennial, and flowers in July.

The Superb American lily (L. superbum), is a magnificent plant, which, says Dr. Wm. P. C. Barton, may be ranked among the finest vegetable productions of the United States. It frequently attains the height of 6 or 7 feet, supporting a profusion of elegant scarlet flowers. It is found on the marshy shores of the Delaware, and in the bogs of New Jersey and other states. A perennial, flowering in July and August.

The common white lily (L. candidum), is too well known to need description. It is hardy, and produces a beautiful flower, the fragrant odour of which is so powerful as to induce fainting if numbers of them be kept over night in a close apartment. The bulb roasted is emollient and soporific. All descriptions of lilies are propagated freely by offsets from the bulbs, which should be taken up when the stem decays, and parted and replanted early in October, 5 to 6 inches deep, in a light, dry soil. The bulbs of martagon must never be transplanted till after the stem is decayed, as they will not bear being disturbed. Many varieties of lilies are produced from seed, which is treated in the same way as tulip seed.

LILY-OF-THE-VALLEY (Convallaria majalis, from the Latin convallita, a valley). This very elegant sweet-scented indigenous perennial is not reckoned among the lily tribe. It grows in woods, heaths, and at the foot of hills, flourishing and shedding its fragrance in May and June. The roots are thread-shaped, creeping, much entangled. Leaves two, radical, elliptical, 3 or 4 inches long, acute, entire, many-ribbed, smooth-stalked. Flower-stalk solitary, simple, radical, naked, semi-cylindrical, bearing a simple curved cluster of several pendulous, cup-shaped, white flowers, with rather distant segments. Berry as large as a black currant, seedy. There are varieties with double or with purple flowers, sometimes seen in gardens; but not easy of cultivation, and far less elegant than the wild kind, which is among the most favourite of our native flowers.

This vegetable is eaten by sheep and goats, but refused by cows, horses, and swine. The flowers when dried have a narcotic scent, and if reduced to powder excite sneezing; hence they are sometimes used as a stimulant. A beautiful green colour may be prepared from the leaves, with the addition of lime. The lily-of-the-valley will grow in any moist, shady situation, and even under the drip of trees, where few other plants would succeed. It is multiplied by dividing the roots in autumn. See Solomon's Seal.

LILY, THE DAY (Hemerocallis, from hemera, a day, and kallos, beauty; alluding to the beauty and duration of the flowers). This is an ornamental genus of exotic flowering plants of the simplest culture, thriving well in any light loamy soil, and readily increased by divisions. The most common species are the yellow day-lily (H. fulva), a native of Siberia, blooming yellow flowers in June, and the fulvous or copper-coloured day-lily (H. fulva), a native of the Levant, blowing fulvous flowers in July and August.

LILY, THE WHITE WATER. Candock, or water-socks. (Nymphaea, from nympha, a water-nymph; alluding to the habituation of the plants.) These are beautiful plants, well worthy of cultivating in every collection. The stave species should be grown in tubs of water, in places sheltered from direct sunlight or strong winds. They are used in the United States, and may be grown in ponds, canals, &c. They are all increased either by seeds, dividing the roots, or separating the tubers. (Paxton.)

The great white water-lily (N. alba) is a beautiful perennial, native of Great Britain, perhaps the most magnificent of all its native flowers, growing in clear ponds and slow rivers. The root is tuberous, horizontal, sending down numerous long, stout radicles which are fibrous at the extremity; leaves floating, a span wide, oval, heart-shaped, with nearly parallel or close lobes at the base, entire, smooth. Every part of the herb is slightly vascular, perspiring rapidly, and, though so succulent, drying very soon. Flowers four or five inches wide, white, with yellow stamens and pistil; the upper surface of the calyx leaves white, often tinged with pale red, generally destitute of scent. The stems are superior to oak-galls for dyeing green. The roots are astringent, and a weak infusion is said to be useful in lepra. The roots are used in Ireland and Jura for dyeing a brown colour. The Egyptians eat the roots boiled, and convert the seeds into bread. The Swedes also have used this root in prevailing dearn, as a substitute for corn; though it requires to be previously divested of its bitter taste by frequent washings. According to Gleditsch, the roots of this species and of the yellow lily are equally useful in tanning and currying. This plant is eaten by hogs, but disliked by goats, and totally rejected by cows and horses.

The white water-lily looks very handsome in some of our larger ponds, or in the bottom of our smaller ponds, where it has a free place without shade, blowing its large flowers in June and July. They have a faint, sweet scent, and expand in sunshine, in the middle of the day only, closing towards evening, when they recline on the surface of the water, or sink beneath it. The same circumstance is recorded of the Egyptian N. lotus, from the most remote antiquity. The stimulus of light, which indeed acts evidently on many other blossoms and leaves, expands and raises with peculiar force these splendid white flowers, that the pollen may reach the stigma uninjured; and when that stimulus ceases to act, they close again, drooping by their own weight to a certain depth. When the flower-seeds ripen in August, the plant sinks again to the bottom. In transplanting the water-lily, the pond must be entered, the stem of the plant felt for, and the roots dug up with a large ball of its mud left round them; place it in an old fish-basked, and remove it speedily, to sink it in the place intended for its...
LIME.

removal. As the basket rots, the plant becomes fixed in its new situation. Propagate by throwing the ripe seed-vessels into large ditches of standing water, when the young plants appear the following spring.

The Great American Water-Lily, one of the most splendid productions of floral nature, is comparatively a rare plant. It is found in a pond about a mile below the city of Philadelphia, and not far from Gloucester Point, a place much resorted to by naturalists and amateur florists during the season of flowering (August). Some have asserted a belief that the seeds were introduced from Europe; but the fact that a plant precisely similar is found in other parts of the country, and even in ponds along rivers west of the Mississippi (the Kansas and Osage, for example), proves the Cymanus or Nelumbo, a native of North America as well as of India, where it is called the Sacred Bean, and consecrated to religious purposes. "There is not," says Professor W. P. C. Barton, "any plant in North America comparable to this for grandeur, simplicity, and beauty. Truly may it be styled, as I have elsewhere called it, the Queen of American Flowers. I regret to say that it is not as abundant in our vicinity as it was five years ago. This may be an accidental or temporary condition, owing to a disturbance of the site where it grows. The leaves are perfectly round, and centrally peltate. They are from a foot to eighteen inches in diameter, of a rich velvety green above, and very pale underneath. They are supported by petioles from two to three and a half feet in length." The flowers are pale-yellow, globose, and about three or four inches in diameter, supported above the surface of the water by petioles or a scape, a yard in length, frequently muricate towards the upper part. From this circumstance, together with an accurate examination of a fine Chinese painting of the India species, which differed in nothing from the American plant, except in the rose-coloured flower, Dr. Barton considers the two species as identical.

The seeds are a kind of nut, very similar to the chinquepin, of a very pleasant flavour, and eagerly sought after by boys. The Indians in the Far-West resort to them as food.

Of the genus Nymphaea, the Fragrant Water-Lily is a species native to the United States, a very beautiful aquatic plant, with white flowers, which exhale a delicious fragrance. The leaves and flowers both float on the surface of the water. It is a perennial.

LILY, THE YELLOW WATER (Nuphar, from nusfar or nylosfar, the Arabic name of Nymphaeum). This, like the last described, is a genus of very beautiful plants, admirably adapted for growing in ponds, cisterns, or lakes; and they are increased by dividing the roots, or by seeds, which have only to be thrown into the water where they are intended to grow. (Parvin).

In England, the only indigenous species are: 1. The common yellow water-lily, or water-can (N. lutea), which is met with very frequent in the wild state in rivers and pools. The whole plant is rather smaller than the white water-lily. Footstalks two-edged, flattened on the upper surface; leaves entirely smooth, and even rounded at the end, and generally at the lobes, which meet and lap over each other. The flowers, which appear in July, are about two inches wide, cupped, all over of a golden yellow, with the scent of brandy or ratafia, which the French call berne called berne bottles in Norfolk. They perhaps communicate this flavour by infusion to the cooling liquors or sherberts, so much used in the Levant. The seed-vessel, a coated berry, when ripe, bursts irregularly, not dissolving away into a mass of pulp, like the Nymphaea. The roots, like those of the white water-lily, are astringent, and contain a quantity of secula. If moistened with milk, they are said by Linnaeus to destroy crickets and cockroaches. Hogs will eat this aquatic plant, but all the other species of live-stock reject it.

This aquatic plant is what is so familiarly known in the United States by the name of splatter-dock, a perennial, blooming its yellow globular flowers in July and August, filling ditches, and extending for miles along the shallow banks of rivers, below high water-mark.

2. The least yellow water-lily (N. punica). This is much smaller than the preceding, and flourishes principally in the highland lakes of Scotland. The marsh-trefoil is often called the dwarf water-lily.

Of the genus Nuphar, another species (Kalamia) found in the United States is the Small Water-Lily, with leaves floating like those of the common splatter-dock, but only about one-third the size; yellow flowers, also floating, and about half an inch in diameter.

LIMB. The border of a flower; also the branch of a tree.

LIME (Germ. leim, glue). This very useful earth is the oxide of a metal called calcium. In England it is obtained by exposing chalk and other kinds of limestone, or carbonates of lime, to a red-heat,—an operation generally conducted in kilns constructed for the purpose: the carbonic acid is thus expelled, and lime, more or less pure, according to the original quality of the limestone, remains. In this state it is usually called quick-lime. The purest quick-lime is obtained from the calcination of white marble. When sprinkled with water it becomes very hot, and crumbles down into a dry powder, called slaked lime, or hydrate of lime, owing to the water becoming consolidated and an essential part of the lime. When exposed for some weeks to the air, it also falls into powder, in consequence of the absorption of moisture; but a portion of carbonic acid is also absorbed, and the lime partially converted into limestone. The uses of lime are very numerous. Its most important application is in the manufacture of mortar and other cements used in building. It is also very extensively used as a manure to fertilize land.

LIME as a manure. There is some reason to infer that lime has been used as a manure from a very remote period. M. P. Cato, in the oldest agricultural treatise which has escaped to us, describes, in his sixteenth and thirty-eighth chapters, with much minuteness, the best means of preparing it. And although, in the early writers on rural affairs, we find but few notices of its use as a fertilizer, yet we may reasonably
LIME.

conclude that its employment was nearly as extensive and as early as that of chalk or marl, which were in very primitive times largely and skilfully used for a similar purpose. Pliny attests the use of it by the Roman cultivators as a dressing for the soil in which fruit trees were planted.

Of all the earthy manures found in England, lime is certainly the most powerful and rapid in its effects on the soil; and if its use is not so extensive on the clays and peaty lands of many districts of the island as is desirable, this does not arise from the limited powers of this earth, but rather from a variety of other causes, such as its expense, the impurity of the lime employed, and an ignorance of its most economical mode of application.

The common varieties of lime used by the English farmers, are procured by calcining either chalk or limestone. Such lime is therefore rarely, if ever, chemically pure, for it almost always contains a portion of silica (flint), alumina (clay), and some red oxide of iron. These, however, are not often present in sufficient quantities to influence the fertilizing powers of the lime to any material extent, as will be readily seen by the analysis of the limestones and the chalk usually employed by the limeburners. Common limestone is composed of:

<table>
<thead>
<tr>
<th>Carbonate of lime</th>
<th>Water</th>
<th>Silica</th>
<th>Alumina</th>
<th>Oxide of iron</th>
</tr>
</thead>
<tbody>
<tr>
<td>95.05</td>

united with various small proportions of the other earths. There is also a very considerable proportion of lime made in the north of England from the magnesian limestone (called by the Yorkshire farmers “hot lime”), all of which differ considerably in composition; that from Sunderland contains, in 100 parts,

<table>
<thead>
<tr>
<th>Carbonate of lime</th>
<th>Carbonate of magnesia</th>
<th>Clay, water, &amp;c.</th>
<th>Oxide of iron</th>

<td>0:26</td>
</tr>
</tbody>
</table>

This “hot lime,” which is well known by the farmers in the neighbourhood of Doncaster, and other parts of the north of England, can only be applied in limited quantities, for the calcined magnesia of the limestone remains for a considerable period in its pure caustic form, without absorbing carbonic acid gas from the atmosphere, and in this state its effect is very pernicious to many kinds of plants. It is only when pure, however, that magnesia is prejudicial to vegetation: by exposure to the atmosphere, it gradually and slowly absorbs carbonic acid gas, becomes carbonate of magnesia, and in this state forms a part of many cultivated plants. Some of the most fertile soils of Britain, in fact, contain it in this form, in considerable quantities.

Limestone occurs of various colours and shades, as well as of different degrees of hardness. In weight the compact varieties are very much alike, being generally a little more than 2½ times (2.7) heavier than water. Limestone may be distinguished from other varieties of rock, by dropping on it some strong acid, such as the acetic acid (vinegar), sulphuric (oil of vitriol), or muriatic (spirit of salt), upon the addition of either of which bubbles of gas are observed to escape when lime is present, but not otherwise.

The action of the fire upon the chalk and the limestones merely deprives them of their water and carbonic acid gas, or fixed air. The farmer must not fall into the very common error of supposing that any thing is added by the fire to the lime; on the contrary, it loses very materially in weight, by being deprived of its carbonic acid gas, burnt or quick-lime losing about 44 per cent. of its original weight, a loss, however, which it gradually recovers by exposure to the atmosphere, which always contains this elastic vapour.

One of the most remarkable properties of quick-lime, is its tendency to combine with water. If quick-lime be moistened with a certain quantity of water, it soon becomes heathen, throws off a portion of the water in the form of steam, and falls to a very fine, white powder, which is a hydrate of lime, always containing 24 per cent. water; if, however, more water be added, the same hydrate is formed, but the excess of water agglutinates the powder into lumps or masses which will eventually become hard, and resemble stone. Still more water immediately applied to quick-lime, dissolves it, and forms lime-water. If quick-lime be exposed to the air, it also falls to a coarser powder by absorbing 12 per cent. of water and 24 per cent. of carbonic acid from the air, constituting a mingled carbonate and hydrate of lime. The same change occurs gradually with that which has been slacked by water and is exposed to the air, the carbonic acid of the atmosphere replacing the water of the hydrate. The carbonate of lime, such as exists in chalk, limestone, &c., is scarcely soluble in pure water, but if the latter contain carbonic acid, as rain water usually does when in contact with the soil, the limestone enters into solution. (Booth’s Geology of Delaware.)

The lime which I have used, observes Mr. C. W. Johnson, has been principally made from chalk, at an expense of about five pence or six pence per bushel. That which I made from the magnesia limestone was from the neighbourhood of Sunderland. This requires less fuel to convert it into lime than the common limestone. For the ordinary kinds, about one bushel of coals is required for five or six
bushels of the limestone; and from my own experiments, I am inclined to agree in opinion with many of the farmers of the midland counties, that the lime procured from limestone is rather more powerful in its effects on clay soils than that made from chalk.

In either case the shape of the kiln, and the steady gradual application of the heat, are very material circumstances to be regarded by those who burn their own lime. The limestone and chalk should be placed in the kiln (which I think is best of an egg shape), in moderately-sized pieces, free from the powdered chalk or stone; and care must be taken to have the earth thoroughly burnt, of which perhaps the best indications are its lightness, and the alteration of the colour of the flame issuing from the top of the kiln, which, when the lime is sufficiently made, loses its red tinge. The price of the fuel, and readiness of access to the limestone or chalk, of necessity governs the price of the lime: in some districts of the north it is made by the farmers for not more than one penny to three halfpence per bushel.

The chemical uses of lime to vegetation may be conveniently divided into two heads; first, its direct action upon vegetation; and secondly, its chemical operation on the matters contained in all cultivable soils.

In its direct action, as a food or constituent of plants, its uses are highly important; for hardly a single plant has yet been analyzed, in which the presence of lime has not been detected, in combination with an acid. It must be regarded indeed as an essential ingredient in almost all vegetable substances, as a direct food of plants.

It is found in the commonly cultivated crops of the farmer, however, in very varying proportions: thus the ashes of the oat-plant contain more than five per cent. of lime; in two pounds’ weight of the seeds of wheat are commonly found about 12 grains of carbonate of lime; in the same quantity of rye, about 13-14 grains; in barley 24-8 grains; 38-75 grains in the oat, and 46-2 in the same weight of rye-straw. It abounds also with magnesia in the wood of trees: the ashes of that of the oak contain about 32 per cent. of the earthy carbonates; those from the poplar 27 per cent.; from the hazel 8; of the mulberry 56; and from the hornbeam 26 per cent. The proportion however of lime found in plants varies with the composition of the soil on which they are produced. Thus the ashes of the leaves of the fir (Picea abies), growing upon a limestone hill, were found contained 43-5 per cent. of the carbonates of lime and magnesia, but the ashes from the leaves of another fir growing upon a granite soil yielded only 29 per cent. of the same earthy salts. There are very few soils fit for cultivation from which this earth is entirely absent, and its addition is commonly found by the farmer to promote the fertility of most barren lands—most the sterile heaths, for these are the very lands whose soils contain hardly a trace of lime; in that of Bagshot, for instance, it exists in a very minute proportion. The action of lime for the aqueous particles of the atmosphere is considerably about my own experiments 1000 parts of lime previously dried in a temperature of 212° gained by exposure for three hours to air saturated with moisture, at a temperature of 60°, 11 parts.

Professor Schubler found that the same weight gained in 12 hours 25 parts, in 24 hours 31 parts, in 48 hours 35 parts, when it appeared to have become saturated with moisture, for in 72 hours it had not again increased in weight. Lime therefore is not without its uses even in this respect to vegetation. Lime and chalk differ in their action, and in their value as fertilizers in several respects; thus lime dissolves and renders soluble the organic matters of the soil, which chalk does not; its action, too, as a direct food of plants, is more rapid, from the superior readiness with which it mingles with the soil. And again, its carriage is considerably lighter, for in the process of lime-burning almost all the water and carbonic acid gas of the chalk are driven off. These amounted in some specimens of Kentish chalk, which I examined, to more than 58 per cent.; so that when the farmer carries 42 tons of recently well-burnt lime, he conveys as much real earth on to his land as is sometimes contained in 100 tons of chalk.

The chemical action of the lime on the soil is also very considerable; mixing with the heavy adhesive clays, it renders them more friable, less liable to be injuriously acted upon by the sun, and much more readily permeable by the gases and vapour of the atmosphere. It renders them, the cultivator tells you, “more easily workable.” And, again, the action of lime upon the organic substances always more or less contained in the farmers’ soils is very considerable; and this benefit is not merely confined to the vegetable remains in the land, but it extends with equal energy to the dead and the living animal matters, with which, in a countless variety of forms, the soil is tenanted. There are few substances, in fact, more destructive to grub-worms, animalculi, &c., than lime. When the lime is applied in the form of quick-lime or slaked lime, the action of the lime, the soil is, as a natural consequence, enriched by their remains. On soils which abound in sulphate of iron, which is commonly the case with those containing an excess of peat, the action of lime is not only highly beneficial in decomposing or rendering soluble the mass of inert vegetable remains, but the lime decomposes the sulphate of iron, and, uniting with its sulphuric acid, forms the well-known fertilizer, the sulphate of lime or gypsum of commerce.

When quick-lime is applied to the soil, it gradually becomes converted, by exposure to the air, into the carbonate of lime (chalk); its action as a solvent ceases, and its presence is now only useful as a direct food or constituent of the farmer’s crops. This, however, affords an opportunity for the beneficial repetition of the dressing with lime, so far as its solvent powers are available. But then, as might, for the above reasons, have been anticipated, the farmer finds that the after-lumings never do so much good as the first; and as by each successive application the lime reduces still more and more the quantity of organic matters in the soil, so it follows as a natural consequence that after each succeeding dress-
ing, the benefit produced becomes less and less, and finally the cultivator informs us that "the land is tired of lime." This result has been experienced to a very considerable extent in the north of England, where the cheapness of fuel and the abundance of the common limestone has, in too many instances, tempted the farmer to add to his land lime in excessive quantities. For such over-limed soils, the only remedy is the addition of organic matters. In such cases, peat will, in moderate quantities, be occasionally found an excellent dressing.

The quantity of lime used per acre of necessity varies with the soil, and the expense with which it is procured. The heavy clay and peat soils require the largest proportions; the light lands need a much smaller quantity to produce the maximum benefit. I have used it at the rate of 25 bushels per acre, mixed with earth, on light soils, and never more than 100 bushels per acre on clays. This is the proportion commonly used on the heavy soils of the midland counties, and the deep clays of the weald of Kent. In Scotland they apply sometimes as much as 360 bushels per acre, and in Ireland still larger quantities have been successfully employed; and on some of the peat mosses of the north of England, more than 1000 bushels have been used with good effect. The employment of such large proportions, however, can rarely be justified, even when the lime is obtainable at a very low rate.

I have used lime, and have been present at other liming operations for many years. I have chiefly employed it either as a top-dressing, or which, for light soils, I much prefer, mixed with ditch scrapings, old banks or pond mud, at the rate of one bushel of lime to a cubic yard of earth. And then, after thoroughly mixing them together, and allowing the mass to remain for a month or six weeks, I have always succeeded in forming a most enriching compost, which, on even the gravelly soils of Essex, applied at the rate of 20 to 25 cubic yards per acre, both for wheat, clover, and potatoes (to which crop, in general, lime is prejudicial), has produced the most powerful effects, certainly increasing by one-third the produce of the natural soil. It is only in the state of mixture with earth, or peat, or salt, that I have found lime profitably useful for light, gravelly soils. Yet I have varied the application in a variety of ways and proportions, but still, for the gravels or sands, the result was never entirely satisfactory. But I have witnessed, as a dressing for the black-hungry gravelly soils of Spring Place, near Neaumar, lime and peat mixed together, at the rate of 1 part of lime and 3 parts of peat, with the most complete success. The peat is reduced to a finely-divided state, and rendered partially soluble by the action of the lime, and is a most powerful top-dressing for young clovers. This is explainable (amongst other reasons) by the fact that the peat employed being saturated with a solution of sulphate of iron, the lime converted it into sulphate of lime, which is a constituent or direct food of clover. Equally successful, on trials of the same nature, which I have mixed with common salt; 2 parts of lime, mixed with 1 part of salt in a dry state, and suffered to remain for three months previous to its being used in a dry place. By applying this mixture at the rate of from 40 to 50 bushels per acre, crops of turnips have been grown under my directions fully equal to any produced by 20 cubic yards per acre of farm-yard compost: and in 1840, the produce of ground thus dressed fully equalled that of some adjoining lands of the same field, which had been manured with the ordinary compost. And an excellent neighbouring farmer, Mr. Foster, of Great Thotam, in July, 1840, made an experiment with turnips, entirely confirming those I had elsewhere instituted. He applied a mixture per acre of 30 bushels of lime with 15 bushels of salt, to 10 acres of a field containing 15 acres. The land previously had a crop of rye, which was fed off with sheep; and on the 2 acres to which the salt and lime were not applied, the sheep had oil cake given to them, and, moreover, the land was sub-soiled to a depth of 18 to 20 inches. The field, consequently, had a good summer fallow. The lime and salt was spread broadcast after the last ploughing, and harrowed in before the seed. The turnips were of the variety called green rounds. The land slopes to the south, and its soil is a light, mouldy turnip soil. In examining them in company with Mr. Foster, in the last week in August, he expressed himself abundantly satisfied with the result. The crop of turnips was equally good all over the field; if there was a shade of difference, it was in favour of the sub-soiled and cake-fed land; but the advantage, if any, was exceedingly inconceivable.

In the use of this mixture, I have found the moisture of the atmosphere highly advantageous in increasing the operation of the lime and salt; an observation, too, which is not confined to the dry, gravelly soils on which my experiments were carried on. Thus, in 1839, on an exhausted, rather heavy turnip loam, 80 bushels per acre of a mixture of salt 1 part, and lime 2 parts, made three months previously, were spread in July, and, when with the white round turnips. The turnip plants came up equally well all over the field; but on the portions where the salt and lime were omitted, they speedily perished; but in every part dressed with the lime and salt, the crop was excellent.

In the dry season of 1840, however, another portion of the same field being treated in a similar manner, the effect produced by the lime and salt was not nearly so decisive; the plants were weak, the crop inferior. I have found the lime and salt equally beneficial as a dressing for wheat and barley; but a description of those experiments will more properly be found under the head Salt and Lime; for when the application is made to the land, the lime and salt have, in fact, entered into new combinations; the compound applied is no longer a dressing with lime and salt, but with a mixture chiefly composed of chloride of calcium and carbonate of soda, with a portion of undecomposed lime and common salt. I have tried several times the mixture of lime and salt, where I suspected the presence of grubs and the seeds of weeds, with farm-yard compost,
but never successfully. Convinced of the ill effects of the lime being thus mixed, I have long since abandoned the practice. There is, in fact, no beneficial object to be attained by this mode. The natural well-fermented dung effects of the lime can do, and in a better manner; for the lime dissolves, and in a considerable extent, decomposes the finer and richer portions of the compost; and it certainly renders the straw and other coarser portions of the manure drier and more difficult to dissolve in the soil. The practice, therefore, seems worse than useless.

In the application of lime to heavy clay land, I have always found that it was best, used either in its simple uncombined state, or after an ultimate mixture of sandy or light calcareous earths, or peat, or salt. But by no means of applying it (and I have varied my experiments in a variety of ways with considerable industry) on the land, could I ever produce superior effects than by applying the lime in its uncombined state, as well burnt and finely divided as possible; and this I have generally done as a top-dressing (merely harrowing it in with the seed), from considering that by the soluble property of lime (1 lb. of lime dissolving in 480 lbs. of water), the rain always conveys it deeper into the soil.

And yet, from an experiment recently made at my suggestion by my next neighbour, Mr. Foster, a very excellent farmer of Great Thumberham, in Essex, I am inclined to believe that the lime will produce effects nearly equally important when it is ploughed into the soil. This trial was made in December, 1839, on a field of 5 acres, whose soil is a cold, stiff, deep, hungry loam, that had previously borne a very poor crop of turnips, which were fed off with sheep. This field has a declination towards the southwest, and has always produced crops of a very inferior description. In this middle of December (after spreading 80 bushels per acre of lime (made from chalk) from the cart's tail, by the shovel, it was immediately ploughed in and drilled with the common red wheat. The effect was excellent, every one of the neighbours agreeing that the land never produced such a crop before. And that this was owing to the lime, was evident from the inferior produce on the spots where the lime had not been spread.

The exact quantity, however, per acre, Mr. Foster is unable to state, owing to his being prevented in the hurry of harvest from keeping it separate: he estimates it, however, at about 43 quarters per acre, and he is nearly of opinion that this large produce (for his land) arose not so much from the thickness of the crop, as from the largeness of the ears.

In the boggy, unimproved lands of Spring Park, the effect produced by the direct use of lime, at the rate of 200 bushels per acre, is excellent. The cost is there 4 pence per bushel, and it is that made from chalk. But on the light, hungry, black gravels of that farm, as well in fact as upon the clays of that district (as I can testify, thanks I apply in general to almost all light soils and situations, never productive of such powerful effects as when mixed with the earthy matters from ditches, ponds, old banks, or headlands. But here let me earnestly impress upon the farmer the necessity and the great advantage of paying much more attention to the mixing of the lime with the earth.

The lime should not only be of the best and recently burnt description, but should be mixed as thoroughly and as finely as possible with the earth. By this means the heat generated in the mass by the slaking of the lime is considerable, and is productive of several advantages: it kills more completely insects of all kinds—seeds of weeds, and the more stubborn roots of weeds. And the mixed earths are rendered considerably more friable, and capable of a much more even and economical distribution on the farmer's crops, than by the ordinary careless way of mixing them. On peat soils, and on those abounding in the tough inert remains of the heath plants, lime is best applied in its purest state, unmixed with any other substances to weaken its effect. Its action on such soils is not difficult of explanation. It dissolves and renders soluble the organic matters of the soil, and it decomposes the sulphate of iron (or green vitriol) which it often contains. In such lands, too, we rarely find any lime: it furnishes, therefore, to them a portion of an earth whose presence is absolutely essential to the profitable growth of all the most valuable vegetables.

How excellent such an addition is to these soils, even when applied only at the rate of 4 bushels per acre, has been proved by some extensive experiments of the Scotch planter, the growth of whose young woods has been very materially and rapidly promoted by merely placing a handful of lime under each plant. Now we have already seen how copiously this earth is found in the ashes, not only of the fir, but in those of all other timber trees. So unvaried, indeed, is the presence of the salts of lime in vegetables, that they have been supposed to produce a plant-supporting effect to that the same salts of lime yield in the bones of animals. And it is certainly worthy of remark that the phosphate and carbonate of lime, of which the bones of all animals are chiefly composed, are precisely the salts of lime the most universally present in vegetables.

Lime must, therefore, be classed amongst those manures which commonly serve to promote the permanent fertility of the land, for unless it is washed by the moisture of the atmosphere, or the flood waters, it can only be removed from the soil by becoming fixed or the crop's returns. In poor, peaty, boggy soils, no other manure can be compared to it, either for powerful effect, or for rapidity of action; and its usefulness is nearly as great on the stiffest clay land. Whenever, therefore, the permanent improvement of such soils shall be considered with that general and that patient attention which the importance of the object demands, at that period the fertilizing powers of lime will be still more generally appreciated, and its services be far more extended that at present.

The quantity of lime applied per acre of necessity varies with the description of the soil; that which contains most organic matter will,
LIME.
of necessity, bear a larger proportion than that which is more free from vegetable or animal remains. The quantity usually applied is much too large, and the dressing too often repeated without proper consideration; and it is not until the land becomes absolutely overcharged with lime, that the farmer begins to have a suspicion that his land is tired of it. In Ireland it is sometimes applied to old pasture lands intended for potatoes, at the rate of 400 bushels per acre; and on some of the moors in Derbyshire, 1500 bushels per acre have been found not too large a quantity. In Scotland the quantity usually applied for light land is about 160 bushels per acre; for stiff clay soils from 240 to 360 bushels. On the stiff clays of the Weald of Kent, the quantity usually employed is about 100 bushels per acre, and that is often repeated every 5 years, on the fallow before wheat, for many years. Lime may be as readily produced by burning limestone with peat as with coals; the heat produced is amply sufficient, and the heat more easily managed.

"I conceive," says Mr. Hillyard of Northamptonshire, "lime to be a stimulant only, and not a manure. Lime gives solidity to light land, the means of retaining moisture, and in some degree prevents the rays of the sun from penetrating so deep into the soil, and drying up the roots. Lime also encourages the growth of clover; but it does not do the good that is equal to the expense, when applied to land that has for a length of time had it periodically laid on. It is the common practice in this county to lime and dung the land for turnips nearly at the same time, just before sowing. To put on materials that must cause such different effects cannot, I think, be quite right, and therefore it would be better not to put on the lime till the next spring, before sowing barley and seeds. I have heard of lime being laid on a stubble or clover ley, and when stacked, ploughed in, thus depositing it at the bottom of the furrow, where it can do but little if any good, and it naturally will get lower. It should be laid on the land after it is ploughed and, by throwing it well incorporated with the soil. Very little benefit," concludes Mr. Hillyard, "is derived from laying on a small quantity of lime: it requires 20 or 25 quarters per acre to do a very essential good."

"In the county of Dublin," says Arthur Young, "they lay 160 barrels, or 640 bushels on an acre; strong loam or limestone finds the greatest benefit from it, and the farmers say it lasts as long as limestone gravel. In the county of Cork, Mr. Aldworth found lime to have a vast effect on strong loam or limestone. On all poor, thin, light soils, and others, on a quarry of stone, especially limestone, that have been long in tillage, lime is found to do no service. Upon wet, cold loams, that have not been sufficiently drained, lime does no good; and when they are dry, unless they are rich, this manure will operate very little; on cold, wet, tenacious clays, it has often failed, and also on strong, stony land. Lord Holderness found some very good land of this description almost ruined from a long course of liming. Where there is a great mass of vegetable or animal matter not putrid, and which cannot putrefy sufficiently, there lime does the business at once, and has an effect which has been thought astonishing.

Arthur Young was of opinion, that the lime made by calcining limestone was much superior for agricultural purposes to that made from chalk, of which last description he had evidently but a poor opinion as a fertilizer. He thought too, and very justly, that this earth was not so advantageously applied, when mixed with farm-yard dung, as when applied in its simple state; a conclusion in which he was no doubt pretty near the truth, although he gives some facts observed by a farmer at Belchamp Water, in Essex, which rather militates against this conclusion: "It destroys," says the Rev. P. Raymond, "all the seeds of weeds in the crop—25 bushels of lime to 20 loads of dung per acre. It is found, however, to be rather detrimental to turnips. Crude lime, laid upon light, dry land, at the rate of one bushel to the rod, has produced benefit for seven years. It is generally in this parish carried on to stiff clay, with great advantage, mixed with dung. It is of still more use to wheat and barley. (Johnson on Fertilizers, p. 294.)"

There is perhaps no other country so richly endowed with this earth as England, for, to say nothing of its great strata of chalk, how endless are the masses and varieties of limestones. Let us not therefore neglect, but extend, by every means in our power, the use of the treasures we possess; for by so doing we may not only increase the fertility of lands already (like the more tenacious clays for instance) in some degree productive of food, but we can bring into cultivation, by the judicious employment of this powerful earth, the most sterile peats, the trembling boggs, the most worthless heaths: the inferior plants, such as the acid sorrel, are banished by its influence, and the soil which once only held the stagnant water impregnated with wholesome vegetable and mineral matters, is now made to produce the most useful of the cultivator's crops; and the improvement, too, is of everlasting importance, for such crops not only furnish additional employment to the labourer, but they now purify an atmosphere which their exhalations in an unimproved state once corrupted.

"Much has been written and said relative to the preservative and destructive effects of lime on organic manures, from which we learn that it operates both ways, according to its chemical state. If employed as quick-lime, and placed in contact with organic matter, its alkaline properties would lead us to infer a decomposing influence, which is confirmed by experience; but the effect is of short duration, and is succeeded by the reverse operation, that of preserving such matter from further decomposition. The truth is, if we could insure a continuance of its caustic state, we might be equally sure of its constant decomposing power, but by this action it generates carbonic acid from the organic matter uniting with it and forming a neutral carbonate, which either acts like other salts in preventing decomposition by its presence or catalytic influence, or
being formed and hardened in the interior of the organized material, protects it from farther decay. But if attention is not directed to prevent excessive fermentation in the dung-hill; and to the same properties we may in part ascribe its utility in the soil, viz., that of permitting the slow and gradual decay of organic matter in quantities suited to the demands of vegetation. It has been supposed that the chief value of lime as a manure lay in its caustic or destructive effects, but that this position is untenable is proved by the successful application of marls, and even powdered limestone, when applied in small doses. Sir H. Davy and others have written on the subject of agriculture, refer the utility of lime to its causticity, and state that "chalk, marl, or carbonate of lime will only improve the texture of the soil or its relation to absorption; it acts merely as one of the earthy ingredients." This view is unquestionably incorrect, for it has been known to produce astonishing effects on peaty soils, when applied in the form of carbonate and not caustic lime, and powdered limestone as well as marl have been successfully used on ordinary soils. Besides, if the formation of soluble matter from insoluble organic materials be the chief effect of lime, this effect should take place immediately, while the lime is in its caustic state; but it appears that it soon becomes carbonated in the soil, or by exposure to the air, and yet its useful effects are more perceptible a considerable time after its application, and may be perceived for many years. Whence it appears that its action on organic matters in the soil is continued (probably not increased) in the soil after carbonation.  

Much of the vagueness in descriptions relative to the use of lime has arisen from an imperfect knowledge of the organic constituents of soils, which have lately been partially developed. Authors have divided the organic matter into soluble and insoluble, by the former of which we understand the humic, crenic, and apocrenic acids, and by the latter, humin, humus-coal, and vegetable fibre; and they state that lime is injurious where there is much soluble matter in the soil, as it forms insoluble combinations. The truth is, the humate of lime is partially soluble, the bi-crate somewhat so, and the bi-crate very soluble. Now, by admitting these acids as active ingredients in soils, we are at no loss to account for the utility of carbonate of lime, for the weakness of the carbonic acid is overcome by their superior attraction, and more soluble salts are formed which may then be received into the rootlets of plants. There can be no doubt, however, that caustic lime is of greater benefit where a soil contains humin and vegetable fibre, as it promotes their incipient decompositions. The utility of lime, therefore, is threefold: first, that of decomposing organic matter, and rendering it a suitable nourishment for plants; secondly, that of combining with organic matter and rendering it capable of being received into the vessels of vegetable organization for promoting vegetation; and, lastly, that of lengthening the time of decomposition of organic matter, which, therefore, yields nutrition in proportion to the demands of a plant in the progress of its growth.  

It has been reported by many to be necessary that lime should be caustic, as it is only then soluble, but it should not be forgotten that the carbonate is also soluble in water containing carbonic acid; and farther, it is not necessary that either the carbonate or quick-lime alone should be dissolved in order to explain its influence in vegetation, for moisture, the medium of chemical action, is always present in the soil, and assists in its soluble combination with the organic acids. There is, however, another action of lime with reference to the soil itself, which seems, viz., that it renders clayey lands looser, and sandy soils more tenacious. The latter of these contrary effects is of a chemical character, and there is little doubt that lime acts like mortar by combining the particles of sand together. The former is partly mechanical, the mingling of less cohesive earthy matter with the clay, and partly chemical, in which the lime dissolved by rains is washed into the crevices and cracks of the clay, where, becoming carbonated, it prevents their farther adhesion. To effect these results most powerfully, it is evident that the lime should be employed in a caustic or water-slaked state. According to these views, therefore, it is a matter of less moment on what kind of land lime should be spread, as it tends to ameliorate its condition or texture, and is the medium of conveyance of nutrition to vegetable life.  

Nearly all the limestone employed in Delaware for spreading on the soil is magnesian, and it is therefore worth investigating how far the magnesia may be injurious. One of the first limestones employed for this purpose in Pennsylvania, from which lime derived much of its reputation as a manure in this section of country, and which has not lost its character to the present time, is nearly of the same composition with Janes' stone; a very fair proof that such a content of magnesia is not injurious under certain circumstances. Sir H. Davy's view of the subject appears to be correct, that magnesia in a caustic state is injurious, but that when carbonated it is beneficial. It was stated that it remains caustic for a long time exposed to the air, and particularly when mingled with lime; therefore, in employing a magnesian limestone, if there is little vegetable matter in the soil it will be apt to injure the crops; but this effect may be obviated by mingling it with fermenting manure, which will rapidly carbonate it. There is another view of the subject which has never been broached, viz., the influence of the organic acids in the soil. If much humic acid be present, it will form humate of magnesia, soluble in 150 parts of water, while humate of lime is not dissolved in greater quantity than lime. But by referring to the quantity required by plants as shown by an analysis of their ashes, we find that oak requires about 2\frac{1}{2} times as much lime as magnesia, and that ashes of straw yield nearly 12 per cent. of carbonate and phosphate of lime, and no magnesia, from which it would seem that the latter is injurious to plants from its...
excess where humic acid is abundant. But if the soil contain much humin, and other insoluble organic matter, its action in a caustic state would be beneficial like that of lime. We have, therefore, in Delaware abundant means of rendering magnesian lime useful, by employing it in conjunction with peaty matter, the black soil of marshes, creeks, &c." (Booth's Geography of Delaware.)

All the grain crops, as well as those of grass, are greatly benefited by judicious applications of lime in some of its various forms. Oats take up a larger proportion than almost any other grain, and hence are observed to be specially benefited by lime. Rye and Indian corn are also greatly benefited by lime, and with regard to wheat, the following strong testimony is from Dr. Jackson, the able American chemist and geologist. "I find," he says, "by chemical examination of several soils, that a very minute quantity of carbonate of lime, viz. from one to two per cent, is amply sufficient to render them capable of bearing heavy crops of good wheat. I am also satisfied that a soil is incapable of producing wheat of good quality if it does not contain carbonate of lime, for this substance is an essential ingredient of this grain."

It has been computed that every person who consumes 1 lb. of wheat bread daily, will, in the course of one year, take into his system 2 lbs. 6 oz. 3 drs. and 44 grs. of phosphate of lime. "This circumstance is supposed to explain the reason why this kind of bread is so superior to that made of other grain, as phosphate of lime forms a principal element of human bodies. It is found in milk, where nature seems to indicate that it is contained for the nourishment of the young animal, from the remarkable fact that, when they are able to take other food, the milk loses its proportion of this substance. Although phosphates of lime are contained in considerable quantities in the adult secretions, it is not known in those of the young, being all taken up for the purposes of nourishment. The shells of eggs are formed of this substance, and Dr. Paris has ascertained the singular fact that, if the legs of a hen be broken, she will lay her eggs without shells until these are repaired, for which the lime is required. Hens will also lay their eggs without shells if there is a deficiency of lime in the yard in which they roam. It is a remarkable circumstance, that although the grain contains the phosphate, the straw contains the carbonate of lime. Carbon is, next to water, the principal support of vegetation." (Cultivator.)

Lime-Kilns and Burning.—A lime-kiln is a furnace or rough structure erected for the purpose of converting limestone into the lime of commerce, by keeping it for some time in a white heat.

The forms of lime-kilns vary; but the best is that of the frustum of a cone, which permits the ignited mass in the upper part to settle down freely as the lower portion is drawn out. In some places the kilns are made like the earth, in the form of inverted cones, and lined with brick. It is calculated that such kilns will burn 150 bushels of lime in 24 hours. When chalk is used, and it is dry, 5 bushels may be burnt with one bushel of coal; but the dampness of the chalk lessens considerably the power of the fuel. Peat is sometimes used instead of coal, and some burners prefer it to coal. Whatever the fuel may be, that is the best which prevents the lime from running together in masses. The best test of the lime being sufficiently calcined is its slaking, and falling into complete powder when water is poured on it.

Some excellent practical remarks upon lime burning, by Sir G. C. Stewart Monteath, were published some time since. He observes:—

"Having been engaged in burning lime for the supply of an extensive district of country for agricultural improvements, and being distant from coal 16 miles, it was desirable to find out the best constructed kiln for burning lime with the smallest quantity of coal, and having been aware, from experiment, that the kilns generally employed in Great Britain for burning lime are of a construction too narrow at bottom and too wide at top, many kilns of this construction being not more than 3 or 4 feet wide at bottom, and 18 feet wide at the height of 21 feet, were found to waste the fuel during the process of calcining the lime, or, in other words, did not produce more than two measures of burnt lime shells for one measure of coal; but it is to be understood that, in whatever construction of kiln lime is burnt, the fuel required to burn limestone must vary according to the softness, or hardness, or density of the stone, and the quality or strength of the coal used.

The same measure of coal in Scotland called chews, when employed, will burn a greater quantity of lime in a given time than the same quantity or weight of small coal, the chews or small pieces of coal admitting the air to circulate more freely through the kiln. Though this fact should be well known to lime burners, yet they frequently employ small coal in burning lime, believing that the fuel is being procured at a less expense, although really at a greater expense, as it requires a much larger quantity to produce the same effect, and a longer time to admit of equal quantities of lime being drawn out of the same kiln in a given time.

"For a sale of lime for agricultural purposes in a limited district, I have found kilns of small dimensions to be most profitable; the construction of a kiln I have employed for many years was of an oval shape, 5 feet wide at bottom, widening gradually to 6 feet at the height of 18 feet, and continuing at that width to 28 feet high from the bottom. A kiln of this construction has been found to burn lime in much less time, and with a smaller proportion of fuel, than kilns of larger dimensions narrow at bottom and wide at top, as heat is well known to ascend more rapidly in a perpendicular than in a sloping direction, from which arises the superiority of a narrow kiln, with sides nearly perpendicular, compared with one with sides that slope rapidly.

"These narrow kilns will admit of being drawn out of the ground daily, if fully employed, more than two-thirds, or nearly three-fourths, of what they contain, of well-burnt lime; and afford fully three of lime shells for one measure of coal, when large circular kilns will not give out more than one-half of their contents every
LIME.

day, and require nearly one of coal for every two measures of lime burnt. In a country sale of lime, the quantity sold every day is liable to great fluctuations: two or three cart-loads will sometimes only be required from an establishment which, the day before, supplied forty; and as lime is known to be a commodity, when exposed to the action of air, which becomes more bulky and heavy, and in that state does not admit of being carried to a distance without additional labour, it has been an object of importance with me to find out a construction of a kiln which will allow of lime being kept for several days without slacking, and at the same time to prevent the fire escaping at the top of the kiln, if the kiln stands 24 hours without being employed, especially during the autumn and winter, when the air is cold and the nights long.

I now employ kilns of an egg shape, and also oval; the oval-shaped kilns are divided by arches across the kiln, descending 4 feet from the top; the object of these arches across the kiln is to prevent the sides of the kiln falling in or contracting, and also to enable you to form circular openings for feeding in the stone and coal at the mouth of the kiln; upon this plan, a kiln of any length might be constructed with numerous round mouths. In the model of the kiln sent to the Highland Society, Book er's conical cover may be seen revolving upon an iron ring placed upon the circular mouth, and having placed a lid to the cover, I am enabled to prevent the escape of heat at the top, and by cast-iron doors at the bottom the air is prevented passing through the kiln; so that, by these precautions, the lime burner can regulate the heat, and prevent its escape for several days, when the fire would be extinguished at this season in the course of 24 hours. This is an object of great importance, as it enables the lime to be burnt as well, and with as small a quantity of fuel in the winter as the summer season, and to supply the farmer with as well burned lime, and at any time of the year, which cannot be done in the common construction of kilns, open both at top and bottom, for the reasons I have before stated. From the great expense attending the driving of fuel from a distance of 55 miles from my own coal-pits, I have adopted the practice of coking the coal, which is a saving of eight-twentieths of the weight; and I find that an equal measure of coal and coke furnishes the same quantity of heat in burning lime, which is somewhat paradoxical, but not the less true. The coal is found to have little effect upon the stone till it is deprived of its bitumen, or is coked in the kiln; for, during the time the smoke is emitted from the top of a lime kiln, little or no heat is evolved. A kiln in which coke is the fuel employed, will yield near a third more lime shells in a given time than when coal is the fuel; so that coke may be used occasionally when a greater quantity of lime is required in a certain time than usual, as it is well known to lime burners that the process of burning is done most economically when the kiln is in full action, so as almost constantly to have a column of fire from the bottom to the top of the kiln, with as short intervals as possible in working the kiln.

"In working a kiln with narrow circular mouths, the stone and coal should be carefully measured, so that the workmen can proportion the fuel employed to the quantity of stones, and it is obvious that the quantity of coal to be used must depend upon its relative quality and the hardness of the stone to be burnt. If this measure was adapted to kilns of any construction, the lime snells would be found better burnt.

"Circular kilns are constructed with similar eyes or openings at the bottom, and not more than 8 feet wide at 18 feet from the base, and contracted to 4 or 5 feet wide at top. In lighting the kiln at the commencement of burning, some care should be taken not to allow the fire to remain below the upper grate. There are two iron grates at the bottom of the kiln: the upper grate consists of iron bars 8 or 10 inches distant from each other across the kiln, between which the pieces of burnt lime fall down upon a lower grate with iron bars one inch from each other, which allows the lime ashes to fall through them into an ash pit; these lime ashes are found very useful as a top-dressing for grass ground, and are a clear gain to the proprietor of lime-kilns for public sale. As a burner of lime for agriculture in an extensive district of country to the extent of 150,000 imperial bushels annually, the value of the lime ashes which fall through the lower grate amounts to more than 150£ annually; the lower grate is 3 feet above the ground, and the upper grate is the same distance from the lower one. The kilns I employ at Criefburn are upwards of 30 feet high, and nearly perpendicular, which is the cause of the great heat in this construction of kilns, and which is found to burn lime more equally than circular kilns of large dimensions. (Trans. High. Soc. vol. ii. p. 127.)

The limestone quarries of Scotland are described by Mr. Carmichael (Ibid. vol. v. p. 57): he observes, when speaking of the uses of this valuable earth, "how sterile must have been the soil, how cheerless the dwellings, and how scanty the resources of Britain before lime came into general use." And on the method of calcining limestone in some of the limestone quarries in Scotland there is a paper. (Ibid. p. 441.)

Limestone Gravel.—There are some traces of this marl in the Isle of Anglesea; but in general, it is seen in quantities only in Ireland, where it is very common. It is in appearance only common gravel, of a blue colour, mixed with stones as large as a man's fist, and also with loam or clay; it has a strong effervescence with acids, and, when used, is attended with the usual effects of marl or lime. For bogs, it exceeds every other marl, as its weight assists in the improvement of that loose and spongy soil. Upon strong clays, the use of it is unrivalled, for it has all the effect of a dressing of lime, and gives friability yet more than chalk does. It destroys moss infallibly. Upon whatever soil it is used, it is found very durable, lasting, in many instances, in great heart, from twenty to forty years. In limestone counties, all blue gravels should be examined; for it is an invaluable treasure, wherever found.

LIME or LYMPE GRASS. See ELYMUS.
LIME PLANT.

LIME PLANT. A name applied in the Northern and Eastern States to the indigenous plant called in the Middle States May Apple (Podophyllum peltatum).

LIMESTONE. A generic term for those varieties of carbonate of lime which are neither crystallized nor earthy; the former being calcareous spar, the latter chalk; when burned, they yield quick-lime. See GEOLOGY, CHALK, LIME.

LIME TREES (Tilia). These are for the most part ornamental, lofty-growing trees, well suited for avenues and parks. They thrive in any soil, and are increased by layers or seeds; if by layers, the tree must be cut down close to the ground, and from its roots a great number of shoots are produced in the following year; these will be strong enough to lay down the succeeding autumn. Trees raised from seed are far preferable to those raised from layers. The Russian bass-mats are made from the inner bark of the lime tree, while the wood, from its being light and white, is much used by the carver and musical instrument maker.

The charcoal is used in the manufacture of gunpowder, and is considered as scarcely inferior for that purpose to the charcoal produced from the alder and willow. If we possess no evidence sufficiently conclusive to prove that the lime tree in any of its forms is truly indigenous in Britain, we have at least enough to show that it has long been naturalized, and that its introduction must have taken place at a very distant period; for, upon referring to the earlier works, such as Turner, Gerard, &c., we find it (in the form of T. E. microphylla) spoken of as a well-known, and in their estimation, apparently, as a native tree. By many botanists (says Mr. Selby), several species of lime are enumerated as inhabitants of Europe; and Sir J. E. Smith makes three distinct species of those cultivated and grown in Britain; viz., T. Europaea, T. grandifolia, and T. parvifolia, the last-named belonging to the T. platypyllyla and T. microphylla of other authors. We are, however, it would seem, Mr. Selby, inclined to adopt the views and follow the opinion of the author of the Arboretum Britannicum, and to consider these not as specifically distinct from T. Europaea, in its usual form, but as marked varieties, or, as Mr. Loudon designates them, races, originally produced from the seed of one, and which have been kept distinct, and perpetuated by means of layers, grafting, and other artificial modes of propagation; a view we think strongly corroborated by the fact that the seeds of the different kinds, or supposed species, do not always produce plants exactly similar to the trees from which they are gathered, but run into varieties, the seed of T. E. platypyllyla often producing plants similar in every respect to those of T. Europaea (the common lime), and so with the other kinds.

The lime tree appears to have been held in repute in ancient as well as in modern times; for we learn from Theophrastus that it was known to the Greeks; and Pliny speaks of it as a tree held in high esteem by the Romans, not only for the ornament and shade it afforded, but for the qualities of its wood, and the various purposes to which it was adapted. Nearly two hundred years have elapsed since it was planted along the streets of continental as well as English towns, where their width would admit of it, as affording a pleasant shade and protection during the summer heats, and it was extensively used in that style of gardening called architectural, as it bore cutting with the knife or shears with patience and comparative impunity. Examples of this style still exist in some parts of England, and are frequent upon the Continent, in France and Holland, where pyramids, arches, and colonnades are formed of this tree, and sometimes these produce an imposing effect. As an ornamental tree in picturesque gardening, the lime is well worth cultivating, as it ranks in the first class in point of magnitude, frequently attaining a height of eighty or ninety feet, and a trunk corresponding in circumference to such an altitude. The lime holds an important place in the Materia Medica of France and other continental countries; but its medicinal powers are very feeble.

Loudon, in his Encyclopaedia of Plants, enumerates eight species or varieties of the linden or lime tree (Tiliaeae). 1. Tilia rubra, the red or common linden. 2. T. intermedia, or intermediate. 3. T. parvifolia, or small-leaved. 4. Platypyllyla, or broad-leaved. All these are found indigenous in the woods of Britain. 5. T. Americana, American lime or linden. (See BASS-WOOD.) 6. T. pubescens, downy and thin-leaved lime tree. 7. T. heterophylla, or various-leaved lime tree. The three last-named species are indigenous to North America. 8. T. alba vel argentia, the white or silver linden, which is stated to be a native of Hungary.

Michaux has described the three American species of lime tree, one of which has been already referred to under its common name of Bass-wood. The American white lime is doubtless a distinct species from the Tilia alba of Hungary.

"I think not," says Michaux, "met with the white lime tree east of the river Delaware, but it is abundant in Pennsylvania, Maryland, Delaware, and the Western States. It does not grow, like the preceding species, in elevated places, nor amidst other trees in the forests, and is rarely seen except on the banks of rivers. I have particularly observed it on those of the Susquehanna, the Ohio, and the streams which empty into them.

"The height of the white lime tree rarely exceeds forty feet, and its diameter twelve or eighteen inches. Its young branches are covered with a smooth, silver, gray bark, by which it is recognised in the winter. The leaves are very large, dentilicated, obliquely heart-shaped and pointed, of a dark-green on the upper surface, and white beneath, with small reddish tufts on the angles of the principal nerves. This whitish tint is most striking on solitary trees exposed to the sun.

"The flowers come out in June, and, as well as the floral leaf, are larger than those of any other lime tree with which I am acquainted. The petals are larger and whiter, and are impregnated with an agreeable odour. The seeds are round, or somewhat oval, and gray-brown."

"The wood of this tree is white and tender, and I believe it is never employed in the arts."

"This and the following species have re-
LIME TREE.

Linen.

cieved no popular specific names, but are both called lime tree and bass-wood: that of white lime, which I have given to this species on account of the colour of its foliage, is peculiarly appropriate.

"The Downy Lime Tree belongs to the southern parts of the United States. It grows on the borders of rivers and large marshes, where the soil is cool and fertile, but not exposed to inundation. It is little multiplied, and consequently is not taken notice of by the inhabitants; for this reason, and because it is the only species of its kind in the maritime parts of the Carolinas and of Georgia, it has received no specific denomination, and is called simply lime tree; to which I have added the epithet downy, derived from a character of its foliage not observed in the preceding species.

"This tree is forty or fifty feet in height, with a proportional diameter. In its general appearance it resembles the American lime tree, which grows farther north, more than the white lime tree, which belongs to the Middle and Western States. Its leaves differ widely in size, according to the exposure in which they have grown: in dry and open places they are only two inches in diameter, and are twice as large in cool and shaded situations. They are rounded, pointed at the summit, very obliquely truncated at the base, edged with fewer and more remote teeth than those of the other lime trees, and very downy beneath. The flowers, also, are more numerous, and form larger bunches, and the seeds are round and downy.

"The wood is very similar to that of the other species, and I do not know that it is ever employed."

In some parts of Europe, the honey gathered by bees from a species or variety of the linden is in great request for its superior qualities, and real or supposed healing virtues. It would be highly desirable to have a tree introduced into the United States which offers such a great resource to the bee culturists. See HONEY.

Insect enemies.—The European species of lime or linden, which has been extensively introduced into the United States as an ornamental tree, has suffered greatly of late years from the attacks of several destructive insects. Some of these are in the form of long, dark-coloured worms or caterpillars, with strong webs, which eat off the foliage; others bore into the wood of the body and branches, chiefly in the crotches, and so destroy the strength of the limb, or the body itself, that one or both yield readily to the wind, or gradually decay and die. There are also the leaf-beetles, the most elegant of the family of Chrysomelians, which inhabit the leaves, not only of the linden, but of the elm, the broods being found in April, May, and June, and even a second brood in September and October. The trees are occasionally injured by leaf flies or beetles and their larvae. After a very minute description of this beautiful leaf-beetle, with its dark-green body, silvery-white wings, ornamented with green spots, and rose-coloured wings, Dr. Harris remarks that he thinks the grubs go into the ground to turn to pupae. When they become so numerous as to seriously injure the lime and elm trees, Dr. Harris recommends the employment of decoctions of tobacco or of walnut leaves, thrown on the trees, or a mixture of camphor or of a garden or fire engine; a method which has been tried with good effect for the destruction of the larvae of Celycoa calmariensis, which appear occasionally in swarms, and entirely strip the leaves from the elm trees in midsummer. Dr. Harris describes a species of lime-looper which proceeds from an umbo-moth greatly resembling that known in Europe, and called by naturalists Hyberia defoliaris. The American insect, however, differs so much in the larva state from the European, as to entitle it to be classed as a distinct species; and accordingly Dr. Harris has called it Hyberia albica, the lime tree winter-moth, from the scientific name of its favourite tree. The fore-wings of the male moth are rusty buff or nankin-yellow, sprinkled with very fine brownish dots, and banded with two transverse, wavy, brown lines, the band nearest the shoulders being often indistinct. In the space between the bands, and near to the thick edge of the wing, there is generally a brown dot. The hind-wings are much paler than the others, and have a small brownish dot in the middle. The colour of the body is the same as that of the fore-wings; and the legs are ringed with buff and brown. The wings expand one inch and three-quarters. The body of the female is grayish or yellowish-white; it is sprinkled on the sides with black dots, and there are two square black spots on the top of each ring, except the last, which has only one spot. The front of the head is black; and the antennæ and the legs are ringed with black and white. The tail is tipped with a tapering, jointed egg-tube, that can be drawn in and out, like the joints of a telescope. Exclusive of this tube, the female measures about half an inch in length. The eggs are beautiful objects when seen under a microscope. They are of an oval shape and pale-yellow colour, and are covered with little raised lines, like net-work, or like the cells of a honey-comb.

As these span-worms appear at the same time as canker-worms, resemble them in their habits, and often live on the same trees, they can be kept in check by such means as are found useful when employed against canker-worms. See SPAN-WORM.

LINDEN TREE. See LIME TREE.

LINEN (Germ. lieanwand). A species of cloth woven with the fibres of the flax plant. The linen manufacture has been prosecuted in England for a very long period; but though its progress has been considerable, particularly of late years, it has not been so great as might have been anticipated. It is only within the last fifty years that any machinery has been constructed in the production of linen cloth; the first mills for the spinning of flax having been constructed at Darlington, about forty-eight years ago. The other seat of the linen manufacture is, in England, Leeds and its immediate vicinity, and in Lancashire, Dorset, Durham, and Salop; in Scotland, Dundee, which, indeed, may be regarded as the chief seat of the British manufacture; and in Ireland, the province of Ulster. The entire value of the linen manufacture of Great Britain and Ireland is esti-
mated at 8,000,000, and the total number of persons employed in it, about 185,000.

LING (Calluna vulgaris). A species of heath. To avoid the inconvenience of giving a new generic appellation to the hundreds of plants familiar to everybody as Erica or heaths, Mr. Salesbury has judiciously called our common ling Calluna, from καλλω, which is doubly suitable, whether with Mr. Salisbury and Dr. Hall we take to express a cleansing property, brooms being made of ling, or whether we adopt the more common antecedent of the word, to ornamental or adorn, which is very applicable to the flowers. This shrub grows almost everywhere, on dry moors, heaths, and open, barren wastes, as well as in woods where the soil is sandy or turfy. The stems are bushy, repeatedly and irregularly branched. Leaves deep green. minute, sessile, acute, keeled, somewhat arrow-shaped, closely imbricated on the young branches, making a quadrangular figure, like a close-beaten chain; they are generally smooth, but in one variety are densely hairy all over. The flowers are stalked, drooping, in longish unilaterial clusters, soon overtopped by leafy shoots. The inner calyx, which is the most conspicuous part of the flower, is of a shining permanent rose colour. The flowers appear in June and July. Grouse and other birds, as well as some quadrupeds, eat the seeds and young shoots. There is a white-flowered variety, and a very beautiful double red one, cultivated in gardens, whose flowers, from a copious multiple of the corolla, resemble little roses. See Heath.

LINIMENT (Lat. linum, I anoint). In farriery, a semi-fluid ointment, or a soapy application to rub upon painful joints. The term is also applied to spirituous and other stimulating applications for external use. Liniments are intended either to lubricate or to stimulate; but in either case they can only be regarded as topical applications, their influence not extending beyond the part to which they are applied. In some instances they are anodyne; and contain solutions of opium in oil. See Flax.

LINSEED or FLAXSEED (Lat. linum semen; Germ. Leinsaat). The seed of the flax plant. See Flax. This seed is small, oval, oblong, flattened laterally, acute at the extremities, glossy, brown; but internally white. It is indorous, and tastes mucilaginous and oily. The husk or testa yields much mucilage to water, and the kernel a large proportion of oil to pressure. Besides upwards of 11 per cent. of oil, linseed contains wax, an acid soft resin, extractive yellow colouring matter, starch, gum, tannic acid, albumen, gluten, emulsive, and some salts. When the seeds are burnt, the ashes contain oxide of copper. The infusion of linseed in boiler water yields a demulcent mucilage, which is much used as a domestic medicine in coughs, and in cases of acidity in the urinary discharge. The linseed should not be boiled in the water, as that extracts the oil as well as the mucilage, and renders the decoction nauseating.

Linseed is much used in the economy of the farm, for feeding cattle and other purposes. A bushel of linseed averages in weight about 51 pounds; this weight, when crushed, produces about a quarter of its weight of linseed oil, and the remainder is cake. The great bulk of this seed is obtained from the Baltic and the Black Sea, and recently considerable quantities have been received from Egypt and Hindostan: of this last, the general character is, that although the seed is good, the impurities with which it is mixed are very considerable, such as the seeds of rape, &c.; for which reason the oil obtained from it does not possess the drying qualities of that expressed from the unmixed linseed, and the dealers in consequence will not give so much for it. This arises not from any intentional adulteration, but from the bad farming and want of cleanliness of the orientals.

Linseed oil contains a very considerable quantity of mucilage, which it almost entirely deposits by time; and hence, old linseed oil is more valued by the painter, but for the grazer, perhaps, its nutritive powers decrease by time. It is said by some persons, that it is to the presence of this mucilage that we must attribute the fattening quality of linseed oil when mixed with other substances, for linseed oil by itself is almost as powerful a purgative as castor oil, for which purpose indeed it is very commonly employed by the farmer; but on the other hand, we must remember, that in small doses, even castor oil is very fattening. Linseed is in fact commonly given to some birds, parrots for instance, for this purpose. Its purgative properties are very inferior to those of castor oil.

LINSEED CAKE. Linseed cake is a well-known and valuable article for the food of live stock, almost equally good for cattle, sheep, and horses. It is the residuum, or refuse, left after the oil is expressed from linseed. 1000 parts of it, according to Davy, contain about 151 parts of nutritive matter. Its price has induced many attempts to economize its application. It has been often given as recommended by Mr. Hillyard, mixed with other substances, whose value he thus estimates:

"The weekly cost of feeding each beast, including the expense of getting up, carting, and cutting the turnips and hay, and attendance, will be—"

"No food," says Mr. Hillyard, "can be given to still-feeding beasts that will fatten them so soon or so well as linseed oil-cake. It certainly is expensive feed, but not so expensive as it appears to be; taking into consideration that it fattens quicker. Beasts that have been fed with it, do not, after a long drift to market, lose their firmness of handling, as those do, fed..."
LINSEED CAKE.

without either cake or linseed, and whose dung is not of equal value. Some winters I have fed with linseed instead of cake, and found it answer very well, although it added to the trouble of feeding. My mode of preparing it has been to break it in a little hand-mill, and steep it in cold water in seven tubs of a size sufficient for one day’s feed; in this way it will have been steeped seven days before it is mixed with cut hay and barley, or (which is better) bean meal. If steeped in hot water, two days will do; if steeped longer than three, it is apt to get a little sour, which, in my opinion, is not quite so well for the beasts. Boiling it is troublesome, but it thus becomes more of a jelly, and mixes better with the cut hay and meal, and it prevents the numerous seeds of weeds, found in foreign linseed, from vegetating. One stone of linseed, in a mixture of other food, will do as much towards feeding as two stone of cake, which is merely the husk of the seed after the oil has been pressed out. Linseed, without being mixed with meal, is of too relaxing a nature.

"Finding at Christmas, 1838, that I could not get English oil-cake at home at less than about 132. 10s. per ton, I determined to feed the 35 beasts then in my stalls, in the following way, and I never had beasts that became better meat; but as the process of preparing the food is very troublesome, I should not recommend this way of feeding without the owner of the beasts will daily see that all is done right:—"

Three feeds daily, of half a bushel of cut hay, which is 5 lbs. each, and 4 lbs. uncut at night; 1 cwt. and not quite a quarter 3 6
Boiled linseed, 2 lbs. daily, 56s. per quarter; 2 0
weight, 50 lbs. per bushel. 1 6
Boiled potatoes, 2 lbs. daily, 1 gallons; 2 0
Molasses (which is feeding, but may be left out when the beasts have taken to the linseed, as it is only given to make the mixture variable). 1 9
about a ½ lb. daily. 1 9
Turnips, or mangel wurzel. 0 9
Barley and bean meal, mixed, 3 gallons. 1 9

"If this mixed food could be pressed together to form a cake, it would be a feeding one, and the cost 11d. per stone. As a proof that this mixture is both palatable and nutritive to beasts, they will not eat, excepting in the night, where they have none of it, any of the sweetest hay that can be put before them." (Proc. Farm, p. 89.)

Many farmers use ground linseed mixed with bran and chaff for their stock, deeming it a necessity, and are more inclined to the employment of linseed cake. Others use the linseed unground. The saving by this mode, however, is doubtful, for it is by no means certain that the oil possesses any very material fattening properties; and if it does not, then the cake is decidedly the cheapest. For at the present prices (1841), 51 lbs. of linseed are worth 7s. 6d., while 51 lbs. of cake, at 11l. per ton, are only worth about 5s.; and admitting that the oil does contain some fattening properties, yet it must be remembered that the value of the oil obtained from a bushel of linseed is worth, for other purposes, about 4s. But, on the other hand, I am aware that a very intelligent farmer near Rumford, Mr. S. Poole, who, in 1840, fed his bullocks with a mixture of linseed oil and cut chaff, and also other bullocks with linseed cake and hay, considered the oil to be the cheapest of the two, and in all respects equally fattening, but then it is certain that this mode requires more attention in the mixture of the oil and chaff than the other plan. He commenced with about a quarter of a pint per day, and gradually increased it to a pint.

The reported results of experiments in feeding cattle with linseed do not always agree. In a standard work we find the following passage: "Two Scots were fed on English linseed cakes; two Devons on unboiled linseed; two others on boiled linseed; and another pair of Devons on foreign; all of them having as much hay and chaff as they could eat. It was a losing concern in every case. The value of the manure was not equal to the difference of the cost and the selling prices; and, strange as it may appear, the greatest loss was sustained, when the beasts were fed on oil-cake; the next when foreign cake was used; the next when boiled linseed was used; and the least of all when the simple unboiled linseed was given.

LINSEED JELLY is easily made by adding to 6 quarts of water 1 quart of linseed, boiling it for 10 minutes. This, mixed with other substances, is sometimes given to live-stock as food, and, mixed with milk, is very nutritive for calves.

LINSEED OIL is an excellent purgative for sheep, from 2 to 3 ounces; for horses, in doses of from 16 to 24 ounces; for cattle, from 16 to 20 ounces. The quality of linseed oil may be determined in the following manner: Fill a phial with it, and hold it up to the light; if bad it will appear opaque, turbid, and thick; its taste is acid and bitter upon the tongue, and it smells rancid; and strong oil, from fine full-grown ripe seed, when viewed in a phial, will appear limpid, pale, and brilliant; it is mellow, and sweet to the taste, and its value is greater the less it resembles common impure oil, and when clarified dries quickly and finely. (Quart. Journ. of Agr. vol. v. p. 467.)

LIP. In botany, the lower petal of any irregular flower.

LIQUID MANURE. Liquid manure is not a mode of fertilizing the land altogether of modern origin, for a fermented mixture of water and night-soil has, from a very early period, been employed by the Chinese farmers; those of Italy certainly practised irrigation in the days of Virgil (Georgics, b. i. v. 106—109), and Catull adds the word aromatic employed a mixture of water and night-soil to fertilize their olive trees (b. xxxvii.). Columella praises very highly the use of putrid stale urine for vines and apple trees (b. ii. c. 15), commending also the lees of oil for the same purpose. More modern agricultural writers have united in praising various liquid preparations; thus Evelyn (whose ingredients most of the authors recommend), in his Treatise on Earth, p. 123—160, gives several recipes, some of which have served as the basis for recent modes of preparing liquid manure, such as the dung of cattle, urine, salt and lime, and nitre. Of these artificial mixtures, salt 1 part, and lime 2 parts, mixed together and allowed to remain in a heap for 2 or 3 mouths (Mr. Bennett turns it 727
over 3 or 4 times in this period), is fully equal, if not superior, to any thus recommended, most of which I have tried. When mixed with water and spread over land intended for wheat, at the rate of from 25 to 35 bushels of the salt and lime to 10 or 15 tons of water per acre (and it answers very nearly as well when carried on the land dry), excellent results are produced. The wheat which I have thus grown on clover leys has been superior in height, and strength of straw, to any I have seen produced under different modes of treatment, and the seed very bright and heavy.

All substances, whether organic, earthly, or saline, which are employed to fertilize the soil, cannot be employed for the same purpose, and can only be rendered thus serviceable to vegetation when they are presented to the roots of plants in solution, or in a fluid state; and although this may appear at first rather a sweeping position, yet such is the real fact, the compost of the farm-yard, the crushed bones of the turnip cultivator, the oil and bones of fish, the gypsum of the grazer, the earths, lime, magnesia, and even silica, and all the saline manures, are dissolved by some process or other before they can be absorbed by vegetation. Every attempt which has been hitherto made to make plants imbibe the most minutely divided powders which chemistry can produce, has been entirely fruitless. Davy ineffectually tried the finest impalpable powder of charcoal, and with much perseverance I have fruitlessly employed the earths, saline substances, and organic matters, for the same purpose.

This absolute necessity for every substance which is the food of plants being of a soluble nature did not escape the sagacity of the early Greek and Egyptian philosophers; it is true they carried their conclusions with regard to subjects of natural philosophy too far, as in this instance, when they asserted that water is the only food of plants; yet they must have patiently noticed many facts in vegetable economy, unnoticed as they were by the light of modern vegetable chemistry, before they could have arrived at a conclusion so nearly approaching the truth. The idea was probably of Egyptian origin, for the cultivators of that country could not fail to notice the magnificent fertilizing powers of the waters of the Nile, whose annual overflow is perhaps the most extensive natural irrigation taken advantage of by the cultivators of the earth.

The same wild dream of water being the sole food of vegetables was again revived, so lately as 1610, by M. Van Helmont, a celebrated Dutch chemist, who made some very plausible, deceptive experiments on a willow tree, which he watered only with rain water; researches, however, whose inaccuracy (owing principally to rain water, as usually collected, not being quite pure) was shown in 1691 by Mr. Woodward. Although, therefore, it is now well ascertained that water is not the only food of plants, yet it certainly contributes universally and largely to their support; and, as it has been well observed by Davy, no manure can be taken up by the roots of plants unless water is present; and water, or its elements, exists in all the products of vegetation. (Lecture 15.)

**LIQUID MANURE.**

It must not, however, be concluded that these carefully considered conclusions, from the results of often-repeated laborious experiments, are erroneous, because transparent water, apparently pure, as in water-glassess, or in irrigation, promotes the growth of bulbs, grass, &c., since the very purest spring water, even rain water, contains foreign substances, as I have clearly ascertained by experiment; and when only chemically pure water is employed to water plants, they cannot be made to flourish. I have fruitlessly varied the attempt in several ways. All the experiments of Dr. Thomson were equally unsuccessful, the plants vegetating only for a certain time, and never perfectly developing their seeds. Similar experiments were made by Hassenfratz and Saussure, and others, with the same unfavourable result. Duhamel found that an oak which he had raised from an acorn in common water, made less and less progress every year. The florist is well aware that bulbous roots, such as hyacinths, tulips, &c., which are made to grow in water, unless they are planted in the earth every other year, at first refuse to flower, and finally even to vegetate. Further, it has been shown, by many very accurate experiments (Rech. sur la Vég. p. 51), at the varied repetition of which I have personally assisted, that the quantity of nourishment or solid matters absorbed by the roots of plants is always in proportion to the impurity of the water; always in proportion to the impurity of the water; thus some beans were made to vegetate under three different circumstances: the first were grown in distilled water; the second were placed in sand and watered with rain water; the third were sown in garden mould. The plants thus produced, when accurately analysed, were found to yield the following proportions of ashes:

1. Those fed by distilled water  - 3-9
2. Those fed by rain water  - 7-5
3. Those grown in soil  - 12-0

And again, all attempts to make plants flourish in the pure earths have failed utterly when they have been watered with pure water; yet a totally different result I have invariably experienced when I have employed an impure solution or liquid manure. My trials have been on both sides of the Channel; in the south, who, having formed of the four earths, silica, alumina, lime, and magnesia, a soil in the most fertile proportion, in vain essayed to make the plants flourish in it when watered with pure water only; yet every difficulty was removed when he moistened it with the water from a dunghill, for they then grew most luxuriantly; and M. Lampadius still further demonstrated the powers of such a foul liquid manure, for he formed plots composed of only a single earth, pure lime, pure alumina, pure silica, and planted in each different vegetables, watering them with the liquid drainings from a dunghill, and he found that they all flourished equally well. The soluble matters of a soil ever constitute, in fact, its most fertilizing portion; and if by any artificial means the richest mould is deprived of these, as by repeated washings in cold or boiling water, the residuum, or remaining solid matter, is rendered nearly sterile: this fact, first accurately demon-
strated by M. Saussure (Rech. 150), I have since confirmed, by a variety of experiments of my own.

The soluble matters or liquid manures consumed by plants are sometimes imbied by their roots and absorbed; in other cases they are decomposed during their absorption. The earths, gypsum, and other salts, are instances of the first class; oil, and other purely animal matters, of the last. Davy found that some plants of mint, which he forced to vegetate in sugar and water, apparently absorbed the sugar unaltered, for they yielded a considerably larger proportion of a sweetish vegetable extract than those of the same weight which he had grown in common water; and it is an ascertained fact, that the roots of plants will absorb or reject the various earthy substances of a soil, or even when placed in a saline solution, in a very remarkable manner: thus, when equal parts of gum and sugar were dissolved together in water, and some perfect plants of Polygonum Persicaria placed with their roots in the solution, it was found that they absorbed 36 parts of the sugar, but only 26 of the gum; and when in precisely the same proportions and manner Glauber salt, common salt, and acetate of lime were used, then it was found that the roots of the Persicaria separated these salts from the solution with much ease, absorbing 6 parts of the Glauber salt, 10 parts of the common salt, but not a trace of the acetate of lime. (Thomson, vol. iv. p. 321.)

These facts will not be uninteresting to the irrigators or occupiers of the English watermeadows, since they may, in some degree, serve to account for the beneficial action of water on such lands—a question not nearly so well understood as it ought to be, and on which widely differing opinions are commonly held by practical farmers. It is a theme intimately connected with the subject of this article, for irrigation is, in truth, a mode of applying the weakest of liquid manures, on a very bold scale, to grass-lands. See Irrigation.

The employment of artificially-prepared liquid manure (though little known at present in England) is very extensive on the Continent: the Swiss farmers call it gulle; in France it is denominated liére; and by the Germans, mist-wasser. They prepare it throughout many of the German states, and in the Netherlands, by sweeping the excrements of their stall-fed cattle into under-ground reservoirs, mixing it with four or five times its bulk of water, according to the richness of the dung: five reservoirs are generally employed, of such a size that they each take a week to fill; and thus each has four weeks allowed to ferment before the mass, which in this time becomes of a uniform consistence, is removed, by means of a portable pump, in water carts, or large open vessels. A similar plan is adopted in the north of Italy, and from time out of mind has been practised by the Chinese. In that empire, however, the cultivators chiefly employ night soil, which is made into cakes for this purpose with lime or clay, in all their large cities, to prepare their liquid manure.

It is from long experience an admitted fact among the German farmers, that there are no manures so powerful in their operation as those which are liquids, such as human urine or bullocks' blood; so that no English farmer need fear deception as to their asserted value. This was proved some years since to the consideration of Professor Hembstadt, of Berlin, by the Saxon and Prussian authorities, who were anxious to apply the contents of the city drains towards fertilizing the barren lands in the neighbourhood of Dresden and Berlin. This talented agriculturist undertook, in consequence, a series of valuable experiments, which, varied in every possible way, were carried on for a considerable period; the result of them, so highly advantageous to the prosperity of Germany, Hembstadt then published. They were repeated with unvaried success by Professor Schübler, and the results may be stated in the following order:

If the soil, without any manure, yield a product of three times the quantity of seed originally sown, then the same quantity of land will produce—

5 times, the quantity of seed sown, when dressed with old herbage, grass, leaves, &c.
7 times, when dressed with cow dung.
9 times, with pigeons' dung.
10 times, with horse dung.
13 times, with human urine.
12 times, with sheep's dung.
14 times, with human manure or bullocks' blood.

Thus it will be seen that, of seven usually employed fertilizers, the liquid manures, urine and blood, were found to be decidedly the most powerful.

Both with regard to the quantity of liquid manure applied per acre, and the mode of spreading it, much must depend upon the circumstances under which the cultivator is placed, and the richness of the liquid he employs. If the impurities dissolved, or mechanically suspended in the water, are equal to 1 part in 10, then 20 to 30 tons per acre of the liquid manure I have found amply sufficient, under ordinary circumstances, to produce the most excellent results; if the fluid mass is purer, then more must be applied. For gardens, and small plots of ground in general, the liquid may be readily and evenly distributed over the beds by means of a watering-pot or garden-engine; for fields it must be carried in water-carts, and distributed either by being let into a transverse trough, placed with holes in the manner of those employed for street wheelings, or the Flemish plan may be adopted (especially when the manure is of too considerable thickness to flow readily through holes), of taking it into the fields in the water-carts, open at the top (furnished with slight movable covers), and then distributing it out of the cart very evenly by means of a scoop; and I have invariably perceived the advantage of ploughing the liquid into the soil as soon as after it was spread on the land as possible. The cultivator will find great advantage if he uses the garden-engine, watering-pot, or cart, from draining the liquid manure before he pumps it out of the reservoir, either through straw, coarse sand, or a basket; the pieces of straw, and other coarsely-divided matters thus separated by the strainer, he will discover add very.
LIQUID MANURE.

Mr. Milburn has given the annexed estimate for cutting, walling, plastering, and covering a tank of the following dimensions:—Length within, 13 feet 6 inches; width, 6 feet 6 inches; depth, 6 feet, equal to 19¼ cubic yards.

Cutting at 3d. per cubic yard 2 0 0
Walling, including bricks and mortar 6 8 0
Plastering and cement 0 16 0
Covering and slabs 2 15 0

This would be a tank sufficiently capacious for a farm of 150 to 200 acres.

To the presence of a large proportion of urine, the richest of liquid fertilizers, must be chiefly attributed the luxuriant effects produced by the liquid manure, as prepared on the Continent, and from the use of the sewerage matters of large towns, as so strikingly proved in the case of the Craigintinny water-meadows, near Edinburgh, where the drainage is employed in the state in which it issues from the sewers, and from its use several crops of the most luxuriant grass are annually obtained. "All urine," said a late distinguished chemical philosopher, "contains the essential elements of vegetables in a state of solution." By a careful analysis, human urine in its fresh state was found, by Berzelius, to contain the following substances:

<table>
<thead>

|                                  | 100   |

Thus it will be seen that there is hardly a single ingredient found in urine which is not either a direct food for vegetation, or furnishes by its decomposition a supply in another form; for in it are thus detected the ammoniacal salts of the dunghill, the phosphate of lime of bones, as well as of many cultivated vegetables, and abundance of easily decomposed animal matters.

The urine of the horse is nearly as rich in animo-vegetable matters; its composition, according to the experiments of Fourcroy and Vauquelin, are as follows:

The following are the constituents in that of the cow, as found by Professor Brande:

730

LIQUID MANURE.

slightly to the fertilizing powers of the liquid, and yet they all materially hinder the even distribution of the manure.

The expense, per acre, of such an application of liquid manure, I thus estimate, supposing the cow-herd to be employed:—

If it shall occur to the farmer that the quantity of solid manure thus added to the soil will not, in reality, much exceed two tons per acre, and that this is, in appearance, a very small allowance, I would remind him that the quantity thus conveyed consists of the soluble or richest portion of the manure, and is, in fact, the extract without any of the straw; or other inert residuum usually carried on to the soil; besides, it is a very erroneous, though common conception, to suppose that all the ingredients must be used in large quantities. I have observed in this paper that a flooding with river water, so productive of heavy crops of grass in the water meadows, does not carry on to the land more than 2 tons per acre of animal and vegetable substances; and in the successful experiments of the late Lord Somerville, at Fairmile, with whale blubber, not more than a ton and a half per acre were applied. The Essex farmers find three-quarters of a ton of sprats amply sufficient; and 2 cwt. per acre of gypsum is the ordinary successful allowance for grass land. The exact evenness, therefore, with which a manure is spread over the land is a highly important consideration as regards the economy of manures. There is no common cultivated plant which more delights in liquid manure than the potato. It naturally luxuriates near to wet ditches: on plots which have received the drainage of a dunghill it grows with the greatest rapidity; I have invariably found that, to any liquid mixture intended as a manure for potatoes, the addition of 5 or 6 bushels of salt per acre is productive of great good, both as regards the quantity and quality of the potatoes.

On clover leys intended for wheat, the liquid should be turned into the soil as early as possible after it is spread; and if this operation is performed in moist, cloudy weather, a very material advantage will be perceptible in the succeeding crop. The warmth of the sun is certainly prejudicial to the thinly-spread liquid manure, composed of finely-divided animal and vegetable substances.

Of the tanks for receiving or preparing the liquid manure, I may remark that I have always found them best made of flints or bricks set in good mortar or Parker's cement; they may be bedded in clay, but I would not recommend the use of clay for the brickwork, since worms are sure eventually to penetrate through it; and I advise the shape to be something like a decanter, larger at the top than at the bottom, in the manner introduced at Eastbourne and in Cornwall, chiefly by the advice of Mr. Davies Gilbert.

It would appear, from some experiments of Dr. Belcher, that the ammoniacal salts of urine have a foreing or stimulating power, which considerably hastens the vegetation of plants. His experiments were made with the common garden cress; and, in his trials, some plants nourished with a solution of phosphate of ammonia were 15 days more advanced than plants growing under similar circumstances, but watered with plain water. In some experiments of Mr. Gregory, who watered half a grass field at Leyton with urine, the portion thus treated yielded nearly double the quantity of hay produced by the other unnatured portion; and these facts of the urinous compound so expressly employed for grass lands, and in the garden and orchard, by Mr. Harley, in the neighbourhood of Glasgow, was attended with results equally satisfactory, producing, when diluted with water or soap-suds, very superior crops of grass on land of a very inferior description. I shall conclude with a few observations on the loss which the cultivated lands of England incessantly sustain from the neglect of the liquid manure of the sewers of her cities and large towns,—a question to which I have before alluded in this paper, and which is not nearly so well understood as it is desirable. Thus, by carefully conducted experiments, and very accurate gaugings, it has been found that the chief London sewers convey daily into the Thames about 115,000 tons of mixed drainage, consisting, on an average computation, of 1 part of solid and 25 parts absolutely fluid matters; but if we only allow 1 part in 30 of this immense mass to be composed of solid substances, then we have the large quantity of more than 3800 tons of solid manure daily poured into the river from London alone, consisting principally of excrements, soot, and the débris of the London streets, which is chiefly carbonate of lime; thus, allowing 20 tons of this manure as a dressing for an acre of ground, there is evidently a quantity of solid manure annually poured into the river equal to fertilizing more than 50,000 acres of the poorest cultivated land! The quantity of food thus lost to the country by this heedless waste of manure is enormous; for, only allowing one crop of wheat to be raised on these 50,000 acres, that would be equal to the maintenance (calculating upon an average produce of three quarters of wheat per acre) of 150,000 persons. London, too, is only one huge instance of this thoughtless waste of the agricultural riches of the soil of England; from every other English city, every town, every hamlet, is hourly passing into the sea a proportionate waste of liquid manure; and I have only spoken of the solid or mechanically suspended matters of the sewerage; the absolutely fluid portion is still rich in urine, ammoniacal salts, soda, &c, when all the mechanically suspended matters have been separated from the other portions. According to very careful experiments, this fluid part often contains 16 per cent. of animal matters, salts, &c., intimately or chemically combined with the water.

No farmer, after such an analysis of the sewerage of a large city, can feel surprised at the important results from the use of that sewer water, as long practised in the vicinity of Edinburgh. After learning the composition of such a foul fluid—its endless mixture of organic matters—its soot—its carbonate of lime—and, above all, its urine, the forcing nature of the ammoniacal salts which that fluid contains, added to the presence of the other matters which are the food of plants, and the constant supply of such irrigation water in all seasons—he will readily give credence to the talented editor of the Quarterly Journal of Agriculture, when he asserts that, by such treatment of the Edinburgh meadows with the sewerage irrigation, they have been increased in value several acres of land yearly.

I have often employed, with decided effect, in my own garden, for vines, peach, and standard apple trees, liquid manure, prepared either by mixing one part by weight of cow dung with four parts of water, or the collected drainage of the stable and cow-house. Of this the vine is by far the most benefited by the application; but to whatever fruit-tree the gardener has occasion to apply manure, there is no form so manageable and so grateful to the plant as the liquid. It has been found advantageous to plants cultivated in stoves to apply even a liquid manure, composed of six quarts of soda to a hogshead of water; and although this is a very unchemical mixture, yet it has been found by Mr. Robertson to be peculiarly grateful and nourishing to pines, causing them to assume an unusually deep healthy green; and for stoved mulberry, vine, peach, and other plants, the late Mr. Knight, of Downton, employed a liquid manure, composed of one part of the dung of domestic poultry, and 4 to 10 parts of water, with the most excellent result—the trees maintaining, at the end of two years, "the most healthy and lustrous foliage imaginable." (Trans. Hortic. Soc. vol. ii. p. 127.)

In whatever way we view the question of liquid manure, an abundant field of research presents itself on every side: it is evidently an investigation likely to amply repay the cultivator for the labour he may be induced to bestowed upon it. By such manures, nourishment for vegetation is more equally diffused through the soil, and becomes more speedily serviceable to the crop, than by any other mode of cultivation. I have endeavoured, also, in this article, to convince the farmer of what I have long remarked in my own practice—that a much smaller quantity of manure, if uniformly mixed with land, is sufficient for all the purposes of fertilization than is commonly believed. Such investigations must be of the highest interest to the farmer and to the public in general, for they relate to the increased produce of the land of England; and not only does a fortunate experiment carry with it its own reward, but even an unsuccessful one is not without its advantages,—it serves, at least, as
LOBELIA.

a beacon to other cultivators, and affords that satisfaction which ever accompanies the acquirement of knowledge. (Journ. Roy. Ag. Soc. vol. i. p. 147.)

LIQUORICE (Glycyrrhiza, from glikus, sweet, and rìca, a root; the sweetness of the root of liquorice is well known). A deep, light, sandy loam suits all the species of this genus, and they are readily increased by slips from the roots with eyes, and planting them in spring.

Common liquorice (G. glabra) is a native of the south of Europe; but it is also cultivated in England. The hollow root, when trimmed, is a leguminous plant, with unequally pinnated leaves, composed of ovate, retuse leaflets; the flowers are in racemose spikes, shorter than the leaves. The legumes are smooth, and six-seeded. The root, when fit for use, is long, about the thickness of the finger, grayish without, and yellow within. The sweet, subacrid, mucilaginous juice contained in the root is much esteemed as a pectoral demulcent. Liquorice requires three years to perfect its growth, when the roots are taken up about the end of November with the spade; they are then washed, the fibres trimmed off, and the smaller roots which are termed "offal," are separated from the larger. The small roots are dried and ground into powder; but the larger, which form the principal article of profit, are packed up and sold to the druggists. A fair crop will yield from 18 to 20 cwt., at an average price of about 45s. per cwt.; but the expense of digging up and preparing it for market is not short of 10s. per acre; which, great as it may appear, is by no means extravagant, if we consider the depth to which the roots run, and the care which is necessary to avoid breaking or leaving any of them in the ground. (Paxton's Bot. Dict.; Brit. Hubb. vol. ii. p. 330.)

LIQUORICE, WILD. A species of the genus Galium (Circæaæ) found in the United States, frequent in rich woodlands, &c. Its root is perennial, and the stems grow 12 to 18 inches high, often branched near the base. The flowers are purplish-white, and appear in June and July. The leaves have a sweet taste, resembling liquorice. See Milk-Vetch.

LITTER. The straw, fern, or other dry substances which are placed under horses and cattle in the stables, cow-houses, farm-yards, &c., for the purpose of keeping the animals clean and warm, and providing a supply of manure. In this last view, all sorts of dry materials should be carefully collected and stacked up for winter use.

LIVERWORT (Anemone hepatica, Hepatica Americana, or Three-leaved Liverwort) is very common in the open woodlands of the United States, where it flowers in Pennsylvania in May, and matures its seed in May and June. This plant has acquired much notoriety, of late years, as a remedy in pulmonary consumption; but its virtues have doubtless been greatly exaggerated. Dr. Darlington thinks it the only species in the United States. (Flora Cestriam.) See Hepatica.

LIVE-Stock. See Horses, Cattle, Sheep, &c. In Great Britain, the live-stock forms the chief wealth of a farm. The term implies cattle; but poultry, too, is strictly live-stock; and in some countries, fish, game, bees, &c., are of that importance that they are considered to be live-stock. In several districts of England, rabbits are so, and that to a very essential extent. In some parts of southern Europe, even the silk-worm is live-stock.

Through the combined exertions of many distinguished writers, and the practical knowledge of modern breeders, a very material alteration for the better in the breeds of live-stock has taken place, and is still progressing; and there is little reason to doubt but that still greater improvements are yet to be effected. To such researches too much attention can hardly be paid; for on the well or ill stocking of the land will mainly depend the cultivator's success. To this end, however, much must rest on the circumstances in which he is placed. See Agriculture in the United States.

LIVE OAK (Quercus virgins). See Oak.

LOAD. A term used in the United States rather vaguely, and meaning different amounts or measures in different places. The general meaning of a load of manure, according to Buel, is what can be drawn by two horses, or two oxen, to the field where it is to be applied. At Boston and other large towns in the Eastern States, as well as other States, the term load is applied commonly to express as much as can be drawn by four and even six cattle upon a hard road, or about 96 cubic feet. A load of earth, clay, or marl, is generally estimated at a cubic yard, or 27 cubic feet.

LOAM. By this term is generally understood a dark-colored, friable, or mellow, slightly acid, sandy clay. It is a compound of dissimilar particles of earth and decomposed vegetable matter, moderately cohesive, and therefore neither retentive of moisture, like clay, nor too ready to part with it, like sandy soil. According as the different ingredients predominate, loamy soils are of different qualities—friable and mellow, middling, or heavy loams. (Pract. Hubb. p. 284.) Loam is supposed to consist chiefly of woody fibre in a state of decay, which, as it progresses, acquires a black-brown colour, and is then moulded into hard loam. It is a continued source of carbonic acid, as almost every particle of it is enveloped by an atmosphere of that gas, which is absorbed by the roots of plants, and replaced by atmospheric air, to be again converted into carbonic acid. Upon this transformation the influence of loam on vegetation is greatly understood: it does not itself nourish plants, but it presents to them "a slow and lasting source of carbonic acid, which is absorbed by the roots." (Liebig, Organic Chemistry in its Application to Agriculture, p. 48–61.) See Humus.

LOBELIA (Lobelia) in honour of Matthew Lobel, author of various botanical works. He was a native of Lisle; became physician and botanist to James I, and died in London in 1616. This is an extremely interesting genus of plants, on account of the beauty of the blossoms, and the medicinal properties of some of the species. The green-house, and stove, shrubby, and herbaceous kinds, grow well in a mixture of peat and sand; yet shrubby kinds are readily improved by cuttings in the same kind of soil, and the herbaceous species by dividing and by seeds. The hardy herbaceous
kinds do well in a light, rich earth, or peat soil; but in winter most of them require the protection of a frame. The green-house annuals and biennials must be sown in pots, and treated as other green-house annuals and biennials. The seeds of the hardy kinds have only to be sown in the open border. *L. longiflora* is one of the most venomous of plants. Barton says the Spanish Americans call it *Rebata cavallos*, because it proves fatal to horses that eat it, swelling them till they burst. Taken internally, it acts as a violent cathartic, the effects of which no remedy can assuage, and which terminate in death. Another American species, namely, *L. inflata*, commonly called Indian Tobacco, is a powerful antispasmodic and emetic, and is much employed to allay the paroxysm of spasmatic asthma. There are two indigenous species: 1. The water lobelia (*L. Dartmanni*), which grows in the lakes of Wales, Scotland, Ireland, and the north of England. The root consists of many long, simple, whitish fibres. Herb smooth, immersed in water like lobelia *tomentosa*. Leaves numerous, two inches long, linear, entire, with two longitudinal cells. The stem is nearly naked, terminating in a simple cluster of light-blue, drooping, alternate flowers, raised several inches above the water, which appear in July and August.

2. Acrid lobelia (*L. viridis*). This grows wild on briny heaths in Devonshire. The root is fibrous; stem a foot or more in height, nearly upright; lower leaves ovate, slightly toothed; upper lanceolate, serrated; the flowers are in erect clusters, terminal, of a purplish-blue colour, appearing in August and September. The whole herb is milky, fetid, and very acrid.

**LOBLOLLY BAY** (*Gordonia lasyanthes*). This American tree is comprehended within the same limits with the long-leaved pine, being confined to the maritime parts of the Southern States, to the two Floridas, and to Lower Louisiana. It is very abundant in the branch swamps, and exists in greater proportion than the red bay, swamp bay, and black gum, with which it is usually associated. In the pine barrens, tracts of 50 or 100 acres are met with at intervals, which, being lower than the adjacent ground, are kept constantly moist by the waters collected in them after the great rains. These spots are entirely covered with the lobolly bay, and are called bay swamps. Although the layer of vegetable mould is only 3 or 4 inches thick, and reposes upon a bed of barren sand, the vegetation of these trees is surprisingly luxuriant.

The lobolly bay grows to the height of 50 or 60 feet, with a diameter of 18 or 20 inches. For 25 to 30 feet its trunk is perfectly straight. The small divergency of its branches near the trunk gives it a regularly pyramidal form; but as they ascend they spread more loosely, like those of other trees of the forest.

The leaves are evergreen, from 3 to 6 inches long, alternate, oval-acuminate, slightly toothed, and smooth and shining on the upper surface. The flowers are more than an inch broad, white and sweet-scented; they begin to appear about the middle of July, and bloom in succession during 2 or 3 months. This tree possesses the agreeable singularity of bearing flowers when it is only 3 or 4 feet high.

The fruit is an oval capsule, divided into 5 compartments, each of which contains small, black, winged seeds. These seeds appear to germinate successfully only in places covered with sphagnum, a species of moss which copiously imbibes water, and in which are found thousands of the young plants, which are plucked up with ease.

The bark of the lobolly bay is very smooth while the tree is less than 6 inches in diameter; on old trees it is thick and deeply furrowed. In trunks which exceed 15 inches in diameter, four-fifths of the wood is heart. The wood is of a rosy hue, and of a fine, silky texture: it appears to be very proper for the inside of furniture, though the cypress is generally preferred. It is extremely light: when seasoned it is very brittle, and if rapidly dries unless it is kept perfectly dry: hence it is entirely neglected in use, and is not employed even for fuel.

The fibres of the bark compensate in some measure for the uselessness of its wood: it is employed for this purpose throughout the maritime parts of the Southern States and of the Floridas. For, although this branch of industry is by no means as extensively practised in this part of the country as in the Northern States, and though these regions afford many species of oak, yet the species whose bark is proper for tanning are not sufficiently multiplied to supply the consumption. As much of the bark of the Spanish oak as can be obtained, of which the price is one-half greater, is mixed with that of the lobolly bay. This tree has the advantage of maintaining very long the circulation of its sap, so that the bark may be taken off during three or four months.

The luxuriance of its vegetation, the beauty of its flowers, and the richness of its evergreen foliage place the lobolly bay among the magnolias; and, with the other species, it contributes to the ornament of the forests in the southern parts of the United States. It is less sensible to cold than the big laurel. (Michaux.)

This tree is used for the *Pine (Pinus tede)*. See *Pine*.

**LOCKED-JAW.** See *Tetanes*.

**LOCKING OF WHEELS.** The means of fastening them so as to prevent their running too swiftly upon the horses, when coming down steep hills. This is effected in various ways; as by chains, sledges, friction-bars, &c. See *Wheel*, and *Wagon*.

**LOCULAR.** A term in botany. A fruit is called unilocular if it contains but one cell, bilocular if it contains two cells, and so on. In many instances, one or more of the cells are abortive, and become obliterated as the fruit ripens.

**LOCUST.** A name given by the English to the large grasshoppers, but which, in the United States, and indeed almost universally, is applied to the group of insects which naturalists have termed *Cicadidae*, and which are also called harvest-flies.

These insects are readily distinguished by their broad heads, the large and very convex eyes on each side, and the three eyeslets on the
LOCUST.

 crown: by the transparent and veined wing-covers and wings; and by the elevation on the back part of the thorax in the form of the letter X. The males have a peculiar organization, which enables them to emit an excessively loud buzzing kind of sound, which, in some species, may be heard at the distance of a mile; and the females are furnished with a curiously con-trived piercer, for perforating the limbs of trees, in which they place their eggs. The musical instruments of the male consist of a pair of kettle-drums, one on each side of the body, and these, in the seventeen-year Cicada (or locust, as it is generally but improperly called in Ameri-ca), are plainly to be seen just behind the wings. These drums are formed of convex pieces of parchment, covered with numerous fine plats, and, in the species above named, are lodged in cavities on the sides of the body behind the thorax. They are not played upon with sticks, but by muscles or cords fastened to the inside of the drums. When these muscles contract and relax, which they do with great rapidity, the drum-heads are alternately tightened and loosened, recovering their natural convexity by their own elasticity. The effect of this rapid alternate tension and relaxation is the production of a rattling sound, like that caused by a succession of quick pressures upon a slightly convex and elastic piece of tin plate. Certain cavities within the body of the insect, which may be seen on raising two large valves beneath the belly, and which are sepa-rated from each other by thin partitions having the transparency and brilliancy of mica, or of thin and highly polished glass, tend to increase the vibrations of the sounds, and add greatly to their intensity. In most of our species of Cicada, the drums are not visible on the outside of the body, but are covered by convex triangular pieces on each side of the first ring behind the thorax, which must be cut away in order to expose them. On raising the large valves of the belly, however, there is seen, close to each side of the body, a little opening, like a pocket, in which the drum is lodged, and from which the sound on each side of the insect opens the valves. The hinder extremity of the body of the female is conical, and the under-side has a longitudinal channel for the reception of the piercer, which is furthermore protected by four short grooved pieces fixed in the sides of the channel. The piercer itself consists of three parts in close contact with each other; namely, two outer ones grooved on the inside and en-larged at the tips, which externally are beset with small teeth like a saw, and a central, spear-pointed borer, which plays between the other two. Thus this instrument has the power and does the work both of an awl and of a dou-ble-edged saw, or rather of two key-hole saws cutting opposite to each other. No species of Cicada possesses the power of leaping. The legs are rather short, and the anterior thighs are armed beneath with two stout spines.

The duration of life in winged insects is comparatively very short, seldom exceeding two or three weeks in extent, and in many is limited to the same number of days or hours. To increase and multiply is their principal busi ness in this period of their existence, if not the only one; and the natural term of their life ends when this is accomplished. In their previous states, however, they often pass a much longer time, the length of which depends, in great measure, upon the nature and abundance of their food. Thus maggots, which subsist upon decaying animal or vegetable matter, come more quickly to their growth than caterpil-lars and other insects which devour living plants: the former are appointed to remove an offensive nuisance, and to do their work quickly; the latter have a longer time assigned to them, corresponding in some degree to the progress or continuance of vegetation. The facilities afforded for obtaining food influence the duration of life; hence those grubs that live in the solid trunks of perennial trees, which they are obliged to perforate in order to obtain nourishment, are longer lived than those that devour the tender parts of leaves and fruits, which, though they last only for a season, require no laborious efforts to be prepared for food. The harvest-flies continue only a few weeks after their final transformation, and their only nourishment consists of vegetable juices, which they obtain by piercing the bark and leaves of plants with their beaks; and during this period they lay their eggs, and then perish. They are, however, amply compensated for the shortness of their life in the winged state by the length of their previous existence, during which they are wingless and grub-like in form, and live under ground, where they obtain their food only by much labour in perforating the soil among the roots of plants, the juices of which they imbibe by suction. To meet the difficulties of their situation and the precarious supply of their food, for which they have to grope in the dark in their subterranean retreats, a remarkable longevity is assigned to them; and one species has obtained the name of Cicada septendecim, on account of its life being protracted to the period of seventeen years.

This insect has been observed in the south-eastern parts of Massachusetts, but does not seem to have extended to other parts of the state. The earliest account that we have of it is contained in Mr. Morton's Memorial, whereas it is stated that "there was a numerous company of flies, which were like for bigness unto wasps or bumblebees," which appeared in Ply mouth in the spring of 1633. "They came out of little holes in the ground, and did eat up the green things, and made such a constant yelling noise as made the woods ring of them, and ready to deafen the hearers." Judge Davis, in the Appendix to his edition of Secretary Mor-ton's Memorial, states that these insects ap-peared in Plymouth, Sandwich, and Falmouth in the year 1804; but, if the exact period of seventeen years was observed, they should have returned in 1803. Circumstances may occa-sionally accelerate or retard their progress to maturity, but the usual interval is certainly seventeen years, according to the observations and testimony of many persons of undoubted veracity. Their occurrence in large swarms at long intervals, like that of the migratory locusts of the East, probably suggested the name of locusts, which has commonly been applied to them in this country. It appears
that these insects come forth at different places in different years.

Dog-day Harvest-fly.—Another species of harvest-fly, though it does not make its appearance in such formidable numbers as the seventeen-years locust, is much more frequently met with. Dr. Harris calls it the dog-day harvest-fly (Cicada concinularis), from its invariably coming about the beginning of dog-days. "During many years in succession," says Dr. Harris, "with only one or two exceptions, I have heard this insect on the 25th day of July, for the first time in the season, drumming in the trees, on some part of the day between the hours of ten in the morning and two in the afternoon."

Dr. Harris describes about twenty other species of the locust family found in Massachusetts, and concludes the subject in the following words:

"After so much space has been devoted to an account of the ravages of grasshoppers and locusts, and to the descriptions of the insects themselves, perhaps it may be expected that the means of checking and destroying them should be fully explained. The naturalist, however, seldom has it in his power to put in practice the various remedies which his knowledge or experience may suggest. His proper province consists in examining the living objects about him with regard to their structure, their scientific arrangement, and their economy or history. In doing this, he opens to others the way to a successful course of experiments, the trial of which he is generally obliged to leave to those who are more favourably situated for their performance."

In the south of France the people make a business, at certain seasons of the year, of collecting locusts and their eggs, the latter being turned out of the ground in little masses, cemented and covered with a sort of gum, in which they are enveloped by the insects. Rewards are offered and paid for their collection, half a franc being given for a kilogramme (about 2 lbs. 3½ oz. avoidipous) of the insects, and a quarter of a franc for the same weight of their eggs. At this rate 20,000 francs were paid in Marseilles, and 25,000 in Arles, in the year 1613; in 1824, 5,542; and in 1825, 6,200 francs were paid in Marseilles. It is stated that an active boy can collect from 6 to 7 kilogrammes (or from 13 lbs. 3 oz. 13½ dz. to 15 lbs. 7 oz. 2½ dz.) of eggs in one day. The locusts are taken by means of a piece of stout cloth, carried by four persons, two of whom draw it rapidly along, so that the edge may sweep over the surface of the soil, and the two others hold up the cloth behind at an angle of 45 degrees. This contrivance seems to operate somewhat like a horse-rake, in gathering the insects into winnows or heaps, from which they are speedily transferred to large sacks. A somewhat similar plan has been successfully tried in this country, as appears by an account extracted from the Portsmouth Journal, and published in the New England Farmer, vol. v. p. 5. It is there stated that, in July, 1826, Mr. Arnold Thompson, of Epsom, New Hampshire, caught in one evening, between the hours of 8 and 12, in his own and his neighbour's grain-fields, 5 bushels and 3 pecks of grasshoppers, or, more properly, locusts. "His mode of catching them was by attaching two sheets together, and fastening them to a pole, which was set upright as the front part of the drag. The pole extended beyond the width of the sheets, so as to admit persons at both sides to draw it forward. At the sides of the drag, braces extended from the pole to raise the back part considerably from the ground, so that the grasshoppers could not escape. After running the drag about a dozen rods with rapidity, the braces were taken out, and the sheets double over; the grasshoppers were then swept from each end towards the centre of the sheet, where there is an opening to the mouth of a bag which has about as much as a bushel; when deposited and tied up, the drag was again opened and ready to proceed. When this bag was filled so as to become burdensome (their weight is about the same as that of the same measure of corn), the bag was opened into a larger one, and the grasshoppers received into a new deposit. The drag can be used only in the evening, when the grasshoppers are perched on the top of the grain. His manner of destroying them was by dipping the large bags into a kettle of boiling water. When boiled, they had a reddish appearance, and made a fine feast for the farmer's hogs." These insects are very prevalent on our salt marshes, it will be advisable to mow the grass early, so as to secure a crop before it has suffered much loss. The time for doing this will be determined by data furnished in the foregoing pages, where it will be seen that the most destructive species come to maturity during the latter part of July. If, then, the marshes are mowed about the first of July, the locusts, being at that time small and not provided with wings, will be unable to migrate, and will consequently perish on the ground for the want of food, while a tolerable crop of hay will be secured, and the marshes will suffer less from the insects during the following summer. This, like all other preventive measures, must be generally adopted, in order to prove effectual; for it will avail a farmer but little to take preventive measures on his own land, if his neighbours, who are equally exposed and interested, neglect to do the same. Among the natural means which seem to be appointed to keep these insects in check, violent winds and storms may be mentioned, which sometimes sweep them off in great swarms, and cast them into the sea. Vast numbers are drowned by the high tides that frequently inundate our marshes. They are subject to be attacked by certain thread-like brown or blackish worms (Filaria), resembling in appearance those called horse-hair eels (Gordius). I have taken three or four of these animals out of the body of a single locust. They are also much infested by little red mites, belonging apparently to the genus Oecypt. these so much weaken the insects by sucking the juice from the bodies, as to hasten their death. Ten or a dozen of these mites will frequently be found pertinaciously adhering to the body of a locust, beneath its wing-covers and wings. A kind of sand-wasp preys upon grasshoppers, and provisions her nest with them. Many birds devour them, par-
LOOSENESS.

particularly our domestic fowls, which eat great numbers of grasshoppers, locusts, and even crickets. Young turkeys, if allowed to go at large during the summer, derive nearly the whole of their subsistence from these insects." (Harris's "Treatise on Insects."

In England, Locust is the common name of a species of insects forming a group or sub-genus of the gyllus of Linnæus. They have coloured elytra, and large wings, disposed, when at rest, in straight, fan-like folds, as in other orthoptera, and frequently exhibiting bright blue, green, or red colours. The thorax is capacious, to afford room for the powerful muscles of the wings, and is marked in many species with one or more crests, or wart-like prominences. The locusts fly by starts, but frequently rise to a considerable height. Certain species, called "migratory locusts," unite in incalculable numbers, and emigrate, resembling, in their passage through the air, a dense cloud: wherever they alight, all signs of vegetation quickly disappear, and cultivated grounds are left a desert. One species (Acridium migratorium, Latr.), occasionally commits devastations in the south of Europe and Poland; and stragglers have sometimes reached England, a circumstance which happened in 1748: but they soon perished. To our ideas of the association of insects, the swarms of locusts which have occasionally appeared in oriental countries seem almost incredible. Major Moor states that a flight which ravaged the Maharta country, and which he saw at Poonah, extended in a dense column 500 miles, and hid the sun like an eclipse. On that occasion, the natives fried and ate them. The devastation which they make is forcibly described by the prophet Joel: "The land is as the garden of Eden before them, and behind them a desolate wilderness."

LOCUST-BORER. See Borers.

LOCUST, HONEY or SWEET. See Honey Locust.

LOCUST TREE (Hymenae, from Hymen, the god of marriage; in reference to the two leaflets). The species of locust tree are highly ornamental; they delight to grow in lawn and peat, and cuttings will root in sand under a glass in heat. The young plants should be planted out in the autumn of the second year, cutting them down within three inches of the ground. They must be preserved from the attacks of hares and rabbits, which are very destructive to them. See Acacia.

LOCUST TREE CATERPILLARS. These are produced from the eggs of a butterfly belonging to a tribe at which, from their habit of flying but a short distance at a time with a jerking motion, have acquired the name of skippers (Hesperia or Hesperiana). They frequent grassy places, low bushes, and thickets. When they alight, they usually keep the hind-wings spread out horizontally, and the fore-wings partially closed, but not entirely so, as in other butterflies.

The Tityrus skipper (Eudamus tityrus), and its offspring, are thus described by Dr. Harris. "Wings brown; first pair with a transverse, square blotch, from their hind, across the middle, from a few spots towards the tip, of a honey-yellow colour; hind-wings with a short rounded tail on the hind angles, and a broad silvery band across the middle of the under-side. Expands from 2 to $\frac{1}{2}$ inches."

"This large and beautiful insect makes its appearance, from the middle of June till after the beginning of July, upon sweet-scented flowers, which it visits during the middle of the day. Its flight is vigorous and rapid, and its strength is so great that it cannot be captured without danger of its being greatly defaced in its struggles to escape. The females lay their eggs, singly, on the leaves of the common locust tree (Robinia pseudacacia), and on those of the viscid locust (Robinia viscosa), which is much cultivated here as an ornamental tree. The caterpillars are hatched in July, and when quite small conceal themselves under a fold of the edge of a leaf, which is bent over their bodies and secured by means of silken threads. When they become larger, they attach two or more leaves together, so as to form a kind of cocoon or leafy case to shelter them from the weather, and to screen them from the prying eyes of birds. The full-grown caterpillar, which attains to the length of about two inches, is of a pale green colour, transversely streaked with darker green, with a red neck, a very large head roughened with minute tubercles, slightly indented or furrowed above, and of a dull red colour, with a large yellow spot on each side of the mouth. Although there may be, and often are, many of these caterpillars on the same tree and branch, yet they all live separately within their own cases. One end of the leafy case is left open, and from this the insect comes forth to feed. They eat only, or mostly, in the night, and keep themselves closely concealed by day. These caterpillars are very cleanly in their habits, and make no dirt in their habitations, but throw it out with a sudden jerk, so that it shall fall at a considerable distance. They frequently transform to chrysalids within the same leaves which have served them for a nursery. The chrysalids are often left by the trees and construct in some secure place a cocoon of leaves or fragments of stubble, the interior of which is lined with a loose web of silk. They remain in their cocoons without further change throughout the winter, and are transformed to butterflies in the following summer. The viscid locust tree is sometimes almost completely stripped of its leaves by these insects, or presents only here and there the brown and withered remains of foliage, which has served as a temporary shelter to the caterpillars. For the modes adopted to destroy these, see Caterpillars.

LOLIIUM. See Ryegrass.

LONDON PRIDE. See Saxifrage.

LONDON ROCKET. See Hedges-Mustard.

LONG-HORNED CATTLE. A breed of neat cattle now nearly extinct, chiefly distinguished by the length of the horn, the thickness and firm texture of the hide, the length and closeness of the hair, the large size of the hoof, and the coarse, leathery thickness of the neck. See Cattle.

LOWGEOUS and Spanish-worms.

LOOSENESS. See Diarrhea, and Diseases of Cattle and Sheep.
LUCERN.

LOOSESTRIFE. (Lysimachia, from luvis, dissolution, and mache, stipe). A very pretty genus of plants, with mostly yellow flowers. All the species are of the easiest culture, and may be propagated by divisions, except L. dupia and L. Linum-stellatum, which must be increased by seeds.

Great yellow loosestrife (L. vulgaris), grows in watery, shady places, particularly the reedy margins of rivers. The root is creeping; stems 3 or 4 feet high.

Wood loosestrife, or yellow pimpernel (L. nemorum). This species, which is one of the elegant though not uncommon English plants, inhabits woods and shady, rather watery places. The shoots are creeping and decumbent, often pendant from banks and rocks.

Creeping loosestrife. Money-wort or herb twopence (L. nummularia). This is a handsome free-flowering plant, which, from its trailing habit, is well fitted for decorating rockwork. It grows wild in wet meadows, boggy pastures, and the borders of rivulets. The herbage is smooth, of a pale green; stems quite prostrate, creeping, a foot or two in length; leaves somewhat heart-shaped; flowers solitary, pale lemon-coloured, rather larger than the last species; stamens glandular. It flowers from June to August, and affords a wholesome food for cattle, especially sheep. On account of its sub-acid and mildly astringent properties, it is considered as one of the most efficacious vulnerary herbs. Bechaglet asserts that the leaves and flowers of this plant, steeped in oil, furnish an excellent remedy for destroying the worms and insects infesting the floors of granaries.

LOPPED MILK. Provincially, milk that has stood till it has become sour and curdled.

LOPPING. The operation of cutting off the lateral or other branches of trees. See Pruning and Plantations.

LOTUS. See Birds'-foot Trefoil.

LOUSINESS. In farriery, an affection of the skin, arising in cattle or other animals, from the irritation of lice or other animalculae, which may be distinguished by the naked eye. Most animals, and even insects, are subject to this annoyance. Lousiness in live-stock is produced by neglect and low keep. The best remedy is more attention to cleanliness, with better food. The lice may be killed by a dressing applied with a brush to the chief affected parts, composed of four ounces of black sulphur, mixed with a pint of train oil, or a small portion of weak mercurial ointment.

LOUSE-WORT. See Rattle.

LOVAGE (Ligusticum, so named because some of the species grow in Liguria). A genus of hardy, herbaceous, and biennial, aromatic plants, which, as flowers, are not worth cultivating. They will grow in any soil, and are increased by seeds.

The Scottish lovage or sea parsley (L. Scoticum), grows on rocks, cliffs, and the sea-coasts of Scotland and the north of England, on a stem a foot high; root tap-shaped, warm and pungent; leaves stalked, twice ternate; footstalks bordered with a purplish compressed membrane at the base; umbels smooth, not very large, bearing white flowers, with a red
dish tinge; these appear in July. This herb is eaten by the natives of Scotland and its islands, either crude as a salad, or boiled as greens. The flavour is highly acrid, and, though aromatic, stomachic, and perhaps not unwholesome, yet very nauseous to those who are unaccustomed to such food. It is relished by horses, sheep, and goats, but refused by cows. The stem yields English opo-nax. The roots are reputed to be carminative, and an infusion of the leaves affords a good physic for calves.

Cornish lovage (L. cornubense). This is a less common species, found sometimes in bushy fields in Cornwall. The root is spindleshaped, and is evacuated at the top, descending to a great depth; when wounded, discharging a yellow, resinous juice. The stem is two or three feet high, solitary, erect, branched, striated, purple at the base. Leaves deep green; the radicles once, twice, or thrice pinnate, rough-edged, cut; stem-leaves ternate, lanceolate, entire. Ribs of the seeds blunted.

LOVE-APPLE. See Tomato.

LOVE-GRASS (Eragrostis, from eros, love, and agro-tis, grass; in allusion to the beautiful dancing spikelets, whence also the English name). It is a pretty species of foreign grass, growing in gardens about a foot high in any common soil.

LOVE-LIES-BLEEDING. The common name of a species of amaranth (A. caudatus).

LOY. A very long, narrow spade, peculiar to the province of Connacht and some parts of Munster, and only suited to stony land, where a wider edge could not so easily penetrate. (M. Doyle's Pract. Husb.)

LUCAMA. A species of fruit growing in Chili, in size and flavour resembling a peach. (Ed. Evag.)

LUCERN, or PURPLE MEDICK GRASS (Medicago sativa, Pl. 8, h). An artificial grass, called by the French grand trefle, which affords perhaps a larger produce of fodder than any other species of artificial grass. Although found growing wild in hedges, pastures, and the borders of fields in dry, calcareous soils, yet it can scarcely be considered a native of England. The stems are erect or somewhat reclining, about two feet high. Leaflets oblong, inclining to wedge-shaped; more or less acute, sharply serrated towards the end, clothed with close, silky hairs on both sides. The flowers are in clusters, many, bluish purple, with a small bristle-like bracte under each partial stalk. The legumes are spiral, with rarely more than two or three turns; they are silky when young.

This valuable grass is best cultivated on a good, dry, warm, barley soil; it is not adapted for heavy or wet soils. Being a deep-rooted plant, it requires a soil in which its roots can penetrate to a considerable depth. It should be sown on land perfectly clean, in the months of March or April, with (or best without) a crop of grain. It is only adapted to the southern parts of England, since extreme cold destroys it. It is best sown alone in drills, at a distance of 12 to 15 inches; the quantity of seed is from 10 to 16 lbs. per acre. Any vacancies in the drills may in the autumn or following spring be made good by transplanting.

LOOSESTRIFE.

By careful weeding and hoeing, and frequent top-dressings (for which purpose gypsum, calcareous matters, ashes, &c., are excellent), the profitable duration of this crop may be extended eight or ten years, giving during that period, on an average, three or four cuttings per annum: the first of which, in favourable seasons, will be as early as the middle of April. It should always be cut before the appearance of the blossom. It may be made into hay, although much better adapted for soilion. An acre will, upon an average, produce fodder for two horses, from the first cutting to October. It is admirably adapted for milch cows, and is, indeed, one of the best livefodder for dairy cows. Lucern, as observed by Mr. Loudon (Encyclo. of Gard.) "is highly extolled by Roman writers; it is also of great antiquity in Spain, Italy, and the south of France; is much grown in Persia and Peru, and mown in both countries all the year round. It is mentioned by Hartlip, Blythe, and other early writers, and was tried by Lisle; but it excited little attention till after the publication of Harte's Essays in 1757 (1764). Mr. Towers, speaking of lucern, calls it "the plant of plants." 'If the grown lucern be cut (as it always should be) during four or five years, and previously I had witnessed its great success and extensive culture in the Isle of Thanet!' "

In cutting for a cow, it will always be advisable to take the plant when it is tender and juicy; and such it will be when about a foot high. I have thus cut my plot over six times after the first year; but they who leave the plants to grow two feet high, will find the stems rigid, fibrous, and less juicy; and that what they gain in bulk will be lost in time and quality. Lucern is known to produce much milk, perhaps more than any other of the artificial grasses (Leguminosae); but some complain that it communicates an austere or bitter flavour. I doubt the fact, but would always recommend that it be not given quite fresh to a cow, particularly at an early period after calving.

If the required quantity be cut over night, it will be fit for the stall by ten o'clock of the following morning, and again the afternoon meal should be exposed to the sun for 2 or 3 hours before it is used. "As to the trouble in managing an established crop, it is really nothing. Though I allow it is good to hoe twice during the summer, as the plot is cut piece by piece, yet one general fork-digging at that period of early spring when the plants exhibit the first symptom of growth, so as to remove every weed, and loosen the surface of the soil, will be amply sufficient to secure the safety and full development of the herb. Upon the whole, lucern is a plant of the utmost value; for if the seed be good, the ground rich and in heart, and rendered deep in the first instance by a thorough trenching, the young plants start into lively growth, attain strength in the shortest possible time, and yield a bulk of luxuriant herbage that cannot be surpassed. If the plant require four years to attain its maximum of power, it is still a giant even from its infancy, advancing from strength to strength. A well prepared field, if kept clean by the forking, will remain productive for more than ten years; but as a change of crop always promotes abundance, it would be advisable to prepare a succession every six years." (Quart. Journ. of Agr. vol. ix. p. 96.)

About 80 pounds weight per day of 24 hours is sufficient for the largest cow, and half this, with corn, for a horse. No stock should at any time be permitted to graze upon it. There are several varieties of lucern, with violet, yellow, and variegated flowers, which are supposed to be only a variation of the same plant, arising accidentally from the seed. However, neither the yellow nor the variegated is ever so strong as the purple flowered, and the success of the lucern for the cultivator. Lucern may be estimated as the choicest of all fodder, because it lasts many years; will bear cutting down four, five, or six times a year; enriches the land on which it grows; will fatten cattle, and often proves a remedy for the diseased.

Those who wish to acquire more minute information relative to the management of lucern, may consult the Rev. Walter Harte's learned Essays on Husbandry; Rocque's Practical Treatise on Cultivating Lucern Grass; and British Husbandry, vol. ii. p. 307.

Lucern is sometimes called French clover, and has been introduced into the United States as a new plant under the name of Brazilian clover, called in South America Alfalfa, the Spanish name for lucern. It is a kind of grass which in some situations has been cultivated with great success in the United States. It is not, strictly speaking, a clover, though in some respects similar. It is a perennial, and in favourable soils the roots are said to live and flourish a great many years. Its advantages consist in affording a greater amount of foliage for any kind of stock than any other plant, with the same labour and expense. "Several years since, while residing in the State of Maine, we made several experiments with lucern, which, although some of them terminated unfavourably, satisfied us that the most favourable soil for it is a deep, sandy loam; and as the alluvial soils on this river are generally of this character, we last spring resolved on giving it a fair trial here. We procured from Boston a small quantity of seed, which was sown on the 'bottom' the last week in May. As the soil had been badly managed for several years previous, we had feared that the great growth of weeds would check and smother the lucerne, and to guard against this, and get a chance to exterminate the weeds, we sowed the seed in drills. This was done very expeditiously and exactly with one of Ruggles, Nourse, and Mason's seed sowers. "In the latter part of the month of July, the lucern had reached the height of 18 inches on an average, and had considerably blossomed. We cut it and fed it green, partly to hogs and partly to milk cows,—both ate it voraciously. In just four weeks from the time it was cut, it had again grown to nearly the same height as before, and was cut a second time,—and on the first of November it was cut a third time,—the crop being heavier than either of the preceding. A piece of common red clover (very flourishing) immediately adjoining, the soil
M. MADDER.

precisely similar, did not yield nearly half as much, in proportion, as the lucern.

"We have no doubt that it may be cut five times another year, and will yield at the rate of a ton and a half of hay to the acre at each cutting." (Culpeper's Herbal.)

Upon analysis, the stems, &c., of lucern are found to contain gypsum, and this furnishes a satisfactory explanation of the fact, that plaster of Paris applied to the crop generally causes it to grow luxuriantly. Live-stock prefer plustered lucern to any other herbage.

LUG. A long measure of land, the same with a pole or perch, 16½ feet. In Gloucestershire it however signifies a land measure of 6 yards, or a rod, pole, or perch of 6 yards. It is a measure by which ditching and other similar operations are performed there. This term is likewise applied to the stick by which the work is measured. It is sometimes called log.

LUNGWORT (Pulmonaria; it derives both its common and generic names from its supposed medical properties in diseases of the lungs). The species of this genus are very pretty flowering plants, well adapted for ornamenting the front of shrubberies. They thrive in any common soil, and are readily increased by division.

LUPINE (Lupinus, from lupus, a wolf; in allusion to its exhausting or devouring the soil). The species of this genus are among the most beautiful of border flowers. They will flourish in almost any soil, but a rich loam suits them best. They perfect their seeds very freely, from which young plants are easily obtained. In agriculture, the lupine is cultivated principally for being turned in as manure. (See Green Manures.) This plant requires but little trouble or labour in its cultivation, as it will thrive in any soil except the bad chalks, and such as are very wet. It will even grow well on poor, hungry, worn-out land, especially if it be dry and sandy. When sown in February or March, after a single very shallow ploughing, and slightly harrowed in, it will blossom two or three times between May and August, and prove an excellent enricher of the ground when ploughed in just after its second blooming. The best time for mowing this sort of crop is after a shower of rain, as the seeds drop easily out of their pods when they are gathered too dry. They must, however, be laid up very dry, or worms soon breed in them. They are inferior to many other plants for the above use.

LUPINE, WILD. Mr. Nuttall has enumerated seven species of the lupine genus found in different parts of the United States and territories. Dr. Darlington has described common wild lupine, an ornamental plant, found in the woodlands and hills of the Middle States. The root is perennial and creeping; stem 9 to 18 inches high, herbaceous, erect, or decumbent, somewhat branching, striated, angular, and pubescent. Flower purplish-blue, with violet shades. Legume or pod about an inch and a half long and one-third of an inch wide, somewhat flattened, hairy, and of a dark tawny colour. Seed obovoid, slightly compressed, smooth, speckled or variegated with whitish and dark brown.

LURCHER. A sort of hunting dog, much like a mongrel greyhound, with pricked ears, a shaggy coat, and generally of a yellowish-white colour. It is a very swift runner, so that, if it gets between the burrows and the rabbits, it seldom misses taking them; and this is its common practice in hunting.

LURID. In botany, signifies a colour between a purple, yellow, and gray.

LYME-GRASS. See Lymnis.

LYCHNIS (from lykeia, a lamp; on account of the brilliancy of the flowers of most of the species). This is an extremely beautiful genus of plants, well meriting extensive cultivation for the brilliancy of their flowers. A red variety is often cultivated in a double state, and called bachelor's buttons; a name, however, which is more frequently given to a species of ranunculus.

LYNCHET. A country term applied to the stripes or grassy partitions in arable fields in England, but mostly to such as are in the state of commongage.

LYNCH-PIN, or LINC-PIN. The small pin, in carts or other carriages, that is put through the ends of the axle-trees, to confine the wheels on them.

LYRAPE. In botany, leaves are called lyrate which are shaped in the form of a lyre.

MACERATION. The act of softening any substance by steeping it in cold water or other liquid.

MACHINE (Gr.). In a general sense this word signifies any thing which serves to increase or regulate the effect of a given force. Machines are either simple or compound. The simple machines are usually reckoned six in number; namely, the lever, the wheel and axle, the pulley, the wedge, the screw, and the funicular or rope machine. Compound machines are formed by combining two or more simple machines.

In husbandry, the term is applied to various implements, such as the Drill, Thrashing, and Winnowing Machines, the Steam Engine, &c. See these respective terms.

MADDER (Rubia, from ruber, red, in allusion to the colour of the roots). This is a genus of interesting plants; any common garden soil suits them, and they are easily increased by seeds or divisions of the roots. The root of R. tinctorum is one of the most valuable dyes with which we are acquainted, and is a very important article of commerce. The plant is herbaceous, several stems rising from the same root; tetragonal, with hooked prickles at the angles. The leaves are four or six in a whorl, lanceolate, with the midrib on the under disk, and the margins acutely toothed. The flowers are small, yellow, supported on axillary trichotomous peduncles.

The dried root of the madder is long, cylindrical, the thickness of a goose quill, branched and covered with a reddish ciliate, which, as well as the bark, is easily separated; the odour is feeble, and the taste bitter and astrigent. It is imported entire from Smyrna and the Levant, but in coarse powder from Holland and France.

789
The cultivation of madder has been attempted in England, and it is still carried on to a limited extent in some districts, but without any very great success or beneficial results, owing to the low price at which it can be procured from the Dutch growers and from Turkey.

Dyers' madder is an agricultural product which has been very successfully and profitably cultivated in the United States. The root of the plant is composed of many long, thick, succulent fibres, almost as large as a man's little finger; these are joined at the top in a head, like the roots of asparagus, and strike very deep into the ground, being sometimes more than three feet in length. From the upper part or head of the root come out many side-roots, which extend just under the surface of the ground to a great distance, whereby it propagates very fast; for these send up a great number of shoots, which, if carefully taken off in the spring, soon after they are above ground, become so many plants. The root is perenni- nal, although the stalk dies down every winter. The soil most suited to the cultivation of madder are deep, fertile, sandy loam, not retentive of moisture, and having a considerable portion of vegetable matter in their composition. It may also be grown on the more light descriptions of soil, of sufficient depth, and in a proper state of fertility. The preparation of the soil may either consist in trench ploughings, lengthwise and across, with pronged stirrings, so as to bring it to a fine tilth; or, what will often be found preferable, by one trenching, two feet deep, by manual labour. The sets or plants are best obtained from the runners, or surface-roots of the old plants. These being taken up, are to be cut into lengths of from six to twelve inches, according to the scarcity or abundance of runners. Sets of one inch will grow if they have an eye or bud, and some fibres; but their progress will be injuriously slow for want of maternal nourishment. Sets may also be procured by sowing the seeds in fine, light earth, a year before they are wanted, and then transplanting them; or sets of an inch may be planted one year in a garden, and then, when they are sufficiently grown, be transplanted to the field plantation. The season of planting is commonly May or June, and the manner is generally in rows nine or ten inches asunder, and five or six inches apart in the rows. Some plant promiscuously in beds with intervals between, out of which earth is thrown in the lazy-bend manner of growing potatoes; but this is unnecessary, as it is not the surface, but the descending roots which are used by the dyer. The operation of planting is generally performed by three dibbers, but some lay-plant them by the aid of the plough. By this mode the ground is ploughed over with a shallow furrow, and in the course of the operation the sets are deposited in each furrow, leaning on and pressed against the furrow-slice. This, however, is a bad mode, as there is no opportunity of firming the plants at the roots, and as some of the sets are apt to be buried, and others not sufficiently covered. The after-culture consists in hoeing and weeding with stirring by pronged hoes, either of the horse or hand kind. Some earth up, but this is unnecessary, and even injurious, as tearing the surface-roots. The madder crop is taken at the end of the third autumn after planting, and generally in the month of October. By far the best mode is that of trenching over the ground, which not only clears it effectually, but fits it at once for another crop. Where madder, however, has been grown on land prepared by the plough, that implement may be used in removing it. Previously to trenching, the haulm may be cleared off with an old seythe, and carted to the farmery to be used as litter to spread in the straw-yards. Drying the roots is the next process, and, in very fine seasons, may sometimes be done on the soil, by simply spreading the plants as they are taken up; but in most seasons they require to be dried on a kiln, like that used for malt or hops. They are dried till they become brittle, and then packed up in bags for sale to the dyer. The produce from the root of this plant is different according to the difference of the soil, but mostly from ten to fifteen or twenty cwt., where they are suitable to its cultivation. In judging of the quality of madder-roots, the best is that which, on the dress of the soil, has a bright-red or purplish appearance, without any yellow cast being exhibited. The use of madder-roots is chiefly in dyeing and calico-printing. The haulm which accumulates on the surface of the field, in the course of three years, may be carted to the farm-yard, and fermented along with horse-dung. It has the singular property of dyeing the horns of the animals who eat it of a red colour. Madder-seed in abundance may be collected from the plants in the September of the second and third years, but it is never so propagated. Madder is sometimes blighted, but in general it has few diseases. (London's Ency. Agr.)

In the Netherlands, where every agricultural process is conducted with such skill and success, madder sometimes forms a crop. It is always put upon land of the best quality, and with plenty of manure. At the end of April or May, accordingly as the young plants are large enough to be transplanted, the land must be ploughed in beds of two feet and two feet and a half apart; the beds are then to be harrowed by side and raked, and the young suckers of the roots or plants are to be put down in rows, at intervals of a foot or a foot and a half, and six or eight inches distant in the row. During the entire summer the land should be frequently stirred, and kept free from weeds. In the month of November, when the leaves are faded, the plants are covered with two inches of earth by a plough, having the point of the coulter a little raised or rounded, so as not to injure the young plants. In the following spring, when the young shoots are four or five inches long, they are gathered or torn off, and planted in new beds, in the same manner as has been pointed out above; and then, in the month of September or October, after the faded leaves have been removed, the old roots are taken up. The madder thus taken up should be deposited under cover, to protect it from the rain; and, after ten or twelve days, placed in an oven moderately heated. When dried sufficiently, it is gently beaten with a flail, to get rid of any clay that may adhere to the plants; and, by means of a small windmill, is ground and sifted.
MADDER.

It is then replaced in the oven for a short time, and when taken out is spread upon a hair-cloth to cool; after which it is ground and cleaned once more. It is then carried to a bruising-mill, and reduced to a fine powder, after which it is packed in casks or barrels for market.

Several interesting communications upon the subject of the culture of madder in the Northern and Eastern States, may be found in the agricultural periodicals. (See American Farmer, New England Farmer, Cultivator, &c.)

Mr. Russel Bronson, of Birmingham, Huron county, Ohio, a successful cultivator of madder, has published a communication upon this subject, which contains the following information:

A location facing the south or south-east is to be preferred. A sandy loam not over stiff and heavy, or light and sandy, or a good brown, deep, rich upland loam, free from foul grass, weeds, stones, or stumps of trees. Where a crop of potatoes, peas, or beans has been cultivated during the season, plough deeply twice, once in September and once in October, and if rather stiff let it lie after the plough until spring. When the spring opens, and the ground has become dry and warm (say in Tennessee, 1st of April, Ohio, 15th, and New York, 25th to 1st of May—I speak of the spring of 1836), plough again deep, the deeper the better, then harrow well and strike it into ridges with a one-horse plough, 3 feet wide and 4 feet vacant, or making a ridge once in 7 feet, raising it, if on rather moist ground, 3 or 10 inches, and dry land 6 or eight from the natural level; then with a light harrow, level and shape the ridges like a well-fored bed of beets, &c.

We will suppose you intend to plant one acre of ground, and that you have purchased 8 bushels of tap roots in the fall and buried them like potatoes on your premises—count the ridges on your acre, and take out of the ground 1 bushel of roots and plant it on one-eighth of your ridges; you will then be able to ascertain how to plant your roots for the remainder. The following is the number of planting, sowing, &c., when the quantities of ground do not exceed 3 or 4 acres. One person on each side of the ridge to make the holes (plant 4 inches below the surface of the bed, or thereabouts, when covered) one on each side to drop the roots, and 1 on each side to cover, pressing the hill in the manner of planting corn; or, 3 persons may be placed on one side, as the case may be, whether you have 1 or more acres to plant. Let the owner be the dropper of roots, and his most thorough assistants behind him. Make the holes from 12 to 18 inches apart, and about 6 inches from the edge of the ridge. As the plants are supposed to have been purchased in the fall, the roots may have thrown out sprouts, and possibly have leaved. In this case, in dropping and covering, you will leave the most prominent sprout or sprouts a little out of the ground, as where a plant has leaved, it ought not to be smothered.

When the plant gets up 3 or 4 inches, weed the hill, or plough with hill horse, between the ridges or beds, but not on them; this will take place 2 or 3 weeks after planting. When up 12 or 15 inches, many of the tops will fall; assist them with 10 foot poles crossing the bed, covering them with a shovel or garden rake, throwing the soil from between the ridges. After loosening with the one-horse plough, you will with a shovel scatter the earth between the stalls rather than throw it into heaps; of course we wish to keep the stalls separate, as they are to form new and important roots in the centre of the beds. About the 20th of June, you may plough between the beds, and scatter more earth on the fresh tops (all but the ends), and when you get through, you may plant potatoes between the beds if you please. I do not recommend it, if you have plenty of land, although I raised 1076 bushels of pink eyes on 8 acres the first year, and 60 bushels of corn. If your land is perfectly clear of weeds, you are through with your labour on the madder crop for this year, except in latitudes where there is not much snow, and considerable frost; in this case cover in October 2 inches or thereabout. In the second year, same operations in weeding, &c., but no crop through; cover once in June. Third year, weed only. Fourth year, weed in the spring, if a weedy piece of ground.

Begin to plough out the roots in Tennessee, [3 years old] 1st September. Ohio, [4 years] same time. New York, 15th or 20th, after cutting off the tops with a sharp hoe. In ploughing out the roots use a heavy span of horses, and a large plough. We ought to choose a soil neither too wet nor too dry, too stiff or light. Shake the dirt from the roots, and rinse or wash, as the soil may be stiff or light; dry in a common hop kiln, or grind them in a mill similar to Wilson's Patent Coffee Mill; this mill weighs from 1 to 2 pounds. The madder mill may be from 60 to 80 pounds weight. Grind coarse, and fan in a fanning mill; then grind again for market. The profit of this crop is immense; the exhaustion of soil trifling, and glutting the market out of the question.

Madder is used in whole, or part, for the following colours on wool, both in England, France, and America, viz. true red, buff, olive, olive-brown, and many others; finally it produces one of the most beautiful, durable, and healthy colours that is at this time dyed; as for calico printers, it enters greatly into their dyes. (Ann. Farmer's Instructor.)

As the tops of the plants spread very much, some advise placing them in hills somewhat like Indian corn, 4 and even 6 feet apart each way, and 2 plants in each hill.

Rules have been laid down by Miller, On the Culture and Manufacture of Madder, for managing the crop, separating and planting the shoots, gathering and drying the roots, and for pounding, casking, and preparing them for sale, according to the most approved English practice. The reader who wishes to attempt the cultivation of madder, will also find some useful hints in the Penny Cyclopaedia, vol. xiv. p. 260, and Brit. Husbandry, vol. ii. p. 332; Beckmann's Hist. of Invent. vol. iii.; and The Complete Farmer, vol. ii. The haum of madder, though sometimes employed in the feeding of cattle, is not very generally used for that purpose, for it tinged the milk, the urine, the sweat, and even the bones of the animals fed.

741
MADDER, THE FIELD.

MAGNOLIA.

upon it. The average annual imports into England are about 180,000 cwt. of madder-root and ground madder. The duty chargeable on consumption is 2s. per cwt. on the prepared madder, and 6d. per cwt. on the roots. Madder was formerly used as a medicine in jaundice; but it possesses no properties which entitle it to be regarded as a remedy in any disease.

MADDER, THE FIELD. See Sheerardia.

MADDER, WILD (Rubia peregrina). This is an indigenous species which is found growing in thickets and on stony or sandy ground in the west of Britain. The root is creeping, fleshy, and tender, of a tawny red, useful in dyeing, but is very inferior to the cultivated madder. The stem is branched, spreading, square, perennial, partly shrubby, its angles rough with hooked prickles, as are the edges and midrib of the broad, shining, dark, evergreen, elliptical leaves, which are four or more in a whorl. The flowers, which appear from July to August, are yellowish green, five-cleft, in forked terminal panicles. The berries are juicy, in pairs, black and shining.

This plant known in the United States by the name of wild madder, is the Galium tinctorium of botanists, or Dyers' Goose-grass. It is a perennial, found in moist woodlands and low grounds, flowering in July and August. The stems rise 12 to 18 inches high, generally erect, and branched. The flowers are white. Pursh says, the North American Indians use this plant for dyeing their porcupine quills, leather, leathers, and other ornaments, of a beautiful red colour.

MAD. A plant, said to be a new genus, growing in Chili. The seeds furnish an oil which has been preferred to any of the French olive oils. (Ed. Encyc.)

MAGGOT. See Fly in Sheep.

MAGNESIA (Fr. Magnésie; It. Magnesia). One of the primitive earths having a metallic basis. It is an oxide of magnesia. It is sometimes found native, nearly in a state of purity; but is generally prepared by calcining the common carbonate of magnesia. It is inodorous and insipid, in the form of a very light, white, soft powder, having a specific gravity of 2-3. It turns to green the more delicate vegetable blues, and requires for its solution 2000 parts of water at 60°. It is found combined with carbonic and other acids in plants.

It is a useful purgative in an acid state of the stomach; and taken daily, with short intervals intervening, it is a useful preventive of red gravel or lithic acid deposits in the kidneys.

As all kinds of grain are found to contain a certain proportion of phosphate of magnesia, the presence of this substance cannot be supposed to be merely accidental. Hence the inference that magnesia must be serviceable as a fertilizer. It enters largely into the composition of limestone, of which it constitutes sometimes almost one half. The magnesian lime has been long applied with the greatest advantage in Pennsylvania and elsewhere. In other places the admixture of magnesia with lime has been considered as producing sterility rather than benefit. See Earths, Lime.

When magnesian lime has been applied to grass in quantity, so as to have produced unfavourable effects upon vegetation, it has been found that after two years its hurtful influence has become exhausted. Great quantities of it are annually taken from Sunderland to Scotland by the Fife shires farmers, and applied by them as a manure, with the greatest benefits, even in preference to other kinds of lime. The same preference is shown by many Pennsylvania farmers, for magnesian lime. Experience has shown that it has been unfairly denounced by Sir H. Davy and Mr. Tennent, as a sterilizer.

MAGNOLIA (named by Plumer after Pierre Magnol, prefect of the botanic garden at Montpellier, and author of several works on plants; he died in 1715). This is a genus of very elegant and showy plants when in flower, and well worthy of extensive cultivation. The hardy kinds, being remarkably handsome shrubs, should be planted in conspicuous situations where they will flower profusely when they attain a good size. M. glaucus, and some others, grow best in a peat soil in a moist situation. They are generally increased by layers put down in spring or autumn, or by seeds; when the layers are first taken off, they should be potted in a mixture of loam and peat, and placed in a close frame till they have taken fresh root. None of the leaves should be taken off or shortened, nor any shoots be cut off, as they will not succeed so well; for the more branches and leaves are on the sooner they will strike fresh root. The Chinese kinds are often inarched or budded on M. obvoluta, one of the readiest growing kinds, which takes readily. The seeds of the North American species are generally taken from fruiting trees, and should be sown as soon as possible after their arrival, in pots of light rich earth, covering them half an inch deep; these may be placed either in a hotbed or a warm sheltered situation, or they may be sown in the open ground, and when the plants are of sufficient size, they should be planted out singly into pots, and sheltered till they have taken fresh root; they should also be protected from the frost by a frame for two or three successive winters, giving them the benefit of the open air in mild weather.

The Genus Magnolia contains about fifteen species, almost exactly divided between China and the United States. There is also one species in tropical America. The trees are distinguished by a bark more or less camphorated and aromatic; the leaves are alternate, entire, and large, partly ovate, and in some species auriculate at the base. The flowers are large, fragrant, white, yellowish, or brown; the seeds scarlet or fuscous.

The following summary of the American species is from Nuttall's Genera of North American Plants.

1. M. grandiflora. The most magnificent tree of the southern states, the trunk often presenting a living column of 80 or 90 feet elevation, almost unobstructed by branches, and terminated by a spreading top of the deepest perennial verdure. 2. Glauca. 3. Magnolia macrophylla. This small pyramidal tree produces the largest leaves and flowers of any other North American plant. The limits of this interesting species appear to be extremely local. First
MAIDEN HAIR.

observed it in Tennessee near the banks of Cumberland river, but of very small size. In the Southern States it is not at present known to the most assiduous collectors in any other spot than a single narrow tract of about 2 miles in length, 12 miles southeast of Lincolnton (Lincoln county, North Carolina). These limits I have carefully examined and found them inviable. A. Tripetala (Umbrella-tree).

MAIDEN HAIR (Adiantum, derived from adiantum in water, for it always remains dry). These are elegant species of ferns with beautiful leaves. They succeed well in a mixture of loam and peat; but they appear to thrive best if planted in loose rock-work where there is a good drainage, and may be increased by divisions or by seeds. A. Capillus seneris is the only indigenous species. It is often supposed that the French syrup called capillaire is made from this plant; but it is from the Adiantum pedatum, a plant growing in the south of France. Our adiantum, however, would make as useful a syrup. It is a refreshing beverage, mixed with water, in fevers. See Fern.

MAIZE, MAIZ, or INDIAN CORN (Zea mays, from zeo, to live, in reference to the nutritive properties of the plants belonging to the genus). A gigantic herbaceous annual plant, belonging to the family of grasses cultivated for their grains (Graminac). Although, in Europe, the word maize is synonymous with wheat, rye, and barley, usually in the United States the term, used alone, applies exclusively to maize.

In one of the counties of Pennsylvania, a man having been indicted for stealing so many bushels of "corn," exception was taken by his counsel, that this was not a perfect description of Indian corn; the exception, however, was overruled by the court, who thus decided that "corn" was the established name for Indian corn.

Maize is the crop, of all others, best adapted to the climate of the United States, where it is cultivated, on every variety of soil, from one extremity of the Union to the other. It constitutes the main stay of the cereal farmer, most depended upon to furnish food and provender for man and beast. The crop raised in the United States in 1839, has been estimated at nearly 400,000,000 of bushels. That of 1842 was much greater. Supposing it to have been 500,000,000, this at an average price of only 40 cents per bushel, would make the total value of the crop no less than 200,000,000 of dollars, which is considerably more than double the value of the wheat crop estimated at $1 per bushel. The article on Agriculture will show the states and districts where the largest proportion of this grain is produced. The amount raised annually, increases in rapid progression.

Although America is doubtless the native country of a plant so important to her interests; still this has been a disputed point. Fuels very early maintained that it came from the East; and Mathioli affirmed it from America. Bentham and Gregory have presented fresh arguments in favour of its Eastern origin. Among them is the name by which it has long been known in Europe: Bilde de Turquie; and varieties, it is said, have been brought from the Isle of France, or from China. Moreau de Jonnes, on the contrary, has recently maintained, in a memoir read before the Academy of Science, that its origin was in America. The name Bilde de Turquie no more proves it to be of Turkish origin, than the name of the Italian Poplar or Irish potato proves that the tree and the plant grew wild in Italy and Ireland. It can only signify that it spread from Turkey into the neighbouring countries. Its general cultivation in Southern Europe, and the production of some new varieties, proves nothing with regard to the country of the species. In favour of its American origin, is the fact that it was found in a state of cultivation in every place where the first navigators landed. In Mexico, according to Hernandez; and in Brazil, according to Zer; and that in the various countries it had proper names, such as Maize, Fioall, &c.; whilst, in the Old World, its names were either all of American origin, or from the neighbouring region, whence it was derived. Immediately after the discovery of America, it was spread rapidly in the Old World, and soon became common, a fact not reconcilable with the idea of its former existence there. To these proofs, Aug. de Saint-Hilaire has added another. He has received from M. de Larrañaga, of Monte Video, a new variety of maize, distinguished by the name of Neorac, that it will be noticed, that the grains naked, they are entirely covered by the glumes. This variety is from Paraguay, where it is cultivated by the Guaycurus Indians, a people in the lowest scale of civilization; and where, according to the direct testimony of one of them, it grows in the humid forests as a native production.

The early authors who have written about America, with few if any exceptions, mention maize as an indigenous grain. Thus Acoste, in his Natural History of the West Indies, calls it "Indian wheat, to make bread of," and says "that it was the only grain found, in the West Indies by the Europeans.—that it grows upon a long reed with large grains, and sometimes two ears on a reed, on one of which 700 grains have been told—that they sow it grain by grain and not scattering, as is done with wheat; and it requires a hot and moist soil. There are two sorts of it" (says our author), "one large and substantial, the other small and dry, which they call 'moroche.' The leaves of it and also the reed are very good._Dollars, and dress it several as well as straw. The grain is better for beasts than barley, but they must drink before they eat it; for if they drink after it, it swells and gives them pain. The Indian eat it hot, boiled, and call it..."
MAIZE.

...and sometimes toasted. There is a sort of it large and round, which the Spaniards eat toasted; they also grind it and make cakes, which they eat hot; and these, in some places, they call maize. They also make bread, to keep, and sweet cakes of it."

As Acoste died in 1600, at Salamanca, in his 60th year, this must be regarded as very early testimony upon the subject. He surely would not have been so very particular in his description of this grain had it been previously known in Europe. Indeed entire ears of Indian corn have been found enclosed in Peruvian and Mexican mummies, preserved long before the discovery of America.

It is probable that some inferior species of the genus to which maize belongs, have been found in Guinea, Turkey, and other portions of the Old World; but that the kinds now so highly valued and generally cultivated were of American origin, there can be no doubt, both from the strongest negative and positive evidence. maize is now extensively cultivated in Asia and Africa. In Europe, it is only in the extreme southern parts, France, Spain, and Italy, that the crop can be raised so as to be profitable.

Varieties of Indian Corn. The varieties of corn cultivated in the United States are very numerous. A list embracing many of these has been furnished by P. A. Brown, Esq., in an interesting Essay on Indian corn. (See Farmer's Cabinet, vol. ii.) The following varieties, distinguished by peculiar characteristics of the grain, cob, &c., are included in Mr. Brown's enumeration. It is an interesting fact, that the rows of grains on a cob, however numerous or limited, always present even numbers.

Yellow Corn. No. 1. The yellow gourdseeds, so called from the resemblance of its long, narrow grains to the seed of the gourd. This has 24, and occasionally even more rows. Mr. Brown makes 7 varieties of this according to the number of rows regulated by admixture with other kinds of corn. No. 8. The genuine King Philip corn, so called from the celebrated chief of the Wampanoags. It has 8 rows, the lowest number found on any kind of Indian corn. It is a hardy plant, the seed of which was originally obtained from the Northern Indians. No. 9. The Sion or yellow-flint corn with 12 rows, derived from the Sioux tribe of Indians which formerly resided in Canada. No. 10. The Sion variety grown in Pennsylvania. No. 11. The Sioux and gourdseeds mixed—16 rows.

White Indian Corn, a division in which Mr. Brown includes the white flint, white flour-corn, and white sugar, or sweet corn. He has omitted the white gourdeed, which is by far the most common corn raised in the South, where it is sometimes found with from 24 to 36 rows of grains upon the ear. No. 12. Genuine white-flint, 12 row corn raised in Virginia. No. 13. White-flint,—10 rows. No. 14. Early white flint, and white flour corn.—12 rows. No. 15. Peruvian corn,—8 rows. No. 16. Pennsylvania, 8 rows,—called in Maryland, Smith's early white. No. 17. New Jersey—8 rows. No. 18. New York, 10 rows, and Mandan Indian corn. No. 19. Mandan corn, and white sugar corn. No. 20. Early sugar corn, with shrunken grains and 12 rows.

Hametite, or Blood-red Indian Corn. 21. Common sized hametite, with 12 rows and red cob. 22. The red cob with white grains. 23. Red cob with yellow grains. 24. Red cob with brown grains. 25. Red cob, with white gourdeed. 26. Red cob with gourdseeds and yellow flint. 27. White cob with red grain. 28. Speckled red and yellow grains on a white cob. 29. The same on a red cob. 30. The dwarf hametite, commonly called Guinea corn. 31. Blue corn, with 10 rows. 32. Texas corn, which which is much longer than most other kinds, in its dwarf or tunic, the whole ear being also enveloped in a husk. 33. Mexican corn, found in the envelope of a mummy. 34. Corn raised in England by William Cobbett. 35. The celebrated Dutton flint corn.

The remarks of the late John Lorain, in his Practice of Husbandry, convey so much information relative to the kinds of corn chiefly cultivated in the United States, the various merits of each kind, and the modes of culture, that we cannot refrain from giving a condensation of them.

There are five original corns in use for field planting, in the Middle and Southern States, to wit: the big white and yellow, the little white and yellow, and the white Virginia gourdseeds. The cobs of the two first mentioned are thick and long, the grains are much wider than deep, and where the rows of grains meet and unite with each other, their sides fall off almost to nothing. This gives the outside ends of the grain a circular form; and communicates to the ear an appearance somewhat like a fluted column. This formation greatly diminishes the size of the ends and sides of the grains; and is the cause of the hard flinty corns being less productive, in proportion to the length and thickness of their cobs, than the gourdseeds. As little white and yellow are formed much in the same way, and the cobs considerably smaller, they are still less productive than the big white and yellow, but ripen earlier.

The grain of those four flinty kinds are very firm, and without indentation in their outside ends. The two smaller kinds seem to be still more hard and solid than the larger; and the colour of the little yellow deeper than that of the big.

The ears of the Virginia gourdseeds are not very long, neither is the cob so thick as that of the big white and yellow. But the formation of the grain makes the ear very thick. They frequently produce from thirty to thirty-two, and sometimes thirty-six rows of very long narrow grains, of a soft open texture. These grains are almost flat, at their outside ends, are also compactly united from the cob to the surface of the ear, without any of that fluted appearance between the rows of grain, which causes the flinty corns to be much less productive in proportion to the size of the ears.

The gourdseed corn ripens later than any other, but is by far the most productive. It is invariably white, unless it has been mixed with the yellow flinty corns. Then it is called the yellow gourdseed, and too many farmers
MAIZE.

I consider it and most other mixtures original corns. I have often heard of original yellow gourdseed corn, but after taking much trouble to investigate the fact, could never find any thing more than a mixture.

So prevalent are mixtures, says Mr. Lorain, that I have never examined a field of corn, (where great care had not been taken to select the seed,) which did not exhibit evident traces of all the corras in general use for field planting, with many others that are not used for this purpose.

None can be longer or more readily traced than the gourdseed. If the smallest perfectly natural indenture appear in the grain of the hardest corras, those grains, with their descendants, may be grown, until a perfectly white gourdseed is obtained, be their colour what it may.

In the northern divisions of the United States, they frequently plant the small Canadian corras. These are solid and very early, but have been generally thought too small to be very productive, and are seldom planted in fields, where the larger corra s ripen.

These corras and others which are still much smaller and earlier, are grown by many for early boiling or roasting while green.

The Canadian corn plant is considerably smaller than the corras in general use for field planting. It is also productive in ears. Therefore, the intervals, as well as the clusters in the row, might be closer together. If the soil were as well manured for this kind of corra as is done for the larger corras (when the farmer is well informed and able to do it), very valuable crops might be obtained from it; particularly if it were only slightly mixed with the gourdseed corn.

There are also red, blue, and purple corras, but none of these are used for field planting; still, having been introduced, they too often appear in our fields, either in their native colours, or in variegated or enamelled grains. The leaves of the plant are also sometimes variegated from the same cause. It is said that a good purple dye is formed by using the purple corras for this purpose; and the stalks and leaves of this plant are purple, or a shade between that colour and green. I have also seen corn with red stalks and leaves, but mixed with more or less green.

As novelty and other causes have introduced such a great variety into our fields, they will continue to appear in them until farmers generally give more attention to the economy of maize, and see the necessity of growing out inferior kinds, so far as it may be practicable. Although they may be divided almost ad infinitum, they cannot be entirely eradicated. They may, however, be readily reduced and kept under, so as not to do any material injury to the crops, provided the cultivator very carefully and annually selects his seed. It may be from the latest remains of these mixed varieties, that nature, from combining causes, sometimes produces plants and animals more perfect than the class from which they sprang.

This variety, as it regards corn, proceeds from the farina segundans, a light minute substance of a mouldy colour, seen on the clothes of those working among the plants, when it is disengaged from the tassels. This is wafted far by high winds, and is the cause of distant and unthought-of mixtures. However, in general, it is lightly and plentifully diffused through the field, and lodges in sufficient quantities on the silky fibres which project from the ears. A single fibre proceeds from each grain. This has been so constructed as to convey the principle of life contained in the farina segundans to the grain from which the fibre springs, even to the further end of the cob. This is done with so much certainty that we rarely see abortive grains, when the plants have been rendered healthy and vigorous by a sufficiency of nutriment and good cultivation. The change produced by this mysterious cause is generally gradual. We first see scattering, whitish looking grains on the ears of the yellow corn growing among the white, and the reverse on the ears of the latter, when grown near to the yellow corras.

The foregoing facts have induced me to make experiments. The result seems to determine, that if nature be judiciously directed by art, such mixtures are as best suited for the purpose of farmers, in every climate in this country where corn is grown, may be introduced. Also, that an annual selection of the seed, with care and time, will render them subject to very little injurious change; provided the desirable properties of any of the various corras be properly blended together. They do not mix minutely, like wine and water. On the contrary, like mixed breeds of animals, a large portion of the valuable properties of any one of them, or of the whole five original corras commonly used for field planting, may be communicated to one plant; while the inferior properties of one, or the whole, may be nearly grown out.

When this object is obtained, and we become acquainted with the proper arrangement of the plants in our fields, so as to promote the utmost product, the crops of maize will by far exceed any estimate which would at this time be considered probable by those who have not carefully examined the economy of this plant.

It should, however, never be forgotten, that a sufficiency of nutriment and good cultivation are quite as necessary to increase and perpetuate the size of grain as plentiful and nutritious food, and proper care and management, are to accomplish the same in animals.

My ears were now at least one-third larger, on an average, than were the ears procured three years ago from Huntington for seed. The same may be also said of some white, flinty corn, procured by my neighbour, Mr. H. Philips, from near Erie, for seed.

The quantity of the gourdseed corn mixed with the flinty yellow corras, may be determined, so as to answer the farmer’s purpose. When the proportion of the former greatly predomi- nates, the grains are pale, very long and narrow, and the outside ends of the cob very flat that but little of the indention is seen. As the portion of gourdseed decreases in the mixture, the grains shorten, become wider, and their outside ends grow thicker. The indentures
also, become larger and rounder, until the harder corns get the ascendency. After this, the outside ends of the grains become thicker and more circular. They also grow wider, and the fluted appearance between the rows increases. The indentures also decrease in size until they disappear, and the yellow, flinty varieties, whilst prejudiced in this particular, much in well flints, not so fully but that the latent remains of mixture will forever subject it to more or less change.

It is more difficult to determine the quantity of big and little yellow corns, which may happen to be mixed with the gourdseed; and at the same time with each other. However, by attention, a tolerably correct opinion of this may be formed. The grain of the big yellow is much wider, and nothing like so deep as that of the gourdseed; and although the grain of the little yellow is not so wide and deep as that of the big, still it is wider than the gourdseed; and its colour is deeper than that of the big yellow, and its cobs are much slimmer, as well as shorter.

When a mixture with the big yellow and gourdseed is desirable, care should be taken, in growing out the little yellow, to preserve as much as possible of the deep yellow tinge and solidity communicated to the grain by this variety, and also of its property to ripen early.

The soft, open texture of the gourdseed renders it unfit for exportation, unless it be kilndried. This has given rise to an unfounded prejudice among the shippers of this grain, in favour of the yellow corns, although they are not more solid than the white, flinty varieties. However, while this prejudice continues, it is best for those who depend on selling it for shipping, to mix the gourdseed with the yellow flints, and for those who consume the produce on their own farms, or can readily sell the white corns, to form mixtures with them and the gourdseed. It is thought that the white corns are the most productive, and ripen earlier than the yellow; but of this I know nothing certain, having generally grown the yellow. There can, however, be no question but that the white furnishes much handsomer meal for culinary purposes. It is also free from that strong taste so readily distinguished by those who have been accustomed to use the white; but as most of the Pennsylvania farmers, and cultivators still further north, have been used to eat the yellow, and habit causes most kinds of food to be agreeable, they seem generally to prefer the strong taste of this variety to the much milder and pleasanter taste of the white. However, in the countries where neither is grown, and to which it is often exported, there can be but little doubt that the white would find a ready market, and that the demand for this very nutritious grain would greatly increase, if none but the white were exported; especially, if laws were passed prohibiting the exportation of the until it had been kiln-dried.

I believe there is no grain that will keep longer or safer than corn, if it be kept on the cob in open dry cribs, and the climate also be dry, unless the weevil be introduced by not carefully cleaning the cribs of every vestige of the grain and vegetable matters introduced with it.

Flinty corns, after they have been well dried in such cribs, may be shipped in tight, dry vessels, with tolerable safety, to the West Indies; but longer voyages subject this grain to greater injuries, although it may arrive in port in tolerable safety; a little damp communicates to maize; and if this does not happen, it is often spoiled by lying in bulk after it arrives, and will be considered much less valuable on this account.

Either the big yellow or white should be mixed with the gourdseed, for planting in every climate where this mixture will certainly ripen. Their cobs being very long, and the grain so much wider and deeper than those of the little yellow or white, the mixture with them will be much more productive. It is also thought, that the length of the ear communicated by the big yellow or white will fully compensate for the shortening the grains of the gourdseed: therefore, if the mixture be properly formed, its product may even exceed that of the original gourdseed corn; I have measured the product from ears of this mixture, which, when shelled, yielded a full pint of corn, after they had lain twelve months in a very dry place, although the mixture had not been well improved.

The little yellow and white, being earlier than the big yellow and white, should form mixtures with the gourdseed corn for being grown in climates more unfavourable for maize. But whoever may form either of those mixtures, will find, that he must grow out either the big or little flinty corns, with many others, as they are more or less mixed.

The speediest and best way to form either of those mixtures, is to select one ear that may possess most of the desirable properties united in it, and to plant the seed where the farina fecundans from the general crop cannot readily obtain access. If it happen to the cultivators, as it has done with me, he will certainly find from the growth of this seed many ears in his patch, very much like the ear that grew the seed, and many very unlike it; however, it may be that he will find some ears approaching nearer to the variety which he wishes to form than the original ear; if so, he will of course select the best, and go on in the same way, until he has full enough for planting his general crop. After this, he should aim at an increased improvement, by carefully selecting his seed annually for the ensuing crop. (Practical Husbandry.)

Of these numerous varieties some are best adapted to the Southern States—the white and yellow gourdseeds: others to the Middle States—the gourdseed and flint varieties, pure or mixed; whilst the heavy flinty grained kinds are almost exclusively cultivated in the Northern and Eastern States—to which they are specially adapted by their disposition to grow and mature with great rapidity; and thus accommodate themselves to the shortness of northern summers. Like all early maturing corn, they are dwarfish, though very productive. The effect of the longer and warmer summers in more southerly situations is to favour greatly the growth of the stalk, which frequently attains 10 or 12 feet in height; but such luxuriance, however splendid in appearance, is, by no means
MAIZE.

attended by a corresponding increase in the product of grain. The time taken by different varieties in growing varies from 6 to 9 months, or more, exceeding. In the South and Middle States the crop occupies from 5 to 7 months, whilst in the Northern and Eastern States the ears come to maturity in 3 or 4 months, and some is even found so precocious as to ripen in 6 weeks. An interesting and plausible explanation of these facts is given in the article on Climate, and its Influence on the Fruitfulness of Plants.

Since Mr. Lorain wrote his excellent book, several demonstrations have been furnished of the great superiority of one variety of corn. One of the most interesting is that made by Thomas N. Baden, Esq., of Prince George’s county, Maryland, who, by carefully selecting the best seed in his field for a long series of years, having special reference to those stalks which produced the most ears, ultimately obtained a variety which yields 4, 5, 6, and even as high as 8 and 10 ears to the single stalk. The particulars of the plan pursued are as follows:

When the corn was husked, he made a re-selection, taking colour and soundness into consideration, giving a regard to the deepest and best colour, as well as the size of the cob. In the spring, before planting the corn, he examined it again, and selected that which was the best in all respects. In planting the corn, he omitted the irregular kernels at both the large and small ends. He has carefully followed this mode of selecting seed corn for twenty-two or twenty-three years, and still continues to do so. When he first commenced, it was with a common kind of corn, for there was none other in that part of the country. At first he was troubled to find stalks with even two good ears on them, perhaps one good ear and one small one, or one good ear and a ‘nubbin.’ It was several years before he could discover much benefit resulting from his efforts; however, at length the quality and quantity began to improve, and the improvement was then very rapid. At present he does not pretend to lay up any seed without it comes from stalks which bear 4, 5, or 6 ears. He has seen stalks bearing 8 ears, and one of his neighbours informed him that he had a single stalk with ten perfect ears on it. In addition to the number of ears, and of course the great increase in quantity unshelled, it may be mentioned that it yields much more than common corn when shelled. A barrel (10 bushels of ears) of his improved kind of corn measured a little more than six bushels. The common kind of corn will measure about 5 bushels only. He believes that he raises double, or nearly so, to what he could with any other corn. He generally plants the corn about the first of May, and places the hills five feet apart each way, leaving two stalks in a hill.

Some of Mr. Baden’s seed-corn was sent to Illinois, with instructions how to manage it, and the product was one hundred and twenty bushels on an acre; there was no corn in Illinois like it, and it produced more fodder than any other kind. (Farn. Cab. vol. ii.)

The Baden corn is a white gourdseed, the stalks of which grow to an extraordinary height, so that the ears are often 6 or 8 feet above the ground, and thesummits twice that elevation. That portion of the ear above the ear, the ears are short and considerably under the average size of the common varieties of corn. When removed but little farther north, as for example to the vicinity of Philadelphia, it seldom matures perfectly. It does not answer well for high-land culture, but flourishes and produces abundance of grain and fodder in the rich flat lands of the Southern and Southwestern States. It verifies the observation that high-growing corn is the least disposed to ripen the ears, and consequently most liable to injury from frost.

Varieties cultivated for particular purposes.—Among the varieties of corn cultivated for special purposes, we may mention the white flint, used for making the beautiful hominy sold in the Philadelphia market; the flour corn, with a round, thick grain, filled with a snowy white powder resembling starch, much used in New Jersey for grinding up with buckwheat, in the proportion of about one-fourth or one-fifth of the corn, giving the buckwheat-meal a lighter colour and otherwise improving it. The early Jersey truck corn, a middle-sized ear, with white and rather flinty grains, the earliest corn raised for the market, but not so sweet as the Early sweet or Sugar corn, which, when dry, has shrivelled grains; there are two varieties of this, the white and red cob kinds. The small flinty-grained corn usually raised for parching or popping is considered a distinct species of maize, under the name of Zea Caragwea, or Valparaiso corn, to which a sort of religious reputation has been attached, from the circumstance of its splitting open when parched or roasted so as to present some resemblance to a cross. Its appearance under this form is peculiarly beautiful, and bears a strong resemblance to the flowers of a cruciferous plant. The flavour is pleasant, and it makes a very pretty dessert-dish.

Preparation of the Land for planting.—In the Middle States corn is planted in all conditions of the land, but in Virginia and Maryland, it generally follows the wheat crop, upon which all the farm-yard manure has been spread. In the upper portion of Delaware and in Pennsylvania, the crop is generally put upon a grass sward or clover lay. Where the soil is a stiff clay, much labour is bestowed in ploughing deep, then rolling and reducing to the finest tilth by means of harrows. As a general rule, after a sward has been turned, care is taken not to harrow so deep as to reach and drag up the sods, which are suffered to lie and decompose, thus furnishing nutrient to the corn, and keeping the ground loose and favourable to the spreading of the roots. Many farmers spread lime upon the land intended for corn, in the autumn or winter, previously to ploughing. Others put the lime dressing on the ploughed ground. Although the first may be considered a good plan, still there can be little doubt that lime operates most effectually when left upon the surface so as to be exposed to the atmosphere, and especially to the full action of rain water with its dissolving agent carbonic acid gas. But the best plan of all is to
spread the lime on the grass the year preceding the tillage in corn, as then the vegetation is greatly benefited, and the lime has full time to dissolve in considerable proportion and impregnate the soil. Where the land is light or sandy, shallow ploughing is frequently practised and much less labour is required to prepare the ground for the crop. In all cases, however, where there is a retentive clay below the soil, no doubt can exist of the propriety of stirring the earth as deeply as practicable, first by the common plough, and next by the sub-soil plough, which loosens the earth or clay below the furrow run by the common plough, without turning it up. This effectual and deep breaking up of the earth allows the water to penetrate quickly into the soil charged with all its fertilizing gases and salts, which would otherwise be rapidly dispersed if exposed to the open atmosphere.

Season for Ploughing.—With regard to the best time for ploughing, this must depend much upon the character of the soil. Late fall or winter ploughing has been thought useful in turning up and exposing to perish, the grubs and other insects which have retreated below the surface for winter quarters; but in Pennsylvania this practice is now generally abandoned in favour of spring ploughing.

The roller, when used, must be drawn in the direction of the furrows, and never crosswise. Then follows the drag-harrow, in the same direction, being the last instrument which, on flushed ground, is employed preparatory to planting. The spikes of this implement should never be set so deep as to reach and drag up the sod, an observation which will apply to all other implements called in requisition during the working of the crop. The harrowing should be continued until the surface of the inverted sward is completely broken up and pulverized.

In the Middle States, it is a very general custom to prepare the ground for corn by a method called listing or double furrowing. This consists of ploughing so as at first to turn two furrow-slices together, leaving a middle space which is subsequently ploughed out by turning an additional furrow on each side. This places the ground in narrow lands or ridges, consisting of four furrow-slices with deep, intervening trenches. The width from the middle of one land to the other is generally about 4 feet. In signing out for planting, a plough is run across these narrow lands, so as to leave an open space 4 feet apart. The plough which performs this cross-ploughing, is immediately followed by a boy who drops 4, 5, or 7 grains of corn directly opposite the middle of each of the ridges, and the operation of planting is completed by a man who covers the seed with a hoe.

Farmers generally agree that corn should be planted as early in the spring as the weather will permit, and some of the best are not even afraid of having the young shoots nipped off by frost. The usual time of planting in the Floridas is early in March, whilst in Massachusetts it cannot be done before the middle of May,—facts which show the great range of climate in the United States.

Mr. Lorain, one of the best authorities upon this and most other agricultural subjects upon which he has treated, says,—When corn is planted very early, it is commonly severely affected by frost; so much so, that many of the plants are cut off by the ground. This is unquestionably an injury to which no judicious farmer would expose the plant, if the advantages obtained by very early planting could be had by planting later. Still if the roots remain unhurt, they are of consequence established, and very soon repair the injury done above the soil, after the frost ceases to act on the plants. Of course they take the lead, and will maintain their superiority over later planted corn. The ears also fill and ripen much better in northerly climates from this practice.

The shooting and filling of them take place when the heat of the sun is much greater; and when less cloudy, cold, dripping weather prevails, and the crop is nothing like so liable to be injured by frost. The grounds are also sooner ready for crops sown in the fall. This mode of management will often enable the cultivator to grow the large and more productive corns, in climates where they have been abandoned, from observing that they did not ripen when planted at the usual time.

When I introduced the large yellow gourd-seed corn, from seed procured from Huntingdon county, every farmer here ridiculed the idea of attempting to grow corn of this description. They considered the soil and climate hostile to the growth even of the smaller corns, and but little was planted. As they waited until the earth was warmed before they planted, the crops were frequently either destroyed, or greatly injured by frost. (Pract. Husb.)

In Pennsylvania, corn generally forms the first crop of the regular rotation, the sod being ploughed without manure, except the occasional addition of a light dressing of plaster of Paris (about one bushel per acre) or a full coat of lime (50 to 100 bushels per acre). The plan of listing and ploughing out, so common in the Southern and Middle States is not followed by Pennsylvania farmers, who flush up the ground so as to present a uniform surface.

Planting.—After rolling, and then harrowing well, the rows are struck out very shallow, and the corn is planted in hills 3, 4, 4 1/2, or 5 feet apart, or dropped in rows from 3 to 5 feet asunder, so as to leave the stalks, when thinned out, about 1 or 2 feet apart. In this last case the tillage has of course to be conducted in the direction of the growth even of the smaller corns, is practised when the grain is in hills at regular distances. The distance of the corn hills or plants apart must be regulated by the kind of corn to be planted, and the nature of the soil. When the growth is high, and the soil rich, the rows should be farther apart than where the growth is low, as is the case with the Northern varieties, which may be planted 3 feet apart.

Whenever manure can be spared for the corn crop, very sure return is a good return; for maize cannot well be too highly manured. If the supply be sufficient, it may be spread broadcast upon the land previous to ploughing; or, what is better, spread upon ground that has
been flushed up in the autumn or winter, and then lightly ploughed in. In the Northern and Eastern States where the summers are hot, a liberal quantity of manure is generally required to assist in forcing the crop to early maturity. When not enough is at hand to afford a good dressing broadcast, it is advisable to apply a portion of short manure to each hill just before planting. Ashes are an excellent manure for Indian corn, and may be dropped upon the hills in the proportion of a gill to a pint. It is common to make a mixture of these with lime and plaster. But there is no doubt that the main benefit of the mixture proceeds from the live ashes. Almost every kind of artificial manure may be advantageously applied to corn, either in the hill or broadcast; and there is none perhaps which acts so promptly upon the young plants as the Poudrette manufactured in New York and other cities, the basis of which fertilizer is night-soil. A gill of this to the hill furnishes a fair dressing, and pushes the young corn forward with such rapidity as to place it very soon beyond danger from the grub, cut-worm, and other insect depredators, by which the plants, especially those on light and exhausted soils, suffer such destruction during their feeble and tardy growth. As conducing to the same end, soaking the seed for 24 or 36 hours in solutions of saltpetre, urine, the drainings of the stables and cattle-yards, &c. &c. have a very good tendency. To protect it from the depredations of insects, birds, and vermin, it is often coated with liquid tar, and subsequently rolled in ashes, plaster, lime, or saltpetre, which last is considered one of the most convenient, cheapest, and best of steeps. Strong solutions of copperas, blue vitriol, and even corrosive sublimate and arsenic, are sometimes used for the same purpose—which last, however, is only soluble in water by the addition of potash, or some other alkali. “The enemies to be combated,” says Buel, “are the wire-worm, brown grub, birds, and squirrels. Of these, the first and two last prey upon the kernels, and against these tar offers a complete protection. I soak my seed 18 to 30 hours in hot water, in which is dissolved a few ounces of crude saltpetre, and then add (say to 8 quarts of seed) half a pint of tar, previously warmed and diluted, with a quart of warm water. The mass is well stirred, the corn taken out, and as much plaster added as will adhere to the grain. This impregnates and partially coats the seed with the tar. The experience of years will warrant me in confidently recommending this as a protection for the seed.

Number of grains to the hill, and depth of planting.—Where there is reason to apprehend much mischief to the young plants from blackbirds, crows, vermin, and insects, it is always best to drop from 4 to 7 grains to each hill, so that some 2 or 3 may have a chance to escape. An old quaint couplet lays down a pretty good (though not sufficiently liberal) rule upon this subject, when it recommends 5 grains—

"One for the blackbird, and one for the crow,  
One for the cut-worm, and two left to grow."

The deficiency is always attempted to be made up by replanting other grain, but the product of this replant is too often feeble, and so late in maturing, as to be frequently injured by the frost in autumn. A much better plan is to replant with the surplus of other hills. But this requires a damp and very favourable condition of the weather. As to the proper depth of covering for the seed, much difference of opinion exists; some advocating shallow covering, that is to say, from an inch to 2 or 2 1/2 inches, whilst others recommend from 3 to 6, 8, and even 10 inches. All covering which exceeds 4 or 5 inches must, under ordinary circumstances, be considered extravagant and detrimental. Those in favour of deep covering say that although the corn does not come up so soon, or appear so forward, it makes a much better growth later in the season; sends its roots lower, and of course is less affected by dry weather, whilst the stalks stand much better against the violence of storms, by which they are often prostrated. They also urge as additional recommendations, that the crows and blackbirds are unable to pull up the young shoots, so as to get at the grain soon with the heaviest plough, whilst the cut-worm may sever the sprout in the common situation just beneath the surface, leaving enough still below to push up and continue the growth. See Drill.

It cannot be doubted, that where the mould is of a light texture, moderately deep covering answers best as a general rule. To cover deep where the soil is a heavy clay loam, would either cause the grain to rot, prevent it from rising, or dispose it to come up twisted, unless opportunely assisted by rain, to soften the packed covering.

Tillage.—The corn once planted, its tender blade pushes through the ground, usually in about a week or ten days, and even sooner when the grain has been previously soaked. Although the field is generally left at rest until the plants have all fairly risen above ground before the tillage of the crop commences, some begin with the harrows even before the corn is up. The first objects to be effected are, to keep the ground stirred and free from grass and weeds. Where danger is apprehended from worms, by which it is so frequently attacked, many maintain that the tillage should not commence very soon, so that some other vegetation being allowed to start up, the young corn will thus be in a measure spared; whereas, if the ground is perfectly clean, the worms, having nothing else to feed upon, will, of course, destroy all the young corn. Instances may occasionally occur where this practice may prove advantageous, but as a general rule, the young corn cannot be kept too clean, or the ground about it too loose.

The modes of tillage vary exceedingly, not only with the variations in soil and climate, but with the views of different persons in the same locality. On stiff, clay soils, there is no doubt that harrowing just before the proper time for the corn to come up, favours this process, by loosening the tenacious soil, especially where a timely rain does not occur to soften the earth. After the corn appears, the harrow should be kept going until the ground is rendered perfectly loose, hands following with hoes or short rakes to clear the corn which may be covered. Then comes the plough,
which, in the Southern and lower portion of the Middle States, is often used to turn a furrow from the young corn. This operation is termed bar-ploughing, because the bar of the plough is run next to the plants. A few days after this, the process is reversed, and the mould-board being turned next the corn, the loose earth is thrown back again. Many think that this second ploughing, called moulding, ought not to be left longer than a few hours before the earth should be turned back again. In some places ploughs are still used for this last pull, being with wooden mould-boards, as these serve best to push the loose earth before them, crumbling and spreading it about the plants more advantageously than ploughs furnished with smooth and polished iron mould-boards. Some use narrow, deep-cutting ploughs, which do this work with comparatively little labour to the horse, and render the soil near the corn much more permeable by the roots, and at the same time, quickly accessible to the rain and atmospheric influences. Whatever tends to favour the extension of the roots downwards, serves to place the crop beyond the vicissitudes of the season.

There is, perhaps, no plant which withstands the effects of drought so well as Indian corn, whilst young; but when its top blades begin to be heavy, its demands for moisture increase so as to cause it to suffer greatly from very dry weather. Heat and moisture are the greatest promoters of its luxuriant growth.

Mr. Lorain's comments upon the custom of bar-ploughing, as practised by a distinguished Maryland farmer and agricultural writer, are very judicious. Mr. Boardly, he says, ploughed from each side of the rows of the plants five inches deep, while the plants were young; he then let them rest 10 or 12 days on the narrow ridges formed by this practice; this was done, that the lateral roots should take their direction under the artificial surface of the ground formed by the ploughshare. If the corn-plant, when scarcely three inches high, be pulled up by the roots from an open free soil, the lateral roots will be found about 12 inches long, beside what remains in the ground; consequently these roots are cut off on each side of the rows, even by the first cultivation, while the plant is yet very young; they are also cut off by every succeeding cultivation. If the furrows made along each side of the rows, by the first cultivation, were kept continually open, and the lateral roots of the plants compelled by this means to cross the bottom of them, a little within the ground, this would not cause the roots to grow under the artificial surface of the ground formed by the ploughshare. Nature immediately after they passed the open furrow, would direct them up into the soil above, to take their natural range through it: especially in that part of it where the most genial heat and nutriment obtained. This is clearly seen when the lateral roots of trees cross ditches, or even deep gullies, at the bottom of them, a little within the ground. They immediately mount upward after they have crossed the bottom of the ditch, and take their natural growth at the same distance from the surface of the soil as would have happened if they had met with no obstacles in getting into it.

The roots of the corn-plant which proceed downward from the stalk, also those that take their course along the rows, are not injured; neither are all those which grow the deepest within the soil in the intervals cut off. Therefore as the corn-plant is very hardy, it is supported by these roots, until nature repairs the damage done by this truly inconsiderate and barbarian practice. It is of consequence by no means wonderful, that Mr. Bordley, who was in many respects a judicious farmer, should by his general good management so far counteract the evils arising from this savage practice, as to grow, under all the disadvantages resulting from it, crops that were more than equal to the general crops of his neighbours. Reason, however, as well as practice, determines that crops obtained in this way must fall very far short of those that may be obtained from a rational system of management. It is also obvious, that his mode of cultivation is well calculated to cause an extensive, useless waste of the animal and vegetable matter contained in the soil. Likewise of the farm-yard manure, if that be applied for the growth of the crop. (Lorain's Pract. Husb.)

The farmers in some of the finest districts in Pennsylvania have of late years made much less use of the plough in cultivating their corn than formerly. They now generally content themselves with moulding, or throwing a single furrow on each side of the young plants, leaving a space between the rows of from 3 to 4 feet untouched. The space left, is afterwards worked by means of shovel-ploughs, and cultivators, which completely destroy the grass, and loosen the ground. This mode of culture is more quickly and economically performed than the old plan of ploughing the whole space between the rows, and leaving the surface comparatively level. If the land be sufficiently loose and deeply stirred, there is little use in hilling it. It is sometimes said corn requires hilling to support it. Nature disapproves this argument, by the strong effects produced by this plant, at the time they are wanted, and for this very purpose. On wet lands, planting on ridges and hilling may be advisable, but such lands should never be chosen for corn. If wet, drain thoroughly in the first place. Allow no weeds to grow in your corn, says Buel, and do not fear to stir the surface in dry weather. Every weed absorbs nutriment enough to make a good ear of corn, and if any remain after the plough cannot be used, pull them up, or cut them with the hoe.

_Thinning and Succouring._—As quickly as possible after it is ascertained that the plants are in a thriving condition, and no longer in danger of being destroyed by the cut-worm and other enemies, they are thinned out, so as to leave only two or three in a hill. Or, should they stand in rows or drills, the plants are left about one or two feet apart. The operation of succouring takes place some time after thinning, and consists in tearing off the side-shoots which, often sprout from the bottom of the main stalk. It is beginning to be thought that this practice
is much more hurtful than advantageous, injuring the growth and development of the corn, and lessening the produce of both fodder and grain. The truth of these opinions seem to have been confirmed by actual experiments. (See Cudictor, vol. viii p. 90.)

Many farmers deem the use of the plough altogether unnecessary and even injurious, and conduct the tillage of the corn crop throughout first with the drag-harrow, and successively with the cultivator, horse-hoe, and hand-hoe. These are kept going very constantly until wheat harvest, after which further culture is suspended, and the corn crop, in common phrasology, is said to be laid by. The plants have now attained from 2 to 4 or 5 feet in height, and thrown out their side-shoots. These should be left to extend themselves uninterruptedly in all directions, which they will do with great rapidity provided the season be favourable and the soil loose and in good tilth. Should they be cut or torn asunder by late and too deep working, the crop must suffer serious injury.

The progressive growth and development of Indian corn are well described by Mr. Lorrain.

The roots and stem of maize, he says, spring from the heart of the grain; the former grows from one to two or more inches long before the latter appears, and progresses so very rapidly, that if pulled up from a loose soil, they will measure about 12 inches long when the stem is only about 3 inches high, although their finer fibres must be left in the ground by this rude operation.

The stem protrudes itself through the soil in the form of a bodkin, and is composed of leaves rolled very compactly together; the first two leaves expand soon after the plant penetrates, the soil, and other rolled leaves continue to unfold in succession from the crown of the plant, until the tassel appears wrapped up in its own leaves: these also gradually spread themselves, until the plant is fully formed.

The leaves increase in width and length from the ground up to where the most perfect ear is formed; after this they decrease in length and width, more rapidly than they increased below, and this decrease is regularly maintained even to the uppermost leaf, which forms itself a little below the tassel.

One leaf grows from every joint in the stalk, but in such a way as to alternate sides; the first formed leaf, and after this every leaf in regular succession, clasps the stalk closely, until it approaches near to the under side of the leaf above; after this it grows out from the stalk, and a beautiful fan-like appearance is at length produced, which is not equalled by any other annual plant cultivated for the value of its fruit; especially when the large luxuriant ears display at their points elegant tufts of silky fibres, which vary in colour when mixtures form the seed.

The height of this plant differs much. The smallest variety that has been noticed by me did not seem to exceed 3 feet in height. The largest plants which I have seen measured but 13 feet. I have, however, heard of some which attained the height of 17 feet. These must have been grown on a very rich, as well as a very deep and open, free soil.

The lateral roots of maize soon spread through the whole soil. The finger-roots, as they are sometimes called, dip much deeper. I have traced at one place below the surface of the soil by a grubbing hoe, in the hands of a rugged workman. How much further their finer fibres might have gone was not ascertained by me, but this convinced me that the roots of maize were capable of drawing very much moisture and some nutriment from a much greater depth than most of the plants cultivated by us. Also, that these manures and smaller roots were better calculated to effect this very interesting purpose than they would have been if nature had formed the whole of them into one single taproot, which extended no deeper. This is one cause, among many others, why maize is capable of contending so powerfully with poverty, and notwithstanding severe and continued drought, better than most other cultivated plants. This should convince us that a plant capable of drawing such important supplies from beyond the range of plants in general, will not prove peculiarly exhausting if it be treated fairly, by having as much manure or as good a soil appropriated for it as is commonly used for those plants which farmers in general have not learned to grow on poor soils without manure.

The prop roots of maize appear about, or a little before, the tassels may be seen. They proceed from the joint at or near the surface of the soil. They are numerous, and form a circle round the plant. That portion of them which grows outside of the ground is hard and woody, similar to the substance which forms the outside of the stalk; but so soon as they penetrate the soil they become softer, and spread through it in search of nutriment; this is just at the time the plant requires most of it.

The tassel and the top of the plants have after this to attain their full size, and the farina fucundans, which impregnates the grain, is to be formed. The ears now begin to shoot, and they are also to be filled and perfected.

The prop roots are exactly calculated to support the weight of the tassels and ears during high winds, and when the grounds are softened by rain. But farmers too generally thwart this simple but wise arrangement of nature, by hilling or ridging up the plants. These inconsiderate operations not only cut and rend the roots, but also compel the plants to grow new sets of prop roots from the joints above. These seldom get sufficiently established in time to support the weight and height of the tassels and ears; and many of the plants are of consequence blown down, or fall by their own weight, when the grounds have been previously much softened by rain.

Maize, from its woody texture and commanding size, might (without straining the term) be called an annual bread tree, producing the best of all corns, and at the same time crops which in magnitude far exceed that of any other grain. Also tops, husks, and leaves which can be readily gathered, and furnish abundant fodder for cattle, equal to the
MAIZE.

The shoots which form the ear commence at the joint in contact with the ground. If the soil be rich or highly manured, they issue from every joint up to where the uppermost ear is formed at the footstalk of the tassel. This last or highest up ear is almost invariably the largest, and ripens soonest. It seldom occurs that more than two ears are perfected on one stalk, unless the clusters of plants are very distant from each other, and but few plants stand in each cluster. If the plants stand thick on the ground, but one ear is commonly perfected by each of them. The abortive ear shoots are called suckers. These are commonly removed, so far as the farmer considers conducive to the welfare of his crop. This should be done as soon as they are large enough to be pulled off effectually. No part of them should be left adhering to the stalk, or they will grow again from the stub left behind.

If this operation be not early commenced and frequently repeated, they become so numerous and large in fields highly manured, especially if the plants stand thin on the ground, that they are greatly injured; not only from the loss of nutriment, but also from the many and large wounds inflicted by the removal of them.

After careful experiment in the removal of suckers, I now pull none above the joint in contact with the ground; and would not remove these if they did not take root in the soil, and by this means become powerful exhausters. Although it commonly happens that several ear shoots above this point prove abortive, no sucker can be removed without injuring the leaf which binds it to the stalk; and so much that it is commonly rendered altogether incapable of conducting moisture. If it be not so excessively injured, the receptacle formed by it is so much deranged by this operation, that it cannot retain the slight portion which may happen to be conducted by the leaf into it.

I am still further encouraged to let so many of these abortive ears stand, as I have observed that so soon as nature has determined the number of ears which existing circumstances may enable her to fill, all her efforts are directed to them, and the abortive ones immediately dwindle, and finally wither; and, for aught we know the stalk covered by it, forms a cavity for to part with the rich matters they had previously gathered, and apply this nutriment to assist in maturing her favourites.

I trust it will appear from what has been advanced, that in place of abusing this invaluable plant as an exhausted of the soil, we should consider it the pride and boast of American husbandry, as mathematical demonstration cannot well afford stronger proof than has been produced that maize gathers a large portion of the nutriment necessary to perfect its fruit from the atmosphere.

Still, it should be remembered that sufficient nutriment, provided in the soil, is absolutely necessary; and therefore, to ensure the perfection of this, and most other plants cultivated by it, it is absolutely necessary to proceed with the usual modes of manuring them. For this reason, I have frequently pointed out the necessity of keeping the soil well covered with animal and vegetable matter.

The middle path is certainly the path of reason and experience, and should be carefully and diligently pursued by the practical farmer, leaving those ideal speculations for the amusement of the learned.

There is no corn crop grown by us which is so certain as maize. Its diseases are few, and most, if not all of them, proceed from an inconsiderate cultivation. I do not recollect ever to have seen them so extensive in any field as to do any very material injury to the crop.

It withstands drought and contends with poverty better than most other plants cultivated by us, either for the value of their grain or roots. It may be advantageously grown in any soil fit for cultivation, not excepting blowing sands or retentive clay.

Still, this crop fails occasionally, especially in the higher latitudes, or situations rendered cold from local causes. It cannot withstand grass or weeds, and is too generally planted by far too late. The seed is also covered too deep, as well as oppressed with clods, stones, or any other rubbish near at hand, which prevents the plant from coming up. Too little seed is planted to secure a sufficiency of plants after birds and quadrupeds have taken that portion which even proper vigilance cannot prevent. (Practical Husbandry.)

Saving the Fodder, &c.—The tops of the Indian corn, when cut off for fodder, should be removed previous to stripping the blades from the stalks below the ear, which last operation should be delayed till near the time of maturity, indicated by some dryness of the leaves and hardness of the grain. The ears are gathered by hand, and the husks, when perfectly dry, stripped off, and, together with the stalks, laid by for winter fodder, while the ears are conveyed to the granary. The green stems and leaves abound in nutritious matter for cattle, and in some places it is cultivated solely for this purpose, especially after early crops of other vegetables; when planted for this object, it should be sowed very thickly. Corn, when well dried, will keep good for several years, and preserve its capability of germination. It is necessary to shade it to do this very extensively, and forms a wholesome and substantial aliment. Domestic animals of every kind are also extremely fond of it. According to Count Rumford, it is, next to wheat, the most nutritious grain. It is considered as too stimulating for the common food of cattle, and is found to be more stimulating than any other kind of
MAIZE.

The fattening and invigorating qualities of Indian corn make it the best of all kinds of food for persons exposed to hard labour or fatiguing duty. In the United States, however, the preference so generally bestowed by the labouring classes on Indian corn, is by no means confined to them, but shared alike by rich and poor, for the sweetness of the bread, and its wholesome and superior invigorating virtues. Mixed with rye meal, it forms the common brown bread of New England; mixed with water alone, it makes a very palatable species of extemporaneous bread. When pounded in a mortar, or ground very coarse and boiled, it forms the "homing" and "grits" which are such great favourites at the south; and the fine meal, boiled thick in water, is the "mush" of Pennsylvania, and the "hasty-pudding" of the Eastern States. In the form of hulled corn, or samp, the whole grains furnish a very palatable, although rather indigestible luxury. Of the husks a beautiful kind of writing-paper has been manufactured in Italy; and when soaked in hot water, they make excellent mattrasses. A grayish paper may be made form all parts of the plant.

Enemies and Diseases.—The bird, insect, and other depredators have been already referred to under the head of Birds, Cuts, Worms, Wireworm, Plant-lice, &c. Among the diseases, the chief one is a dark or blue-black spungy growth, which sometimes takes the place of the blighted ear of corn. The mass sometimes grows till 5 or 6 inches in diameter, and is to be considered a luxuriant or rank species of fungus. As the species of parasitic plants to which this belongs are so readily destroyed by applications of common salt, there is reason to believe that soaking the seeds well in salt-water previous to planting, or scattering salt over the ground, will prevent this disease.

In all the fields of maize, says Mr. Lorain, which have been examined by me, some plants entirely barren have been seen without any apparent cause.

The fungus appears to be principally occasioned by wounds inflicted during cultivation. The plants commonly bleed from these wounds, and a fungus is formed. This, when in contact with the ear, is certain destruction to it, unless the fungus be soon seen and removed. When it is formed on other parts of the plant, it frequently corrades them so much that they are incapable of perfecting their fruit. The only remedy known to me is speedy removal, and repeating the operation if the fungus should reappear: which generally occurs. But even this tedious remedy is too often found insufficient. It is, therefore, far better not to create this disease, by mangling the plants, either by the savage practice of harrowing over them, or by covering them with clods, stones, or sods, as is too often done by the inconsiderate mode of hilling or ridging them up. Although many of the plants are killed by these injudicious practices survive and appear to flourish, even when the fungus is not removed, still, numbers of them become too debilitated to perfect their fruit.

A reddish kind of rust sometimes appears on the leaves, but seldom does much apparent injury to the ears, unless it becomes extensive, however, the same rust sometimes fixes upon the stalks and causes them to decay.

When this is near the ear, or the decay is extensive, the plant produces little or no grain; but I have never seen very extensive injury done by this disease. The cause of it is unknown to me. It may, however, proceed from the bruises and wounds inflicted by an inconsiderate cultivation; especially as the tassel, wrapped in its own leaves, may be seen formed in the plant when it is quite young. Too many farmers think the health and vigour of the plants are greatly promoted by harrowing over them, and mangling their tops while they are young. Also, by cutting and rendering the roots of them, provided this be not done after the tassels and ear shoots appear; than which nothing can appear more preposterous. (Practical Husbandry.)

It sometimes happens, as the effect of storms, that the pollen is blown or beaten off the tassel before all the silk has protruded from the ear. The consequence of this is a failure in the development of grains in the extremity or other portion where the silk was deficient. It has been urged, among the reasons for letting the suckers grow, that being later in tasseling and less exposed to high winds, they assist to promote the process of fecundation after the tassels of the main stalks have shed their pollen. As an evidence of this, it has been stated that the earliest ears are always best covered with grain, while those which push late often exhibit a quarter or a half of naked cob,—the consequence of imperfect impregnation.

Harvesting the Crop.—This is effected very differently in different portions of the Union.

1. In Pennsylvania, and the Northern and Eastern States, the corn is usually cut off at the surface of the ground, as soon as the grain has become glazed, or hard upon the outside, and whilst the blades are still green, put immediately into shocks, and left to sun and air some time standing in the field. The corn after becoming sufficiently dry is hushed and cribbed, and the stalks with all the attached fodder and husks are carted home and stacked for provender.

2. In the Southern and Southerly portions of the Middle States, the corn is commonly husked in the field, the stalks having previously had the blades stripped below the ears, and the tops lopped off above the ears. When, therefore, the ear has been separated, the naked stalk is left standing with the husk, which is soon afterwards eaten off by cattle.

There are some other modes of gathering corn and securing the fodder, but those described are by far the most general. In some parts of the fertile Western States, where the crops are extremely luxuriant, with the absence of facilities to get the grain to market, it is common to husk out and secure enough of the corn for family use and then turn the hogs and cattle into the field to consume the remainder.

By the first of these methods the crop may be secured before the autumnal rains, with all its valuable fodder, and the ground cleared in time for a winter crop of wheat, or rye. The juices retained by the stalk are sufficient to nourish the corn to maturity. By the second mode there is always a loss in the grain pro-
duct, which is never so well filled after the blades and tops have been removed in a green state. This has been proven by actual experiments, for the particulars of which see Juell's Farmer's Instructor; also Farmer's Register, vol. ii. p. 91; and Colman's Fourth Report, p. 16.

All, or nearly all the accounts we have published of great products of Indian corn, agree, says the editor of the Cultivator, in two particulars, viz.: in not using the plough in the after culture, and in not earthing, or but slightly, the hills. These results go to demonstrate, that the entire roots are essential to the vigor of the crop; and that roots to enable them to perform their function as nature designed, must be near the surface. If the roots are severed with the plough, in dressing the crop, the plants are deprived of a portion of their nourishment; and if they are buried deep by hilling, the plant is partially exhausted in throwing out a new set near the surface, where alone they can perform all their offices. There is another material advantage in this mode of cultivating the corn crop—it saves a vast deal of manual labor.

There is another question of interest to farmers, which relates to the mode of harvesting the crop, that is, whether it is best to top the stalks, cut the whole at the ground when the grain is glazed, or cut the whole when the grain has fully ripened. Experiments made by Mr. Clark, of Northampton, one of the best practical farmers of Massachusetts, and of other gentlemen, show that the grain suffers a diminution of six or eight bushels to the acre, by topping the stalks; and there seems to be no counterbalancing benefit to the fodder, unless at the expense of carrying the stalks to the borders of the field, that they may be secured before the crop is gathered, and before they become blanched and half-ruined. And it is no protection against early autumnal frosts, but rather exposes unripened grain to be more injured. Hence so far as regards these two modes, all who have made a comparison seem to concur in the opinion, that stripping the corn of its tops and leaves is a bad practice.

The stalks and tops of corn, if well cured, furnish an excellent fodder for neat cattle and horses, all kinds of stock being very fond of them. They serve greatly to increase the amount of manure, collected in the cattle-yard. In Pennsylvania, in the Southern parts of which the crops of corn are very luxuriant, the fodder is generally considered worth at least $4 per acre as provender. A distinguished farmer in Whitemarsh, Montgomery county, obtained, in 1842, from a 30 acre field, sufficient corn-fodder to winter 30 large steers intended for spring beef. The stalks had been cut down with blades, &c., attached. Corn is occasionally sown broad-cast for the purpose of being mown down as green provender for milch cows, &c., for which it answers an admirable purpose. It has been also cured as hay, and on some highly fertile or rich spots has yielded 6 tons of hay or fodder.

Preserving Corn.—Corn is usually preserved by storing away the ears cleared from the husks, in small or narrow granaries called cribs, the sides and ends of which are constructed of logs or laths, so as to leave interspaces of about 1 inch, or rather more, permitting a free circulation of air. If the cribs be wider than 8 or 10 feet, the middle part is very apt to have the corn injured, especially when put away before becoming thoroughly dry. In the Southern States, corn in the crib is often seriously injured by the weevil when attempts are made to keep it over the summer. But in the Middle and Northern States, it may be preserved for many years on the cob. In the Louisiana Register it is stated that sprinkling the corn whilst housing, with a solution of common salt and water (in the proportion of about one pint of salt to a gallon of water), will entirely prevent the insect from breeding. The ears of corn are there frequently stored up in the husks, which are rendered much more grateful to stock by the addition of salt.

There is perhaps no plant—certainly none of such vigorous growth,—which will so long continue highly productive when raised year after year upon the same soil. In a communication to the Farmer's Register, by Mr. Shal- tice, of Mathews county, Va., he says that there are in the county named, small tracts of land which have been in corn, year after year, as far back as the recollection of the oldest inhabitants extends. The same fields planted in corn successively for more than half a century, at present yield fair crops. Such land, when new (judging by the product of contiguous recently cleared land), yielded from 3 to 5 barrels per acre. At present the product is from 2 to 3 barrels, with the occasional application of very meagre dressing of manure.

With a fair supply of manure, the land can be readily made to yield as much and even more than it did when first brought under cultivation. As, in the tillage of this crop, all vegetation is carefully destroyed, the materials constituting the soil or mould must have decomposed very slowly indeed. Where there is much sand in the soil, exhaustion takes place very quickly; but Indian corn can be cultivated on land, long after it has ceased to afford compensating crops of any other grain.

Expenses of Culture.—These are very differently estimated in different parts of the United States, being influenced by a variety of local circumstances. The following estimate and accompanying statement is from Jonathan Roberts, Esq., a very eminent agriculturist residing in Montgomery county, Pennsylvania:

"An estimate of the expense of cultivating an acre of maize 15 miles northwest of Philadelphia: Soil, a calcareous loam.

Ploughing sward $3.00
Harrowing to proper fineness 2.00
Marking out and planting 2.00
3 loads (2-horse wagon) manure to dress the hills 3.00
Horse-hoeing, at least three times 2.00
Moulting and horse-hoeing 2.00
Harrowing 1.00
Saving fodder 1.00
Rent of land 5.00
Wear of gears and plough 1.00
Amount of expense $29.00

Amount of crop 60 bushels, at 60 cts. per bushel 36.00
Fodder 4.00

Leaving a balance in favor of the corn-crop of $17.00
This estimate," says Mr. R., "is predicated on practical husbandry, with a fair season. It is not found economical, in a regular course of cropping, to manure corn land beyond hill dressing. The decomposing sward will be found equal to its production. The renovating process of manure should be applied in putting in the winter crops with the cultivated grasses. Lime should not be immediately applied before sowing the winter crops. Its application ought to follow the maize in the fall, or at the latest in the following spring. By such a course of culture ground may be kept improving in fertility. It is not the part of practical farming to increase the crop of corn by an expensive manuring; it must be taken as one of a series of ploughed and green crops. On a good soil, and with a good season, corn may run to 70 and 80 bushels an acre. Good management will be directed to produce a series of good crops, with an improvement of soil.

With great deference to an agriculturist of such matured experience, we cannot help expressing an opinion that some of the items in the statement are rated too high, and that it would perhaps be more correct to bring down the expenses at least as low as those in the following estimate furnished by Judge Buel. This last, it must be remembered, does not include manure, so much more of which is usually required at the North, as greatly to increase the expense of the crop.

Estimated expense of cultivating an acre of Indian corn in the State of New York:

</tbody>
</table>

In the New England States the expenses of culture are stated to exceed these calculations considerably. Mr. Colman, in his Fourth Agricultural Report to the Legislature of Massachusetts, gives the following estimates for different townships.

"In Northfield, the estimate was made as follows:

<table>
<thead>
<tr>
<th>Item</th>
<th>Cost</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ploughing</td>
<td>$4.00</td>

| 70 bushels corn, at $1 00 | $70.00 |
| **Balance in favour of corn** | **$52.50** |

Several other estimates of the expense of cultivating an acre of Indian corn, varying from 14 to 25 dollars, are given by Mr. C. The above statements are from farmers of the highest respectability for intelligence and exactness, and may be relied upon.
MAIZE.

Dr. Dana calls the fat forming principles in favour of corn, will excite but little surprise in those who have witnessed the effects of the several substances on animals, and will go far to establish the position assumed by Payen and Boussingault, that plants are valuable for giving fat to animals, in proportion to the vegetable oils ready formed such plants contain.

Average for 16 years = 63 cts.

The above average prices are for Southern flat yellow corn, commonly called gourdsseed, which generally sells for about 3 cents less per bushel than the Pennsylvania round or flint corn, which last is heaviest by 3 or 4 lbs. to the bushel. The amount of white flat corn sent to the Philadelphia market is inconsiderable, being only occasionally in demand for shipment to Southern ports, where the white corn is preferred for bread, whilst in the North the preference is always given to yellow corn meal. White flat corn usually sells about 3 cents lower per bushel than the flat yellow.

Measuring Corn, Shelled or on the Ear.—The following rule for this purpose is given by William Murray, Esq. of South Carolina. It is not to be regarded as strictly accurate, but an approximation.

Having previously levelled the corn in the house, so that it will be of equal depth throughout, ascertain the length, breadth, and depth of the bulk; multiply these dimensions together, and their products by 4, then cut off one figure from the right of this last product. This will give so many bushels and a decimal of a bushel of shelled corn. If it be required to find the quantity of ear corn, substitute 8 for 4, and cut off one figure as before.

Example.—In a bulk of corn in the ear, measuring 12 feet long, 11 feet broad, and 6 feet deep, there will be 316 bushels and 1/3 of a
MAIZE.

bushel of shelled corn, or 633 bushels and 

\( \frac{1}{2} \) of ear corn— as:

The decimal 4 is used when the object is to find the quantity in shelled corn, because that decimal is half of the decimal 8, and it requires two bushels of ear corn to make one of shelled corn. In using these rules a half bushel should be added for every hundred, that amount of error resulting from the substitution of the decimals. (Southern Agriculturist.)

Distances of Planting.—The following table furnished by Judge Buel, exhibits the difference in planting and serves to explain, in part, the manner in which large crops of this grain have been obtained. It is assumed in the estimate, that each stalk produces one ear of corn, and that the ears average one gill of shelled grain. This, says the judge, is estimating the product low; for while I am penning this (October), I find that my largest ears give two gills, and 100 fair ears half a bushel of shelled corn. The calculation is also predicated upon the supposition that there is no deficiency in the number of stalks, a contingency pretty sure on my method of planting.

The fifth mode I have tried. The ground was highly manured, the crop twice cleaned, and the entire acre gathered and weighed accurately the same day. The product in ears was 103 baskets, each 84 lbs. net, and 65 lbs. over. The last basket was shelled and measured, which showed a product on the acre of 118 bushels 10 quarts. I gathered at the rate of more than 100 bushels the acre from four rods planted in the third method last summer, the result ascertained in the most accurate manner. Corn shrinks about 20 per cent. after it is cribbed. The sixth mode is the one by which the Messrs. Pratt, of Madison county, obtained the prodigious crop of 170 bushels per acre, the largest crop on record. These gentlemen, I am told, are of opinion that the product of an acre may be increased to 200 bushels.

I am told the Messrs. Pratt, above alluded to, used seven bushels of seed to the acre, the plants being subsequently reduced to the requisite number. (Quoted's Farmers' Instructor.) See also Planter's Table.

According to the mode usually adopted in Pennsylvania, and other States in which the high-growing varieties of corn are planted, the cornhills will average a distance of 4 by 3 feet, which gives 3,600 hills to the acre, and allowing 2 stalks to each hill, this makes 7,200 stalks per acre. In more northern situations where they are compelled to rely upon the quick-maturing varieties, the lowness of the stalks admit of closer planting, the hills averaging about 3 by 2 feet apart, with 4 stalks per hill, by which means an acre is made to contain 5,808 hills, and no less than 23,232 stalks—every stalk, in a good season and with proper tillage, yielding a good ear.

Sugar from Maize.—Every one familiar with Indian corn in its growth, must have observed the very great sweetness of the juice exuding from the green stalks, when broken or cut. This, together with the great resemblance between the true sugar-cane and maize, afforded ample ground for believing that sugar could be procured from its juice. But whether this can be manufactured with profit, still remains to be fully demonstrated. Partial experiments have afforded favourable results, among which the following may be mentioned. The juice of maize contains as much, if not a larger proportion of sugar than that of the sugar-cane. This sugar is precisely similar in its crystallizing and other properties to that of the cane.

The attention of scientific investigators has for some years been directed to this subject, and it has been regarded as an important discovery that the removal of the shoot forming the rudiments of the ears, before these have had time to fill, has caused the stalks to retain all their saccharine matter at an advanced stage of their growth. Very recently this has been contested. At a recent meeting of the French Academy, the distinguished philosopher, M. Biot, read the report of a committee, which paper contained the following statements: Of the corn stalks experimented upon, the ears had been removed from one portion, and left to grow on others. The juice obtained from the stalks which had been castrated, yielded 12 per cent. of sugar; that expressed from the stalks on which the ears had been permitted to grow, 13 per cent. It would hence appear that the results of former experiments showing great apparent advantages from castration, were fallacious, the operation being rather injurious than otherwise. The rapidity with which maize attains its growth, admits of its being removed from the soil sufficiently early to give place to a winter crop. This, in France, is accomplished by a process which has the great advantage it has over the sugar-beet, for which it is proposed as a substitute. In those countries where the climate is not sufficiently warm to bring the grain of Indian corn to perfect maturity, such as England and Northern France, it is probable that the plant might be brought sufficiently forward to admit of the manufacture of sugar. Mr. Webb, of Wilmington, Delaware, has made some interesting experiments upon this subject, which are highly worthy of attention. (See Farmer's Cabinet, 1842, and Ellsworth's Report, 1843.) The results afford reasons for believing that the manufacture of sugar from maize may be advantageously carried on in the United States,

MALE FERN.

especially in the Western States, where such luxuriant crops of maize can be raised at little expense.

MALE FERN. See Fern.

MALIC ACID. This vegetable acid exists in the juices of many fruits and plants, alone, or associated with the citric, tartaric, and oxalic acids; and occasionally combined with potash or lime. Unripe apples, pears, sloes, barberries, the berries of the mountain-ash, elderberries, currants, gooseberries, strawberries, raspberries, bilberries, Brambleberries, whortleberries, cherries, annas, afford malic acid; the house-bleck and purslane contain the malate of lime.

The acid may be obtained most conveniently from the juice of the berries of the mountain-ash, or barberries. This must be clarified, by mixing with white of egg, and heating the mixture to ebullition; then filtering, digesting the clear liquor with carbonate of lead, till it becomes neutral; and evaporating the saline solution till crystals of malate of lead be obtained. These are to be washed with cold water, and purified by re-crystallization. On dissolving the white salt in water, and passing a stream of sulphureted hydrogen through the solution, the lead will be all separated in the form of a sulphuret, and the liquor, after filtration and evaporation, will yield yellow granular crystals, or cauliflower concretions, of malic acid, which may be blanched by re-dissolution and digestion with bone-black, and re-crystallization.

Malic acid has no smell, but a very sour taste, deliquesces by absorption of moisture from the air, is soluble in alcohol, fuses at 156° Fahr., is decomposed at a heat of 342°, and affords by distillation a peculiar acid, the pyromalic. It consists in 100 parts, of 41-47 carbon; 3-51 hydrogen; and 55-02 oxygen; having nearly the same composition as citric acid. A crude malic acid might be economically extracted from the fruit of the mountain-ash (sorbus accompaniata), applicable to many purposes; but it has not hitherto been manufactured upon the great scale. (Curt's Dict.)

MALLOW (Malva, altered from the Greek molache, soft, which comes from malacho, to soften, in allusion to the enollient qualities of the species). This is an extensive genus of plants, some of the species of which are very ornamental. Among the most interesting of the hardy herbaceous species, are M. moschata, M. muromana, and M. purpurea. They should be planted in the flower-border, and increased by divisions of the roots, or by seeds. The annual species should be sown in the open ground; but few of these are worth cultivating.

In England, the indigenous species are three in number. 1. Common mallow (M. sylvestris), a perennial weed which is very common about hedgerows, roadsides, and in cultivated as well as waste ground. The root is tapering, branching, whitish; stem upright, much branched, widely spreading, 1½ to 3 feet high, in a barren soil recluent; leaves deep-green, soft, and downy, with seven acute lobes; foot-stalks and flower-stalks hairy; the flowers, which appear from May to August, are numerous, of a shining purple, veiny, on simple aggregate stalks. The leaves are mucilaginous and emollient, like the marsh-mallow; and were formerly often used in food to prevent costiveness. The fruit is a depressed disk, and is called by the country people "cheeses."

2. Dwarf mallow (M. rotundifolia). This species is also very common in waste ground, and by footpaths near towns and villages. It is annual in habit; has a tapering root. The whole plant is smaller than the last, and is quite prostrate, with numerous stems scarcely branched. Leaves roundish, heart-shaped, with five, often seven, shallow lobes. Flowers pale lilac-coloured, several together on axillary hairy stalks; the stalks when in fruit are bent downwards.

3. Musk mallow (M. moschata). This is a less common perennial species, found in the grassy borders of fields, &c., on a gravelly soil. The root is tough and woody; the herbage is bright green, more or less rough, with spreading, simple, not stary hairs, unaccompanied with any short, dense, woolly pubescence, and exhaling a musky odour, especially in hot weather, or when drawn tightly through the hand. Stems about two feet high, leafy, round, but little branched. Radical leaves kidney-shaped, cut, soon withering away; the rest in five deep, pinnatifid, jagged segments. The flowers, which appear in July and August, are on long, axillary, simple stalks, rose-coloured, large and handsome; calyx hairy, its outer leaves linear-lanceolate.

Five North American species of the genus Malva are described by Nuttall. One of these, the M. coccinea, is very beautiful, with scarlet flowers disposed in dense racemes, and is found from the confluence of the river Platte and Missouri, often extending over the plains in such quantities as to communicate a brilliant redness to thousands of acres. Dr. Darlington describes two species as found in Chester county, Pennsylvania, one of which is the woodland or wild malva (M. sylvestris), sometimes called high malows. It is a naturalized foreigner, met with in fields and waste places, which, when it has escaped from gardens. The other species is the round-leaved malva (M. rotundifolia), commonly called low malows, and running malows. This is common in yards, gardens, and grass-lots. It is also a foreigner, and so extensively naturalized as to be somewhat troublesome. It is a popular ingredient in domestic practice for poultices, drinks, &c. "The M. crispa and M. moschata are frequent in our gardens, and the latter has in a few instances strayed beyond the garden limits, but can scarcely be considered as naturalized. Several species have been recently found in the distant territories of this Republic, and in British America; but it is doubtful whether any genuine malva is indigenous in the old thirteen states." (Flor. Cestrica.)

MALLOW, THE MARSH. See Marshmallow.

MALLOW, THE TREE. See Tree-mallow.

MALT (Fr. mal; Ital. malto; Lat. maltum). The term malt is applied to designate grain which, being steeped in water, is made to ger-
The process of malting is performed by steeping any quantity of good barley in cold water for a period which (as regulated by law) must not be less than forty hours; but beyond that period the steeping may be continued as long as it is thought proper. The proportion of water immersed depends partly upon the barley, and partly upon the length of time that it is steeped; but the result of a good many trials proves that the medium increase of weight from steeping may be reckoned at 47 lbs. in every 100. The average increase of bulk is about one-fifth. After the grain has remained a sufficient time in steep, the water is drained off, and the barley thrown out of the eistern upon the malt floor, where it is formed into a heap, called the couch, about 16 inches deep. In this situation it is allowed to remain about 26 hours. It is then covered by means of wooden shovels, and diminished a little in depth. This turning is repeated twice a day or oftener, and the grain is spread thinner and thinner, till at last its depth does not exceed a few inches. The temperature which it is wished to preserve by these frequent turnings varies from 55° to 62°, according to the different modes of malthsing pursued. Soon after the rudiments of the future stem, called acrospire by the maltsters, has appeared, the process of germination is stopped by drying the malt upon a kiln. The temperature at first does not exceed 90°, but it is raised very slowly up to 140°, or higher according to circumstances.

Barley, by being converted into malt, generally increases 2 or 3 per cent. in bulk, and loses at an average about 20 per cent. in weight, of which 12 are ascribed to kiln drying, and consist of water which the barley would have lost had it been exposed to the same temperature; so that the real loss does not exceed 8 per cent.

The following is Dr. Thomson's analysis of barley, and the pale malt made from it.

The gluten in this case is a most important component, as by its transformation, when the malt is converted into wort, ferment is generated; whilst the saccharine matter, which is increased fourfold, is the origin of the alcohol of the beer. Oxygen is appropriated by the gluten at the same time that the transformation of the sugar is going on; and thus carbonic acid and yeast are disengaged simultaneously.

In brewing ale, porter, and table beer, three different kinds of malt are employed: 1, pale or amber malt, which yields the saccharine or fermentable extract; 2, brown or blown malt, which is not fermentable, but is used to impart flavour; 3, roasted, black, or, as it is sometimes called, burnt malt, which is employed instead of burnt sugar, merely as a colouring matter for porter.

The manufacture of malt has been carried on in England to a great extent from a very early period; but it is singular that notwithstanding the products obtained from it have always formed the principal beverage of the great bulk of the people, instead of increasing with the progressive wealth of the population of the country, it remained nearly stationary for more than a century, and it is only within the last 8 or 10 years that there has been any increase in the manufacture. This extraordinary result is most probably to be attributed to the introduction and universal use of tea, coffee, &c., and to the heavy duties that were formerly levied on beer and malt. The present duty on malt from barley is 2s. 7d. per bushel, and from bere or bigg, 2s. The quantity of malt charged with duty in the United Kingdom during the three years ending 1838, was 41,814,811 bushels; and the revenue derived from it averaged in the same period 5,882,976l.

The following is the quantity of malt consumed by the brewers of London and its vicinity from the 10th of October, 1830, to the 10th of October, 1840.

The 6 Geo. 4. c. 107, s. 52, enacts that "malt may not be imported into the United Kingdom for home use under pain of forfeiture; but it may be warehoused for exportation." The importation of malt is, however, now allowed under very high duties, fluctuating with the price of home produce; but under no state of the market can any addition be thus made to the quantity of malt in this country, because barley which has undergone a voyage of much length is unsuited to the process of malting. See BARLEY, BEER, and BREWING.

MALT-DUST. The dust or substance that separates from the malt in the act of drying, or during its preparation. It is sometimes called malt-combs, and has been found useful as a manure or a top-dressing when sown over the cereal grasses in the early spring season.

The proper quantity of this dust is, if top-dressed, for wheat, 36 to 40 bushels; if drilled with the crop, for barley and turnips, 30 to 34 bushels. It is also eminently calculated for grass lands; and if applied in the latter proportion, it will produce a very considerable increase of the best feed. The common price at most malt-kilns is from 8s. to 6s. per quarter. Malt-dust is also in some places employed in the feeding of milk cows and pigs.

MALUS (Latin, an apple). The wild crab (Pyrus malus, see CRAB-TREE) is the only apple indigenous to England, and it is on this stock that most of our valuable apples have been grafted and raised by the ingenuity of the gardeners, who have, by sowing the seeds and studying the soil, so improved and multi-

759
plied the varieties of this most excellent fruit, that it has now become of great national importance, affording an agreeable and wholesome diet, in a thousand shapes, to all classes. Leonard Mascall was the first who introduced the common or cultivated apple into England, about the year 1525. The varieties of the apple are now so numerous that the Horticultural Society's catalogue includes more than 1400. The apple, like most other hardy trees, may be propagated by seeds, cuttings, suckers, layers, or engrafting; by seeds for obtaining new varieties, and by the other modes for extending the number of such as are in esteem.

In every garden and private orchard, apples for ten different purposes are desirable:

1. For summer culinary use, the codlings, while not fully grown or imperfectly ripe, are fit for using in June, July, and August.
2. For summer eating or table use, the jenneting pomroy, &c., which ripen in the end of June or in July. Margaret, summer pearmain, &c., (July). Kentish fill-basket, Hawthorn dean, &c. (August).
3. For autumn baking, the codlings and Darknott's red-streaks, Eve apple, court penda, nonsuch, &c., which ripen in September. Piles' russet, Carlisle pippins, embossed, &c. (October). Wormsley pippin, golden Harvey, queenling, golden russet (November).
4. For autumn table use, the Kirton and Dalmahoy pippins, Loan's pearmain, Colville, Kent, Godolphin, &c., which ripen in September; orange and ribstone pippins, gray rennet, fameuse, violet, &c. (October). Franklin's golden, and Borsdorf pippins, Dredge's russet, margil, &c. (November).
5. For winter culinary use, the Nimier's dumpling, Burknot, John apple, Mansfield tart, &c., which are fit to use in December. Hall door, royal pearmain, Dutch queening, Aclam's russet (January). Brindwood pippin, cockagee, tankerton, box-apple (February).
6. For winter table use, the golden and Kentish pippins, golden and Canadian rennets, brandy, &c., which are fit to eat in December. The Norfolk storing, Hubbard's sykehouse, white court pender, &c. (January). Dredge's Queen Charlotte, Feams, Skenn's kernel, and Dalmahoy pippins, royal pearmain, &c. (February).
7. For spring culinary use, the quince, white Colville, Lord Camden's rennet, winter pearmain, which keep till the end of March. Spencer pippin, Trevoorder rennet, Macdonald's Scotch nonpareil, Spaniard, &c. (April). Norfolk paradise, Loan's pearmain, English rennet, &c. (May).
8. For spring table use, the hollow-eyed, Cornwall rennet, Hughes's new golden pippin, &c., which will keep till the end of March. Cockle and Whitmore pippins, golden and Piles' russet, Wheeler's extreme, &c. (April). Stone and Spencer pippins, Royal George, Ward, &c. (May).
9. For summer culinary use, till the apple season returns, the Lord Cheney's green, Baxter's pearmain, stout codling, &c., which will keep till the end of June. Norfolk beaufin, Norfolk storking, French crab (July).

10. For summer table use, till the apple season returns, the Dredge's fame, oaken peg, carnation, &c., which keep till the end of June. Nonpareil, Yorkshire greening, Norfolk Colman, which keep till the end of July.

Although the apple flourishes in every part of the United States, if we except the extreme southern portions, the fall and winter varieties commonly come to the greatest perfection in the Northern States and northern portions of the Middle States, where this fruit constitutes a very profitable resource to the farmer, both for the home markets and exportation to the Southern States, the West Indies, and Europe, and even to Asia. Good judges assert that the apples of England and France are not to be compared, for excellence of flavour, to those produced in the United States.

The following directions for the culture and subsequent management of apple trees, is from the valuable manual published in 1842 by William Kenrick, nurseryman, near Boston. The seeds or pomace of the apple should be sown in autumn in a rich soil. When the young plants appear in spring, they should be carefully thinned to the distance of 2 inches asunder, and at afoot from each other in the row, in a rich and loamy soil. In the summer following they are inoculated, or they are engrafted or inoculated the year following. Size and age for transplanting to the orchard.—An apple tree, when finally transplanted to the orchard, ought to be at least 6 or 7 feet high, with branches in proportion, and full 2 years from the bud or graft, and thrifty. Apple trees under this size belong properly only to the nursery.

Distance.—The distance asunder to which apple trees should be finally set, when transplanted to the orchard, depends upon the nature of the soil, and the cultivation to be subsequently given. If the soil is by nature extremely fertile, 40 foot distance may be allowed, and even 45 and 50 feet in some very extraordinary situations; for before the trees become old, they will completely shade the ground. If, however, the soil is not very extraordinary by nature, or so rendered by art, this distance would be too great; for the trees would become old, and their growth would be finished, before the ground could be covered by their shadow: 30 feet only may therefore be allowed in land usually denominated of good quality, and but 20 to 25 feet in land of ordinary quality. But where economy of time, of land, and of all things else is consulted, but one-half of this distance will answer for a series of years.

The quinuncx mode is recommended for close arrangement, and short-lived trees may be set in the intervals.

The size to which an apple tree may attain, and the ground which should be allotted to it, depend also, in some measure, on the particular variety of apple; some sorts being well

760
known to attain to a much greater size than that of others.

The period of growth, or the duration of the apple tree is comparatively limited; this is sufficiently evident from the perishable nature of its timber. Those species of trees only will continue living and growing for centuries, whose timber may be preserved incorruptible during the lapse of a long succession of ages.

Soil and situation.—A rich soil, rather moist than dry, is that adapted to the apple tree; but what is usually termed a deep pan soil is to be preferred.

On such a soil, whether on the plains, or in the valley, or on the sides and summits of our great hills, which almost always consist of good land, and even in situations the most exposed, the apple tree will flourish.

One of the most productive apple-orchards in the immediate vicinity of Boston is situated on the north and north-west sides of a hill, the most exposed to cold winds. The soil of great hills is generally of far superior quality to that of the plains; and it is a very mistaken opinion, which seems adopted by some, that the soil of all hills must of necessity be dry and deficient in moisture. It is the plains and the knolls that are but too generally thus deficient, not the great hills, which almost always abound in springs.

Land half-covered with rocks, and incapable of being cultivated with the plough, is in some respects admirably suited to the apple tree; for, in such situations, they are not liable to suffer from drought; they receive nearly a double portion of moisture from the rains that fall, and a greater degree of heat by the reflected rays of the sun.

They may even flourish on sandy plains, if, where the tree is to be placed, an excavation is formed 6 or 8 feet in diameter, and 3 or 4 feet in depth, and half-filled either with useless small stones, intermixed with rich loam, mud from the low grounds, clay, or gravelly clay, or mixtures of any of these substances with a portion of manure, and the remainder of the excavation filled to the surface with rich loam.

Management of the Land.—If the ground intended for the orchard cannot conveniently be kept wholly in a state of cultivation during the first years, a portion, at least, ought to be.

A strip of land to each row, of 8 or 10 feet in width, well manured, may be kept cultivated, and the vegetables which may here be raised will amply repay the expense and labour bestowed during the first 4 or 5 years. After this, if the trees have grown well, as they probably must have done, cultivation at a distance in the intervals becomes even more important than within the limited distance of a very few feet from the trunk of the tree; for, on examination, it will be found that the small fibres or sponge-lests, by which alone the tree derives all the nourishment it receives from the earth, are now remote from the trunk of the tree; they are now to be found seeking pasture beyond the limits of its shade, and it becomes necessary that the whole ground should be kept in a high state of cultivation for the 4 or 5 following years. After this period it may occasion-
MALUS.

35. Kenrick, a large round fruit, pale green, with bright red next the sun. Flesh tender and occasionally stained with red. A native of Newton, Massachusetts.

41. Orange Pippin, called also Marigold Pippin, and Isle of Wight Orange; in size, form, and colour, much resembling a middle-sized orange. Flavour pleasant and good for dessert. Excellent for cider. In Monmouth county, New Jersey, considered one of the most saleable, profitable, and productive of all fall apples.

42. Orange Sweeting, or Golden Sweet; rather large, flattened at the base and summit; colour yellow or orange; flesh sweet and excellent. In high estimation at Providence, Rhode Island, where it is brought from Connecticut. — September. Keeps till December.

49. Spice Sweet. Fruit large, very sweet and excellent. Native of Taunton, Massachusetts. Sometimes called Spurr Apple. — September.

53. York Russeting; remarkably large, conical-shaped, and studded towards the base; colour russet-yellow; juicy, subacid, and good. Valuable for market, cooking, &c. — October to December.

WINTER APPLES.

55. Eupus Spitzenberg, large, very beautiful, and excellent; shape oblong; colour deep scarlet, deepening to dark crimson next the sun; flesh juicy and high-flavoured. A very celebrated fruit, ripening in December, and keeping till March. The Flushing Spitzenberg differs from this in being round or flat.

56. Baldwin. This capital variety is a native of Massachusetts, a large, beautiful, and famous fruit. Shape round, of a pale colour in the shade, and fine scarlet-crimson on the sunny side; sometimes entirely red. Flesh white, juicy and sugary, and of an agreeable acid flavour. The most popular winter apple in the Boston market. Ripens in November, and keeps till February and March.

59. Yellow Ellflower. A large and beautiful fruit, of an oblong or conical form, colour bright yellow, with an occasional blush next the sun. Rich and finely flavoured; excellent for dessert and cooking, and a prime favourite in the Philadelphia market. Ripens in October and November, and will keep nearly all winter. The seeds are so loose as to rattle in the middle when shaken.

63. Chandler, a superior variety from Conn.
necitcut, where it is deemed one of the best of
winter fruits. Large, flat, with dull red stripes
next the sun. Eye large and in a deep cavity.
Flavour equal to the Baldwin. Keeps till March.

67. Danvers' Winter Sweet, or Epses Sweet.
Large and beautiful. Colour bright yellow,
with a faint blush next the sun. Fine for
dessert and baking. Native of Danvers, and a
popular market fruit.

74. Golden Bull. Size rather above medium;
ribbed at the sides; colour golden yellow.
A very popular apple in Maine.

84. Lady Apple, or Pomme D'Api. Very
small and beautiful. Skin bright and yellow,
with a red blush on the sunny side.—November.
Keeps till March.

85. Minister. Large, oblong, and tapering
towards the eye, like the Bellflower, with large
ribs, or calville-formed; striped, with bright
red on a ground of pale greenish-yellow. Flesh
yellow and high flavoured. Esteemed by Man-
ning one of the first fruits New England has ever
produced.—November to January. Origin,
Rowley, Massachusetts.

86. Late Round Sweet. Very large; form flat-

76. Mela Carla, or Malcarle, Charles Apple,
Pomme Ferviale. One of the most famous of
fruits; size rather large; form globular, but
slightly ovate. Eye and slender stem both in-
serted into deep cavities. Skin beautiful waxen,
with a little marbled with faint green near the eye.
Splendid crimson colour on the sunny side.
Flesh white, delicate sweet, with rose perfume.
—September. Keeps till spring. In Italy this
is considered the best of all apples in the world.
It is there cultivated extensively for exporta-
tion. Near Boston, this apple proves good but
not excellent.

88. Monstrous Pippin, or New York Gloria
Mundi; a fruit of uncommon size. Colour
yellow with numerous spots of white; eye
very deep. Excellent for cooking. Origin,
Long Island.

90. Murphy. A large and splendid fruit, re-
sembling in appearance the Blue Pearmain,
but more oblong and rather smaller. Colour
dark red, streaked or blotched with darker red,
and covered with bloom. Keeps till February.
Origin, Salem, Massachusetts.

Resembles the Esopus Spitzenberg, and high-
ly esteemed.

97. Ramadell's Red Pumpkin Sweet; a beau-
tiful fruit; over medium size; round or oblong;
colour a dark and beautiful red, covered with
a dense blue bloom. The tree a prodigious
bears, native of Connecticut. Fruit saleable
and profitable; keeps till January.

98. Rhode Island Greening; Jersey or Bur-
lington Greening; a very large apple, flattened
at both ends; colour yellowish green at matur-
ity, covered with dark clouds or blotches;
rippens in September, and keeps till March. A
highly esteemed and profitable fruit. Tree
bears abundantly every other year, and, in
the New England States, is preferred for its
productiveness to the Green Newtown Pipp.

99. Ribston Pippin, also called Formosa Pip-
pin, and Glory of York; in England esteemed
very highly; medium size, and globular form;
colour pale yellow, mottled with red next the
sun. Keeps till February.

100. Red Seek-No-Parther. A large round
fruit, contracted towards the summit; colour
fine deep red; flavour sweet and excellent.
Keeps till March. A Rhode Island fruit.

101. Roxbury Russetting. A fine old native of
Massachusetts; fruit large and of a slightly
flattened form; colour, brownish yellow russet,
with an occasional blush next the sun; skin
rough. Keeps well till June and July. Raised
in great quantities near Boston, for exporta-
tion, &c.

102. Scalloped Gillyflower. Said by good judges
to far excel the Black Gillyflower, and much
resembling the Cornish variety.

103. Swear. This and the Jonathan apple
are esteemed equal, at least, if not superior to,
the Newtown Pippins and Spitzenburgs. Size,
medium; shape, round; skin, greenish yellow,
with a blush next the sun, and thickly dotted
with brown spots, intermixed with some scar-
les. Keeps till April.

104. White Spitzenberg. A beautiful, fair, and
fine flavoured fruit, about the size of the Esop-
us Spitzenberg. Keeps all winter, and sells
well in the Albany market.

105. Wine Apple, or Hay's Apple; also called
Large Winter Red, and Fine Winter. Fruit
very large and beautiful; colour, bright red on
the sunny side, with sometimes a few stripes
and blotches of yellow on the shady side.
Flesh rich and excellent. Keeps till February
and March. Tree very productive, and fruit
very saleable in the Philadelphia market.

106. Winter Sweeting; called also Seaver
Sweeting, and Grafton Sweeting. Fruit large,
round and conical; colour, pale yellow, with a
blush on the sunny side. Flesh yellow, sweet
and fine-flavoured. Keeps till March.

107. Winter White Calville, or Bonnet Carré.
Fruit large and of a bright yellow colour, with
a bright red blush on the sunny side; form
rather flat and ribbed; flesh white, tender, and
pleasant. Keeps till March.

108. Yellow Newtown Pippin. A large flat
fruit, of a bright yellow colour, and faint blush
next the sun. Keeps all winter, and flourishes
better in the New England states than the
Green Variety.

CEREMONIAL CIDER APPLES CULTIVATED IN THE UNITED STATES.

109. Harrison, or Long Stem. A native of
Essex, New Jersey. The celebrated Newark
cider is made from this apple; one tree in Es-
sex county, New Jersey, produced 100 bushels
in one year, and 10 bushels make a barrel of
cider, which will yield 14 quarts of brandy.
The fruit is below the medium size, rather
long, and deeply indented at the ends; stem
very long; colour yellow, covered with black
spots. Fruit ripens 1st of November. Flesh
yellow, firm, tough, and dry.

110. Talladega. A Virginia fruit, about the
size of a grape-shot, or from 1 to 2 inches
in diameter; colour white, streaked with red.
111. Virginia Crab, or Hewes's Virginia Crab. A very small round cider apple, of a small, red colour, with streaks of pale yellow.

Varieties for Preserving or Ornamental purposes.

112. Red Siberian Crab. Tree a profuse bearer, and very beautiful when the fruit is at maturity, resembling at a little distance a plum or cherry tree; fruit in clusters of a bright scarlet colour, with long stems. Much used for preserving.

113. Yellow Siberian Crab. The tree, foliage, and fruit equally beautiful with the preceding kind, which it even excels in productiveness. The little apples grow in clusters, with long stems; colour golden yellow.

114. Chinese Double Flowering. Tree small, bearing very double flowers in clusters, resembling small roses; very superb when in full bloom. Fruit very small, but tolerable for eating.

Southern Apples.

The following are stated to be some of the most esteemed varieties of native apples of Virginia. Part are described from the authority of Mr. Coxe, and the remainder on the authority of a Virginia.

115. Beverley's Red. The fruit is very large, the skin smooth, of a crimson colour; flesh very white, of a pleasant flavour. A winter fruit.

116. Cart Honeys, or Gilpin. The tree is a great bearer. The fruit hangs long on the tree in autumn. A small fruit, rather oblong; the skin smooth, of a deep crimson colour, with occasional yellow stripes; the flesh yellow, tender, and of good flavour. A native of Virginia; highly esteemed for its excellence as a table fruit in spring; also a good cider fruit. Coxe.

117. Curtis. The skin is smooth, of a red colour; flesh juicy and pleasant. Ripe middle to end of August.

118. Gloucester White. The tree is of vigorous growth, and beautiful form, and very productive; the fruit of medium size, its form varying from flat to oblong; of a fine yellow colour, clouded with spots of black; the flesh yellow, breaking, juicy, rich, and delicious. It ripens early in October; and, according to Mr. Coxe, is not only a most excellent dessert fruit, but makes exquisite cider. Much cultivated and of high reputation in the lower counties of Virginia.

119. James River, or Limber Twig. Branches drooping or pendent; the fruit is of a greenish colour, with a bluish next the sun; the flesh very juicy, and pleasant at maturity. Winter. It keeps a long time.

120. Lippincot. A fruit of Maryland. Very handsome, and striped; excellent; one of the best of all early apples. July and August. R. Sinclair.

121. Pryor's Red. The fruit is very large; colour brownish red; its flesh at maturity juicy, and very fine. A winter fruit.

122. Ravel's Janet, or Rockrimmon. The form is globular, flattened; the colour red and green; flesh very fragrant, more juicy, and of superior flavour to the Newtow Pippin, and keeps equally as well.

123. Royal Pearmain. Fruit fine, of a large size, flattened; skin rough, of a fine russet colour, but red next the sun, and faintly streaked with russet; flesh a rich yellow, firm, but at maturity, tender, sweet, and of very sprightly flavour. A good table apple; excellent for cider; and highly esteemed by the planters of Virginia, near Richmond, from whence Mr. Coxe procured it. The tree bears uniformly and abundantly. It ripens in October, and will keep till February or March.

124. Striped June Apple. The fruit is as fragrant as a pine-apple melon. It ripens the last of June and beginning of July.

125. Virginia Greening. The fruit is of medium size; colour green, striped with red; flavour very superior. A winter fruit.

Gathering and Preserving the Fruit.

Various theories have been offered for preserving apples in a sound state for winter use, or for distant voyages. Some have proposed gathering the fruit before it is ripe, and drying it on floors before it is put up; this has been tried; the apples lose their sprightly flavour, and keep no better than by some less troublesome modes. Dr. Noah Webster has recommended that they should be put down between layers of sand which has been dried by the heat of summer. This is without doubt an excellent mode, as it excludes the air, and absorbs the moisture, and must be useful when apples are to be shipped to a warm climate.

Chopped straw has also been highly recommended to be placed between the layers of fruit; but I have noticed that the straw, from the perspiration it imbibes, becomes musty, and may probably do more hurt than good. When apples are to be exported, it has been recommended that each be separately wrapped in coarse paper, in the manner oranges and lemons are usually put up. This is, without doubt, an excellent mode. And Mr. London has recommended that apples destined for Europe should be packed between layers of grain. Packing in oats is said to succeed very well.

Great quantities of fine winter fruit are raised in the vicinity of Boston, and put up for winter use, for the markets and for exportation. The following is the mode almost universally adopted by the most experienced; and by this mode apples, under very favourable circumstances, are frequently preserved in a sound state, or not in 50 defective, for a period of 7 or 8 months. The fruit is suffered to hang on the tree to as late a period as possible in October, or till hard frosts have loosened the stalk, and they are in imminent danger of being blown down by high winds; such as have already fallen are carefully gathered and inspected, and the best are put up for early winter use. They are carefully gathered from the tree by hand, and as carefully laid in baskets. New, tight, well-seasoned flour-barrels, from the bakers', are usually preferred: the baskets, being filled, are cautiously lowered into the barrels and reversed. The barrels, being quite filled, are gently shaken, and the head is gently pressed down to its place, and
secured. It is observed that this pressure never causes them to rot next the head, and is necessary, as they are never allowed to rattle in removing. No soft straw or shavings are admitted at the ends; it causes mustiness and decay. They are next carefully placed in wagons, and removed on the bulge, and laid in courses in a cool, airy situation, on the north side of buildings, near the cellar, protected by a covering on the top, of boards, so placed as to defend them from the sun and rain, while the air is not excluded at the sides. A chill does not injure them; it is no disservice; but when extreme cold weather comes on, and they are in imminent danger of being frozen, whether by night or day, they are carefully rolled into a cool, airy, dry cellar, with openings on the north side, that the cold air may have free access; they are laid in tiers, and the cellar is in due time closed and rendered secure from frost. The barrels are never tumbled or placed on the head. Apples keep best when grown in dry seasons, and on dry soils. If fruit is gathered late, and according to the above directions, repacking is unnecessary; it is even ruinous, and should on no account be practised till the barrel is opened for use. It has been fully tried.

When apples are to be exported, Mr. Cobbett has recommended that they should, if possible, be carried on deck; otherwise between decks. Between decks is the place, and in the most dry, cool, and airy part.—(Keart.)

INSECTS INJURIOUS TO TREES AND FRUIT.

Among the insects that have been brought to America with other productions of Europe, may be mentioned the Apple-worm, as it is commonly called, which has become naturalized wherever the apple tree has been introduced. This mischievous creature has been sometimes mistaken for weevils, plum-worms, and others; but, however, it may be easily distinguished by its shape, habits, and transformations. Although the plum-weevil prefers stone-fruit, it is sometimes met with in apples. On the other hand, Dr. Harris says he has never known the apple-worm to be found in plums. It is, he observes, not a grub, but a caterpillar, belonging to the Tortrix tribe, and in due time is changed to a moth, commonly called the Collingsmoth, or fruit-moth of the apple. An anonymous writer, in the Entomological Magazine of London, has well remarked that this moth „is the most beautiful of the beautiful tribe to which it belongs; yet from its habits not being known, it is seldom seen in the moth state; and the apple-grower knows no more than the man in the moon to what cause he is indebted for his basketfuls of worm-eaten windfalls in the stiffest weather.”

Some interesting facts collected by Dr. Harris, serving to establish the difference between the plum-weevil and apple-worm (rolling caterpillar), will be found under the head of PLUM-WEEVIL.

The apple-worm has been long known in Europe, and its history has been written by some of the ablest naturalists. Accounts of it have also been furnished in the New England Farmer and other good American periodicals.

The apple-worm moths may be found in the early part of summer, about the time of the first ripening of the fruit. They are sometimes seen in houses in the evening, trying to get through the windows into the open air, having been brought in with fruit while they were in the caterpillar stage. Their fore-wings, when seen at a distance, have somewhat the appearance of brown watered silk; when closely examined, they will be found to be crossed by numerous gray and brown lines, scalloped like the plumage of a bird; and near the hind angle there is a large, oval, dark-brown spot, the edges of which are of a bright copper colour. The head and thorax are brown, m ciled with gray, and the hind-wings and abdomen are light yellowish-brown, with the lustre of satin. Its wings expand three-quarters of an inch. This insect is readily distinguished from other moths by the large, oval, brown spot, edged with copper colour, on the hinder margin of each of the fore-wings. During the latter part of June and the month of July, these fruit-moths fly about apple trees every evening, and lay their eggs on the young fruit. They do not puncture the apples, but they drop their eggs, one by one, in the eye or hollow at the blossom-end of the fruit, while the skin is most tender. They seem also to seek for early fruit rather than for the late kinds, which we find are not so apt to be wormy as the thin-skinned summer apples. The eggs begin to hatch in a few days after they are laid, and the little apple-worms or caterpillars produced from them immediately burrow into the apples, making their way gradually from the eye towards the core. Commonly only one worm will be found in the same apple; and it is so small at first, that its presence can only be detected by the brownish powder it throws out in eating its way through the eye. The body of the young insect is of a whitish colour; its head is heart-shaped and blackened; the tips of the fringed wings are white. The last ring is also black; and there are eight little blackish dots or warts, arranged in pairs, on each of the other rings. As it grows older, its body becomes flesh-coloured; its head, the collar, and the top of the last ring, turn brown, and the dots are no longer to be seen. In the course of three weeks, or a little more, it comes to its full size, and meanwhile has burrowed to the core and through the apple in various directions. To get rid of the refuse fragments of its food, it gnaws a round hole through the side of the apple, and thrusts them out of the opening. To fill up this hole also the insect makes its escape after the apple falls to the ground; and the falling of the fruit is well known to be hastened by the injury it has received within, which generally causes it to ripen before its time.

Soon after the half-grown apples drop, and sometimes while they are still hanging, the worms leave them and creep into chinks in the bark of the trees, or into other sheltered places, which they hollow out with their teeth to suit their shape. Here each one spins for herself a cocoon, thick, cases, as thin, delicate, and white as tissue-paper. Some of the apple-worms, probably the earliest, are said by Kol lar to change to chrysalids immediately after
The causes of mange are, sudden changes of temperature, hot stables, bad diet, joined to want of cleanliness. The perspirable matter being never properly removed by friction, and being frequently mixed with dust, &c., completely plugs up the external exhalents, whereby they become obstructed, and a diseased action taken place. It may also be caused by infectious matter coming in contact with the skin; as when a sound horse rubs himself against the stall in which a manguy horse has been kept. The principal symptoms are, the horse growing very thin, without any apparent cause, attended with a staring of his coat. This is soon followed by eruptions, which discharge a thick yellowish matter, forming a kind of scurf, which peels off, and is succeeded by fresh eruptions, and the hair falls off. This, though partial at first, soon spreads all over the body, is attended with an itching, and causes the horse to rub against every thing he comes near. In this disease great attention to cleanliness is necessary.

In the horse the following will be found the best remedy. Bleed to the extent of two or three quarts, according to the constitution of the animal, and after first preparing the horse by bran mashes, give the following dose of physic:

Barbadoes aloe — 6 drachms
Powdered ginger — 2
Castile soap — 2
Oil of carraways — 20 drops.

Honey or treacle sufficient to form a ball. After which give the following alternative balls: 2 ozs. each of powdered black antimony, powdered nitre, flour of sulphur, Castile soap, and aniseed powder, 1 oz. of rosin, added to a sufficient quantity of honey to make eight balls, one to be given every night.

The following ointment may be applied externally:

Black sulphur — 8 ozs.
Mercurial ointment — 4
Soft soap — 2
Train oil — 1 pint.

These ingredients to be well mixed, and one third part carefully rubbed in daily. If the above ointment should be found ineffectual, 4 ozs. of spirit of tar may be added.

Dogs and swine are frequently subject to mange. For the common scabby variety in the dog, the following ointment is recommended:

Powdered sulphur — 4 ozs.
Marials of ammonium, powdered — 1
Venice turpentine — 1
Lard, or other fatty matter — 6
Well mixed.

MANDRAKE. Mandragora; the name is derived from mandra, an ox-stall, something relating to cattle, and agaurus, cruel; on account of its poisonous effects on cattle, when accidentally gathered with their fodder (where the plants abound). These plants, which are natives of the south of Europe, thrive well in a light soil, in a shaded situation. They can only be increased by seeds. The roots are very apt to rot during winter. The root has an uncoth form, which is supposed to resemble the human shape; on which account it was imagined to be capable of preventing barrenness. It is, however, an acro-narcotic poison, and when taken proves fatal by the extreme purging which it causes. The common people still believe in its properties; but the root of a species of Bryony (Tamus communis) is usually sold for it in the herb shops.

MANGE. A cutaneous disease, which attacks several domestic animals, especially the dog, and which is attended with an eruption and loss of hair. In the horse it is known to exist by the animal’s constantly rubbing or biting himself, so as to remove the hair, and sometimes produce ulceration; the hair of the mane and tail frequently falls off; and small scabs may generally be observed about the roots of those which remain. This disease is seldom met with, except in common stables where scarcely any attention is paid to the horses, and where their food is of the worst quality; horses highly kept, if not properly attended to, are also subject to this disease, which is very contagious.
MANGEL WURZEL.

General Beacons, then Governor of St. Helena, writing to the English Board of Agriculture, and describing the extraordinary produce of some plants, the leaves of which had been repeatedly cut to serve as a substitute for spinach, says:—It certainly possesses advantages over every other plant hitherto introduced in the field. Its produce is immense; and I have found it to grow, with considerable luxuriance, upon land where no other vegetation was ever seen. It has also the singular property of being nourished by the dolphin-dy, which is here extremely destructive to cabbages, turnips, and radishes. I have very often observed, where alternate plants of cabbages and mangel wurzel were growing in the same rows, and touching each other, that whilst the former were absolutely annihilated by the destructive insect, not one was to be seen on the mangel wurzel leaves."

Lord Spencer reports the result of a trial on the comparative feeding properties of mangold wurzel and Swedish turnips. "Believing," says his lordship, "that mangold wurzel contains more saccharine matter than Swedish turnips, and ought, consequently, to be the more nourishing root of the two, I determined to try, practically, whether an ox fed upon mangold wurzel increased in weight more than one fed upon Swedish turnips, in proportion to the quantity of each consumed. In order to have rendered my experiment perfectly accurate, I ought to have ascertained the weight of hay consumed by each beast during the progress of the trial; but I did not do this, although I am pretty confident that the quantity consumed by each was nearly the same. I selected two steers, tolerably, and at least equally, well bred. No. 1, calved March 29th, 1823, and No. 2, calved May 6th of the same year; and on the 24th of December, 1825, I put No. 1 to Swedish turnips, and No. 2 to mangold wurzel. I ascertained their weight by measurement, and both of them measured the same, viz. 4 ft. 10 in. in length by 6 ft. 5 in. in girth, making them to weigh 668 lbs. each. On the 23d of January, No. 1 had consumed 1624 lbs. of Swedish turnips, and measured 4 ft. 10 in. in length by 6 ft. 6 in. in girth, making him to weigh 703 lbs., and to have increased in weight 55 lbs.; or at the rate of 48½ lbs. for every ton of Swedish turnips consumed. No. 2 had consumed 1818 lbs. of mangold wurzel, and measured 4 ft. 10 in. in length by 6 ft. 8 in. in girth, making him to weigh 721 lbs., and to have increased in weight 53 lbs., or at the rate of 46½ lbs. for every ton of mangold wurzel consumed.

"This difference, however, might have arisen from No. 2 having a greater propensity to feed than No. 1. I therefore now put No. 1 to mangold wurzel, and No. 2 to Swedish turnips. On the 20th of February, No. 1 had consumed 1884 lbs. of mangold wurzel, and measured 4 ft. 11 in. in length by 6 ft. 8 in. in girth, making him to weigh 734 lbs., and to have increased in weight this month 31 lbs., or at the rate of 36½ lbs. for every ton of mangold wurzel consumed. No. 2 had consumed 1880 lbs. of Swedish turnips, and measured 4 ft. 11 in. in length by 6 ft. 8 in. in girth, making him to weigh also 754 lbs., and to have increased in weight during this month 13 lbs., or at the rate of 154 lbs. for every ton of Swedish turnips consumed. I then put both to mangold wurzel, and divided the food equally between them. On the 19th of March, they had each consumed 1792 lbs. of mangold wurzel; No. 1 measured 5 ft. in length by 6 ft. 10 in. in girth, making him to weigh 784 lbs., and to have increased in weight 50 lbs.; No. 2 measured 5 ft. in length by 6 ft. 9 in. in girth, making him to weigh 765 lbs., and to have increased in weight 36 lbs.

"It would appear, therefore, as if the propensity to feed of No. 1 was greater than that of No. 2 in the proportion of 50 to 31; but, notwithstanding this, in the first month, when No. 1 was upon Swedish turnips, and No. 2 upon mangold wurzel, No. 2 beat No. 1 in the proportion above stated of 65½ to 48½. It appears as if there could be no great inaccuracy in estimating the relative weight of the animals, as, soon after the experiment was concluded, I sold No. 1 to the butcher for 54½, and No. 2, at Smithfield, for 24½."

"It will be for practical men to decide upon the value of this trial; what appears to me to be the most conclusive part of it is, that No. 2, who had during the first month, when he was feeding upon mangold wurzel, increased in girth 3 inches, in the next month, when his food was changed to Swedish turnips, did not increase in girth at all; and when, in the third month, he was feeding again upon mangold wurzel, he again began to increase in girth; because it is very well known, that, if an animal is changed from ore to less nutritious food, the probable consequence will be that his growth will be stopped. The result appeared to me so decisive that I have not tried the experiment with the same accuracy since; but I did try, the following year, the feeding a cow alternately on Swedish turnips and mangold wurzel, and though I have not by me the details of the trial, I remember that the result confirmed the experiment of the previous year."

Mr. Miles of Kings Weston, in the same volume of the Journal, p. 298, commenting on the communication of Lord Spencer, describes so fully and explicitly the best mode of culture, &c. of this root, that I cannot do better than adopt his paper entire.

"Notwithstanding the favourable results of Lord Spencer's experiment with mangold wurzel, the consideration will naturally suggest itself to the mind of the farmer, previously to his adopting the cultivation of this root, whether, although the mangold wurzel may bring on his cattle faster and better than the Swedish turnip, it is not more difficult of culture, more tender in its habits, and less productive in bulk per acre than the Swedish turnip; and I think, therefore, it may not be unprofitable to lay before the readers of the journal, first, the chemical analysis of the highest or lowest order of turnip and of mangold wurzel as given by Sir H. Davy, and of the sugar beet and orange-globe mangold wurzel as lately obtained on the same plan by the celebrated Bristol chemist, Mr. Herepath; and then to point out the system
adopted by myself in the west of England in the cultivation of mangel wurzel, which has been attended with complete success.

"By this table, it is apparent that equal quantities of Swedish turnip, orange-globe, and mangel wurzel contain very different proportions of nutritive matter, the latter more than doubling the former in quantity; and should the mangel wurzel be of equally easy culture with the Swedish turnip, it seems almost unaccountable that it should not yet have come into more general cultivation. I have grown the common red sort for six, the sugar beet for four, and the orange-globe for three years; these kinds have regularly come into course with Swedes upon light land; the product has always been equal, in most cases far heavier. The Swedish turnip has enemies innumerable; I have never observed the mangel wurzel attacked either by fly, slug, or wireworm. Equally a cleansing crop with the Swede, it stores better, and lasts good for a longer period. In the summer of this year I was using sugar beet with stall-fed cattle, which cut perfectly good and crisp in August. The mode of culture I adopt, up to depositing the seed in the ground, is the same as that adopted in Northumberland for ridging the Swede; great care, however, must be taken that the seed of the mangel wurzel is not buried too deep, or it will not vegetate. Dibbling, as you never can inoculate with equal skill does not always do the seed drill well, if properly prepared by steeping, which I should recommend, for at least 24 hours before planting. To insure, therefore, a proper depth, I have been in the habit of using an iron wheel, round the outer circumference of which, 18 inches apart, iron points project, broad at the base and tapering towards the point, about 2½ inches long; this is wheeled upon the top of the ridge, the man walking in the furrow, and thus holes are formed which can never run into the excess of great depth, and into which the seeds are deposited by women and boys following the wheel, and generally covering the seed by drawing the foot as they advance at right angles with the ridge over the holes; the roller follows, and thus the sowing terminates. One man with the wheel will keep six persons well employed in depositing the seed after him. This system was recommended to me by my friend Mr. Webb Hall, and since I have adopted it my crop has never failed.

"The after-culture and the storing is similar to that of the Swede; great care, however, should be taken in never permitting two plants to grow in the same spot, which will be the case frequently, should only one capsule even be deposited in each hole, as every capsule contains many seeds. Should the tops remain uncult, the plant will stand a considerable degree of frost; it should, however, be stored early in November; the best and cheapest method is to build it up against some high wall contiguous to your beast sheds, not more than 7 or 8 feet deep, carried up square to a certain height, and then tapering in a roof to the top of the wall; protect the sides with thatched hurdles, leaving an interval between the roots and the hurdles, which fill up with dry stubble; cover the roof with about a foot of the same, and then thatch it, so as to conduct all moisture well over the hurdles placed as a protection to the sides. In pulling the plants care should be taken that as little injury be inflicted upon them as possible; cleansing with a knife should on no account be permitted, and it is safer to leave some of the leaf on than by cutting it too close to impair the crown of the root. The drier the season is for storing the better, although I have never found the roots decayed in the heap by the earth, which in wet weather has been brought from the field, adhering to them. As to the productiveness of the different sorts, in one year I have grown a larger quantity of sugar beet per acre, in another of mangel wurzel; both these, however, I consider exhaust the land in a greater degree than the Swede; but I have formed a very high opinion of the orange-globe, though not so large a producer generally as the two other sorts; it appears always to throw at least two-thirds of its weight above ground, neither is its tap-root larger nor its fibrous roots greater than those of the Swede turnip. Care should be taken in giving cattle every species of this root, as if taken in excess it is apt to scour; indeed, from the avidity with which cattle eat the sugar beet, and from its viscous properties when quite fresh from the ground, it should be stored so as to come into consumption the last of the roots.

"In following up this I should commence with Swede turnip, proceed with the orange-globe, then with mangel wurzel, and finish off with the sugar beet; thus not only frequently varying the food, but using them in the order corresponding exactly with the nutritive matter contained in each description of plant. I have found, indeed, equally with Lord Spencer, that it will not do to return from any sort of mangel wurzel to Swede turnips, as even beasts in the straw-yard have for three days refused such a change. I may add that the earlier in April your mangel wurzel is sown the better, the deeper the theil the greater probability of a heavy crop, but that although both the mangel wurzel and sugar beet require a deeper and stronger land than the Swede turnip, yet that the orange-globe will flourish wherever the latter will succeed."

Mangel wurzel may be grown on stiffer soils than those adapted for the turnip, and it is better food for milk cows, as it does not, like turnips, give to the milk a taint. It cannot bear the cold so well as the Swedish turnip, and hence is more cultivated in the southern portions of England than in Scotland.

Mr. W. Lester (Quar. Journ. of Agr. vol. iii, p. 365) describes a method of making ale from this root.
MANGER.

A trough or crib in the stable, in which corn or cut provender for the horse is placed. The usual method is to have them the whole breadth of the stall; but this is unnecessary, as, if 18 or 20 inches in length, and 14 or 16 in breadth, they will be sufficient for every useful purpose. In the fixing of them, they should be so contrived as to admit of being removed for the purpose of being cleaned. This could, however, never be done in the old method of fixing them, but by a little contrivance may be easily effected. It is, in many cases, a convenient plan to have them in the corners or angles at the heads of the stalls. See Stable and Stall.

MANHADEN (Omphæa manhaden). A species of herring frequenting the waters of the New England States and Long Island, where it goes under the various names of Bonny Fish, Mass or Marshbunker, Harehead, and Paulitanger. The usual length of the manhaden is from 10 to 14 inches. From July to the last of August, the shores of the sea swarms with shoals of this fish, which, being very oily, is but little resorted to for food, though the better adapted for manure, to which purpose it is most extensively applied, and with such beneficial effects that lands formerly worn out so as hardly to compensate for their tillage, now yield abundant crops of wheat, grass, &c. It is taken in large numbers upon the coast of Massachusetts, where it is used for mackerel-bait, manure, and is also becoming an article of commerce. For the former purpose it is worth from $2 to $4 per barrel, in proportion to the demand. At Lynn, in 1836, 1500 barrels were used for bait for other fishes, and as many more were thrown upon the land. At Province-town they are used only for mackerel-bait. At Sandwich, where they are very abundant, the inhabitants strew them upon their lands by the cart-load; and thus, for miles, immense quantities enrich the soil. It is computed that a single manhaden of ordinary size is equal in richness to several bushels of manure. It is getting likewise to be thought worthy of preservation as an article of food. In 1832, 300 bbls. were inspected; in 1833, 480; 1834, 1008; 1835, 1443; 1836, 1488.

Mr. John Wells, of Long Island, in a communication to the editor of the Cultivator, gives the following information in relation to the mode of applying this fish as a manure, and the good effects derived from the practice.

"I have," he says, "used fish manure 40 years successively on my land is much better than when I first commenced fishing. I make use of from 50,000 to 150,000 of fish, I know here by the name of mossbankers, per annum; and could I get a million, I should have none to spare. There is no manure that I use equal to fish for a crop of wheat, and all kinds of roots; but they do not have that effect after repeating that they have at first. But this is the case with all kinds of manure. Thence the necessity of mixing manures. 10,000 moss-bankers per acre are sufficient for a crop of wheat, without any other manure. My practice is, to put on 12 or 15 large wagon-loads of litter, and 5,000 fish per acre; and then I calculate for a good crop of wheat, and after the wheat a good burden of grass for 3 or 4 years. The same quantity of manure makes a good crop of Indian corn. The manure fishery is the making of the east end of our island. I think I may say that the production of our land is 3 times as much as it was before we commenced fishing. But it must not all be attributed to fish. We exert every means to make and collect manure, for without it we cannot raise our bread. For a farmer to break up a piece of land, and lay it down poorer than it was at first, is like borrowing money to pay his interest. It is astonishing to me that there are some few farmers yet, who will let their manure lie and ferment in the yard, when they must know that they lose half its virtue; for there is no time that it brings forth vegetation so well as when in a state of fermentation under the soil. I might say that our soil is a sandy loam."

The best history of the manhaden, which is a favourite food of the whale, is by Latrobe, published in Transactions of the Am. Phil. Society, vol. v.

MANNA (Fr. manne; L. mannae). The concrete juice of the Fraxinus ornus, a species of ash growing in the south of Europe. The juice exudes spontaneously in warm, dry weather, and concretes into whitish tears; but the greater part of the manna of commerce is obtained by making incisions in the tree, and gathering the juice in baskets, where it forms irregular masses of a reddish or brownish colour, often full of impurities. Manna consists of two parts: one a saccharine, crystallizable principle, named manna, closely resembling sugar; the other an acrid, uncrystallizable principle, which is the purgative agent in the manna. This substance is now seldom used, except as a purgative for infants.

MANIOC. The Indian name of the starchy, nutritious matter obtained from the shrub Jatropha manihot, from which cassava and tapioca are made in the West Indies. See Tapioca.

MANURES. The word manure, according to Todd, is derived from the French manœuvre. Lemon gives the derivation as follows: "Manure, 'omnia a manu operando.'" Skinner—"All improvements in agriculture brought in by the hand." Webster, Eng. Dict., says, "Manure, Fr. manœuvre, but in a different sense; Norm. manœuvre, to manure; maniv, Lat. manus, hand, and oever, to work, Lat. operar." A manure may be defined to be any fertilizing compound or simple ingredient added to a soil, of which it is naturally deficient; and as all cultivated lands, by cultivation, lose lime, spilca, car' onate of lime, alumina, decomposing organic matter, and certain saline substances, it is evident that in cases where any one of these is contained in the land in insufficient quantities for the supply of cultivated vegetables, that then the addition of that substance, either in its simple or in a compound form, constitutes the great art of manuring.

Fertilizers therefore naturally divide themselves into 3 classes: 1. The earthy, which are by far the most permanent, portions of a soil, and are usually applied in the largest proportions; 2. The organic (vegetable and animal), which are the least permanent, and are used in
much smaller quantities than the earthy; and, 3. The saline, which are the most sparingly applied of all fertilizers, are the most readily absorbed by plants, and whose period of duration in the soil is longer than the organic, but less than the earthy. A manure is either useful to vegetation, by affording, in its simple or decomposed state, direct food or constituents, or else it is a fertilizer, by adding to the soil additional power to absorb and retain atmospheric gases and moisture. We shall see, hereafter, that most manures which are commonly applied to the land assist the growth of plants in both ways. Looking at the question abstractedly, it must be evident, that as animals receive almost the whole of their nutriment either directly or indirectly from the vegetable kingdom, their excrement, or their decomposed bodies, returning these to the soil, must form the best manure.

With regard to inorganic substances, clay of the earthy manures, and some of the saline fertilizers, act principally by their absorption and retention of moisture. Gypsum, it is true, enters into the composition of some of the grasses, and, in minute proportions, other salts do the same; but, if we except phosphate of lime (the earthy salt of bones), none of the salts can be considered to be a very general direct food of plants. Davy very clearly explains the desirable objects in the fertilization of soils: he says, "The plants growing in a soil incapable of supplying them with sufficient manure or dead organized matter, are generally very low, having brown or dark-green leaves, and their woody fibre abounds in earth. Those vegetating in peaty soils, or in lands too copiously supplied with animal or vegetable matter, rapidly expand, produce large bright-green leaves, abound in sap, and generally blossom prematurely. Excess of poverty or riches is almost equally fatal to the hopes of the farmer; and the true constitution of the soil, for the best crop, is that in which the earthy materials, the moisture, and manure are properly proportioned, and the decomposable vegetable or animal matter does not exceed one-fourth of the weight of the earthy constituents." (Elements of Ag. Chem. p. 264.)

Of the organic manures, those which the most readily putrefy are the most rapid in their effects; but then they are the most speedily exhausted: thus oil and fish, the most rapid of fertilizers, are exhausted by the few first crops; while bones, which decay more slowly, will last some time longer. The effect of chopped woolen rags is excellent for two years in the rich clay hop-gardens of Kent, and for three or four in the light, chalky, arable soils of the valley of the Kennet. Farm-yard dung, when applied in different states of freshness, illustrates the same position. M. Hassenfratz manured two pieces of the same kind of soil, the one with a mixture of dung and straw highly putrefied, the other with the same mixture newly made, and the straw almost fresh; he observed, that during the first year the plants which grew on the land manured with the putrefied dung produced a much better crop than the other; but the second year, the ground which had been manured with the unputrefied dung produced the best crop: the same result appeared the third year; after which both seemed to be equally exhausted. "Another experiment of the same chemist," adds Dr. Thomson, "renders this truth still more evident. He allowed wood-shavings to remain in a moist place for about 10 months, till they began to putrefy, and then spread them over a piece of ground as a manure. The first 2 years the piece of ground produced nothing more than others which had not been manured at all; the third year it was better; the fourth year it was still better; the fifth year it reached its maximum of fertility; after which it declined constantly till the ninth, when it was quite exhausted."

It is of the highest importance to the cultivator that he obtains a correct knowledge of the mode in which those manures operate which are found to be advantageous to the growth of his crops. He must discard from his mind all those false conclusions which are sometimes drawn with regard to an imaginary power assigned to plants of generating vegetable substances, for they can effect no such miraculous results. It is true that they can combine the gases or elements of vegetable matters together, and form gluten, starch, gum, sugar, woody fibre, &c.; they can absorb and arrange with these the earths and saline bodies; but the oxygen, the carbon, the nitrogen, and the hydrogen, of which the first-named are composed, and which plants usually obtain from either the atmosphere or by the decomposition of organic matter, they can no more create than they can form in the lime or the silica, which are as commonly present in most vegetables as sugar, gum, or woody fibre. Davy proved this when he made a plant of the oat grow in pure carbonate of lime, and watered it with pure distilled water. It grew but languidly, and although it had a free supply of the atmospheric air, yet the access of all dust was carefully prevented. Upon analyzing the plant, it was found to have much increased in carbonate of lime, but its silica and flint (clay), or a grain of flint being found to yield more: this Davy attributed to the loss of its husk during vegetation. (Lectures, p. 312.) Whatever earthy or saline matters, therefore, are found in vegetables, must have been either derived from the natural soil or furnished by the manures added to it—whether it be carbonate of lime (chalk), or silica (earthy matter of flint), alumina (clay), sulphate of lime (gypsum), or phosphate of lime (earthy salt of bone). It should also be a received axiom with the farmer, that there is no part of the grocer's soils, which is either animal or vegetable manure but what is, either in its gaseous or solid state, the natural food of plants: thus the gases emitted by the putrefaction of a dunghill are so much lost to the vegetable matters of the soil, and such an injury is never submitted to by the intelligent cultivator, but from an unavoidable necessity. Hence the value of green manures; for in these cases every portion of the decaying and fermenting fertilizer is gradually absorbed by the roots and leaves of the succeeding crop.

When the cultivator is in doubt with regard to the possible advantages of any manure, whether earthy, saline, vegetable, or animal,
he need only ask himself this question: Does this manure contain any constituents found in my crops, and is the land I cultivate deficient in any of them? An inattention to this consideration has been the cause of much disappointment and many mistaken conclusions: for instance, manures by application of gypsum to artificial grasses, and even to turnips, is very useful; on others it produces no effect. Strange opinions were in consequence long entertained with regard to this manure, until it was found that the soils on which it was valueless naturally contained it in abundance, and that those soils in which it did so much good were nearly or entirely deficient in this essential ingredient of clover, lucern, &c.; for it was now evident, that to add gypsum to a soil which already contained it in sufficient quantities, was as useless as to add sand to a sandy, or clay to a clayey soil.

There is little doubt but that plants derive all their constituents from the soil or the air, in either the gaseous or liquid state; that in the light they absorb carbonic acid gas and emit oxygen is well known; by this means, therefore, they readily obtain the necessary supply of carbon. The hydrogen of vegetable substances is most probably furnished by the decomposition of either water or the carburetted hydrogen emitted during the putrefaction of animal and vegetable substances. This latter seems peculiarly grateful to plants in those situations where it is copiously emitted, as near to stagnant pools, over drains, &c., where vegetation is always rank; and when present in the atmosphere, as in coal-mines, the green colour of plants growing in it is preserved even when they are deprived of light. The earthy or saline matters of vegetables, such as silica, carbonate, phosphate, and sulphate of lime, &c., are all in minute proportions soluble in water; they are found more or less in all cultivated soils, and when they are deficient, their addition, as I have before observed, constitutes the great art of manuring; but there are such endless varieties of soils that there is hardly a manure that will suit every description—each soil must be separately examined—practice is the only substitute for chemical investigations.

Thus, wood-ashes of the beech or bone-powder form excellent manures for soils deficient in the phosphates; lime, where chalk is altogether absent, and so on; and whilst we attend to the nature of the soil, we must also ever recollect, as one of the most important principles of agriculture, that whatever is completely removed from a soil by crops, must be in some way or other restored by artificial means.

That various earthy, animal, and vegetable substances, when applied to the roots of plants, accelerate their growth, has been known from a very early period; but in what manner these fertilizers serve as the food of vegetables has not been certainly determined. That they must all be in a fluid state, is supposed to be almost self-evident; thus are the attempts of Sir Humphry Davy to make plants absorb the fine impalpable powder of charcoal obtained by washing gunpowder entirely failed.

The soluble matters consumed by plants are probably, in general, absorbed by their roots unaltered, although, in other cases, decomposed during their absorption. In the experiments of Davy, he caused the roots of some plants of mint to be analyzed, which had grown both in pure water and in sugar and water. 120 grains of the roots of the mint which had grown in common water yielded 3½ grains of deep olive extract, of a sweetish and astringent taste; 120 grains of the roots which had grown in sugar and water afforded 5 grains of pale greenish, sweetish extract, not so astringent as the other. (Lectures, p. 270.) These experiments, therefore, are evidently in favour of the opinion that plants absorb many of the constituents of manures in an unaltered state, and the experiments of the late Mr. G. Sinclair with saline substances are still more decisive. See SALT.

The roots are the chief organs for absorbing the food of plants; and of the roots it is nearly established that the extremities, or spongoles, are the only parts which have the power of absorption; and hence one reason why they increase in length as the soil at their extremities is exhausted of nourishment. It is from this cause that liquid manure is so valuable a fertilizer; for in the dissolution of the excreta of animals in water, as practised so advantageously in foreign countries, and long ably recommended by Mr. Knight, the late president of the Horticultural Society, for the adoption of the English farmers, the dung is merely rendered more easily soluble by the plant, and better diffused in the land. No new compound is formed by the mixture; the action of the dung, mixed with four or five times its weight of water, is apparently much less energetic; and yet this plan is decidedly advantageous, successfully produces the most luxuriant crops, is an old practice on the Continent, is gaining ground in England, and the more it is known the oftener it will be adopted. Yet hitherto in England much too little general attention has been paid to liquid manures; by many farmers the drainage of the farm-yard and the house is generally disregarded, and allowed to escape in the best way it can, into the nearest ditch or river, being supposed to contain nothing that is the food of plants; and this, too, by the very same persons who are particularly careful in the preservation, as food for their hogs, of every portion of a miserable dish of cabbage-water. See LIQUID MANURE.

There are certain properties in which all fertilizers, to a certain extent, agree:—thus they all contain one or more vegetable constituents, and they have all a strong attraction for atmospheric moisture (the insensible vapour always contained in the atmosphere). This property is of very considerable advantage to vegetation. The comparative powers, in this respect, of various manures may be judged of from the results of my experiments, which will be found in the following table. In these the animal matters were employed without any admixture of straw. (Essay on Salts, p. 8—19.)

There is reason to conclude that some manures act as stimulants to plants, and excite them to a more vigorous growth: it is probable that the same materials are dissipated in this way, and that saltpetre and other saline fertilizers do the same. I have often occasioned to notice the increased luxuriance and productiveness of fruit trees, such as cherries and pears, by the application of common salt. (Essay on Salt, p. 4.) Priestley made similar observations. "It seems pretty plain," to give the words of Dr. Thomson, "that the vessels of plants are made to contract by various stimuli: the experiments of Coulomb and Saussure render this probable; and an observation of Dr. Smith Barton makes it to appear that plants growing in water vegetated with much greater vigour, provided a little camphor was thrown into the water. (Chemistry, vol. iv. p. 338.)"

Of the organic manures, the richest abound in azote, or nitrogen; and, in fact, there are, as Dr. Liebig observes (Organic Chem. p. 70), "numerous facts showing that the formation in plants of substances containing nitrogen, such as gluten, takes place in proportion to the quantity of this element, which is conveyed to their roots in the state of ammonia, derived from the decomposition of organic matter. Ammonia, which is composed of 14-15 of nitrogen and 1 of hydrogen, is capable of undergoing such a multitude of transformations, when in contact with other bodies, that in this respect it is not inferior to water, which possesses the same property in an eminent degree." "The employment of animal manure," he adds (p. 86), "in the cultivation of grain, and the vegetables which serve for fodder to cattle, is the most convincing proof that the nitrogen of vegetables is derived from ammonia. The quantity of gluten in wheat, rye, and barley is very different: these kinds of grain also, even when ripe, contain this compound of nitrogen in very different proportions. Proust found French wheat to contain 12-5 per cent. of gluten; Vogel found that the Bavarian contained 24 per cent.; Davy obtained 19 per cent. from winter, and 24 per cent. from summer wheat, from Sicilian wheat 21, and from Barbary wheat 19 per cent. The meal of Alsace wheat, according to Boussingault, contains 17-8 per cent. of gluten; that of wheat growing in the Jardin des Plantes 26-7; and that of winter wheat 3-98 per cent. Such great differences must be owing to some cause, and this we find in the different methods of cultivation. An increase of animal manure gives rise not only to an increase in the number of seeds, but also to a most remarkable difference in the proportion of the gluten which they contain." And he adds (p. 175), when speaking of the action of manures, "according to the common view, the action of solid animal excrements depends on the decaying organic matters, which replace the humus, and in the presence of certain compounds of nitrogen, which are supposed to be assimilated by plants, and employed in the production of gluten and other azotized substances. But this view requires further confirmation with respect to the solid excrements of animals; for they contain so small a portion of nitrogen, that they cannot possibly, by means of it, exercise any influence upon vegetation."

The following table of manures, constructed from the experiments of MM. Payen and Boussingault, showing the number of loads required in both the moist (or ordinary) and dried (or prepared) states to equal 100 loads of farm-yard dung, so far as the quantity of the nitrogen they contain is concerned, will be interesting, I think, to the farmer. (Gard. Chron.)
It is a very common error to suppose that manures of a vegetable or animal nature impart any sensible warmth to a soil; the analogy sometimes attempted to be drawn between the action of a fermenting dung-heap and some 15 or 20 loads of fermented dung, or half a ton of chopped woollen rags, spread thinly over an acre of ground, is too absurd to be admitted. Yet, although the dung does not sensibly increase the warmth of the land, the temperature of the earth, and the free access of the gases of the atmosphere have a very material influence upon the duration of the manure in the soil. Thus, in the heavy clay and deep alluvial soils it remains much longer than in the sandy, chalky, or gravelly. In the first its good effects may be traced for three or four years; in the last it is usually consumed in one, two, or at the utmost three years. To the last description of land, therefore, the judicious cultivator usually applies his compost in a half-purified state, in order that it may remain longer in the soil: this is now the practice of some of the most enlightened agriculturists.

Too little attention is paid, in general, to the mixture of manures by the farmer. This remark not only applies to those of the farm-yard,—little care being usually taken to spread evenly those of the horse, the cow, and the pig, although it is notorious to the best cultivators, what was stated by the late Mr. Blakie, in his Essay on the Management of Farm-yard Manure, that this chief of fertilizers is very considerably improved by an even mixture,—but the remark applies to almost all other manures. Thus, old heaps of weeds, pond-mud, scourings of ditches, and all the earths in which there is any organic matter, are best applied to the soil after being mingled with lime or common salt. Peat, sawdust, wood-chips, and tanners' bark, nearly inert substances in themselves, become excellent manure when mixed with stable-dung. Sprats, and all other fish, are successfully and economically added to three or four times their bulk of mould; and even bone-dust is successfully applied with a third of its weight of the dung of the sheep, and may be then drilled as advantageously with the turnip-seed as the bones in their simple state. Then, again, mixing together some kinds of manures produces, by their chemical action, a third or fourth, which is more valuable than either. Thus, when salt and lime are united together, in the proportion of one part of the former to two parts of the latter, the chemical action takes place, the mass swells, and the salt is gradually decomposed; and in the course of three months, if the heap is suffered to remain undisturbed, both the salt and the lime nearly disappear, and two new substances are formed by the combinations into which their constituents have entered, viz. soda and chloride of lime; both excellent manures. In other cases, the mere mixture of two well-known fertilizers, without any chemical action between the two, produces much greater effects than that of both when used separately. Thus, a compound of salt and stout possesses the most extraordinary fertilizing effects. The late Mr. G. Sinclair, in his Prize Essay on Salt, describes it "as remarkable," when applied to carrots; a fact which I have often witnessed myself. (My Essay on Salt for Agriculture, p. 145.) The Rev. Edmund Cartwright was the first to notice the same result with potatoes (Com. to Board of Agr. vol. iv. p. 376); and the same benefit is evident when the mixture is used as a top-dressing for wheat; in which observation my experience is confirmed by that of others. (My Essay on Salt, p. 41.) There are a few instances, however, in which substances used as manures are best employed in their simple state. Thus, seaweed, which many of the farmers on the sea-coast throw on their dung-heaps, is much better employed by itself, turned into the earth in the freshest and greenest condition; and to all green manures, and to those which contain salts of ammonia, such as urine, or the liquor from gas-works, the same remarks are applicable. See Mixture of Soils.

The proportion in which fertilizers are applied is generally unnecessarily large, even of organic manures; and although this bad practice has been regularly diminishing as agriculture has become better understood, yet much remains to be done, in preventing that wasteful expenditure of dung which is continually taking place.

It is more than probable, that the use of the improved manure-drills, by the even distribution of the fertilizer, and bringing it more closely into contact with the crop, will effect much towards this very desirable saving; for it must be evident to the most careless, that in the manner in which compost is commonly spread over a field,—suffered to be dissipated by long exposure in heaps to the sun and wind, and afterwards spread over spaces in which there are not any plants to absorb, during its fermentation, the disengaging gases, a very considerable portion of it is lost to the farmer's crops. See Manures applicable by the Drill.

It is almost needless to remark upon the importance of such investigations as these, both to the cultivator and to the botanist; nor, of the caution necessary in drawing conclusions from experiments in which vegetation is concerned. "Life," said Davy, "gives a peculiar character to all its productions; the power of attraction and repulsion, combination and decomposition, are subservient to it; a few elements, by the
MANURES.

diversity of their arrangements, are made to form the most different substances, and similar substances are produced from compounds which, when superficially examined, appear entirely different. And, as he well remarks in another place, when speaking of the subject of this article—"The doctrine of the proper application of manures offers an illustration of an important part of the economy of nature, and of the happy order in which it is arranged. The fermentation and putrefaction of organized substances, in the free atmosphere, are noxious processes; but in the surface of the ground they are salutary operations. In this case the food of plants is prepared where it can be used, and that which would offend the senses and injure the health, if exposed, is converted by gradual processes into forms of beauty and of usefulness." (Agr. Chem. pp. 54—309.) All researches like these carry with them their own reward; for not only does a successful experiment do so, but even an unsuccessful one is not unattended with advantages: it at least serves as a beacon to other cultivators, and is sure to afford to the farmer that pleasure and increased power which ever accompanies the acquisition of knowledge. (Johnson on the Fertilizers, p. 32.) See Gases, Earths, Salts, Water, Farm-Yard Manure, Bones, Chalk, Lime, Liquid Manure, &c.

(C. W. Johnson "On Fertilizers," p. 90.)

Manures, on rendering them more portable and applicable by the Drill. —The application of manures in a more concentrated form than that in which they naturally present themselves for the cultivator's service, was an effort reserved for modern agriculturists; an improvement chiefly induced by the increase of population, which almost compelled the farmer to force into cultivation the poor inland soils of England and the Continent; lands which could only be enriched by fertilizers brought from other districts, and from places where men congregated together in large masses. This necessity was, some years since, first felt and acted upon by many of the large continental cities, such as Paris, Berlin, Frankfort, and some of the other chief German towns. The contents of the cesspools were, in consequence, collected; their fertilizing matters were mixed with drying, disinfecting substances, and when thus reduced to powder, or into cakes, sold at a considerable profit. The enlightened constituted authorities of these places felt that they were, by so doing, conferring great and important benefits not only on their fellow-citizens, but upon the distant cultivator. They did not confine their attention to the farmers in their own direct vicinity; because they well knew that those, in common with the immediate agricultural neighbours of all large cities, have a ready access to an abundance of organic manures, since the cultivators so favourably situated carry their produce with facility into such populous places, and return with their carriages loaded with manure. And yet, when the German and French authorities thus harnessed,—thus rendered more portable, the manure of their large towns, they made no discovery; they merely practised what the Chinese had preceded them in from time immemorial, and what, in Flanders, is an old and long-cherished custom. The only improvement which the citizens of Paris and Frankfort have made is, that they form with their night-soil an enriching powder; while those of China and of Belgium still manufacture their manure, with a portion of either clay or marl; so that the powder of Paris can be either applied with the drill or dibble, but the Chinese and Flemings are obliged to dissolve theirs in water, before it can be used as a liquid manure with advantage. In England, however, notwithstanding the example of our neighbours, little or nothing has yet been done to render the commonest manures, such, for instance, as night-soil, more portable. The nightmen and scavengers are still compelled to hurry away their collections only at stated hours and in the dead of the night; are fined for any neglect, and harassed in all possible ways, rather than that this, the most powerful of all the animal fertilizers, should be preserved for the use of the farmer in any way that might endanger the olfactory nerves of the citizens. But an endangerment upon sensitive noses is not essential; the night-soil might be preserved without any offence to the most sensitive. But this manure has been hitherto little known or employed in this country; its powers have been misrepresented; all sorts of prejudices have been created against it. I propose here briefly to show, first, the composition and fertilizing powers of various manures; and, secondly, to examine the modes which have been recently adopted to render them inodorous and more easily portable, so as to bring them within the reach of even the farmer who has to contend with the poorest, the most upland soils of Britain, far away from its great towns. And, although I confine my attention in this essay chiefly to one fertilizer, yet there are other manures, now well known to, and extensively employed by the cultivator, whose powerful action, when judiciously used in very small proportions, well illustrates the truth of what I have so often ventured to urge upon the farmer's attention, viz., that a much smaller quantity of manure, composed of any description of organic decomposing matters, is sufficient, when applied in a skilful manner, to produce more luxuriant effects than is commonly believed. The very great importance of applying fertilizers in immediate juxtaposition with the young plant, even in very small proportions, as by the drill, is only now beginning to be considered with even patient attention; and yet there are many circumstances with which the farmer is well acquainted, which ought to convince the most inattentive that such is the fact. The small quantity of oil-cake drilled with the seed; the few bushels of bones successfully applied in the same way per acre; the woollen rags of the Berkshire farmers (half
MANURES.
a ton per acre only); the 2 cwt. of gypsum applied to sainfoin and clover; the 1 cwt. of salt-petre, or of nitrate of soda, used on the same extent of land, all indicate the truth of the case, that it is not absolutely necessary to apply fertilizers of any kind in such great masses as are commonly deemed essential by the cultivator. I was told not long since by an excellent farmer of Middlesex, Mr. George Sherbourn, that he had succeeded in producing the finest crops of turnips by merely mixing about 30 bushels of coal ashes per acre with 3 gallons of train-oil, and drilling these ashes with the seed. It is a folly, therefore, to contend that the careless way in which organic manures of all kinds are usually employed is the most economical, and susceptible of no improvement. Such complacent feelings have ever been the bane of agricultural improvement; for it is then certain to follow as a natural result, that the system which the cultivator deems perfect will, in his hands, remain as he found it. Having no hope for better things, better modes will by him never be discovered.

Some recent experiments on a very broad scale, in the forest of Darnaway in Scotland, have shown that the application of a quantity of lime under each seedling tree, even so small an amount as 4 bushels per acre, has been productive of the most excellent effects, imparting to the plantation a degree of luxuriance hardly credible. The same advantage, therefore, which is derivable from the application of a very small quantity of organic manure, in immediate contact with the growing plant, is evidently also derivable from a much smaller quantity of earthy manures than the farmer commonly supposes.

There are several advantages derivable from placing the seed in direct contact with the manure, to which the farmer very rarely attends. For instance, the germinating seed in the immediate neighbourhood of the fertilizer is by this means well nourished at the very period of its growth when it most needs assistance to enable it to develop and extend its roots. The young plant, so situated, is not exhausted in its extension; it avoids the usual fate of those crops which tenant poor soils, whose roots are obliged to penetrate some distance in search of the requisite degree of nourishment. On the contrary, the strength of the plant is thrown into the stem and the leaves, and the crop flourishes luxuriantly; for the leaves and roots of the invigorated and healthy plant are enabled to absorb the gases and vapour of the atmosphere, by which the plant is nourished in the most complete manner. The very mechanical effect, too, of placing the decomposing organic manure in direct contact with the roots of vegetables, facilitating the free access to them of the atmospheric gases and vapour, would be alone a sufficient reason for the adoption of the manure drill system, even if we say nothing of the other certain advantages of the plan, such as, in the case of decomposing fertilizers, the presentation of the gases of putrefaction to the roots of the plant, at the moment of their extraction, and the economical and foreing effects of this mode of distributing the manure. The farmer, in fact, tells us that the plan is probably a good one, but then his explanation of the derived benefit is very erroneous. He informs us, that thus to push forward the growth of the young crop is very likely to be good husbandry, especially on light soils, since, by this means, where the ground is well covered with the crop, "the moisture is kept in, and the sun is kept out." If the cultivator would but remember, that the quantity of moisture transpired by a given surface of a growing crop is considerably less than that emitted by the most naked foliage, he would no longer be content with such an explanation as this.

Dr. Hales ascertained that a cabbage transmits into the atmosphere by insensible vapour, about half its weight of vapour daily; and that a sunflower, three feet in height, transpired, in the same period, nearly two pounds weight. Dr. Woodward found that a sprig of mint, weighing 27 grains, in 77 days emitted 2543 grains of water; a sprig of spearmint, weighing 27 grains, emitted, in the same time, 2568 grains; a sprig of common sage, weighing 49 grains, evolved 3708 grains; and a lathyrus, of 98 grains, emitted 2501.

If I were asked to produce any evidence of the extreme difficulty with which agricultural improvements, even of the most undoubted value, are introduced, I should at once instance the manure-drill, the progress of which has been slow—for it has shared the fate of very many other scientific efforts: it has been zealously opposed by the ignorant, neglected by the indolent, and ridiculed by the prudent farmer, as an innovation upon the good old system of the days of the patriarchs of agriculture, when the earth brought forth its fruits in abundance, and the very seeds were not sown by man. But even here this solitary argument of the adherent to old customs fails; for the Chinese (the most expert of farmers) and the cultivators of Japan and of Arabia have drilled and dibbled in their seed from time immemorial. The natives of the Carnatic do the same; and after they have thus deposited their seed, the Hindoos, by a kind of subterranean pipe, which passes under, and looseneth, to the depth of about eight inches, the soil under, about three drills' breadth at a time. And so prejudiced are the natives of those empires, too, in favour of the customs of their ancestors—so rarely do they introduce new modes of cultiva-
tion, that it has been very reasonably con-
cluded that the drill system, so far from being entitled to the appellation of "the new husbandry," ought rather to be classed with those branches of the sciences which degenerated, or were lost in the dark ages.

Sir George Staunton, in his Account of Lord Macartney's Embassy to China, says (vol. ii. p. 375)—"Near Sanchoo, wheat was perceived growing for the first time in China. It was, though on a dry sandy soil, where no rain had fallen for the three preceding months, looking remarkably well. It was very neatly sown in drills, or dibbled, according to the method used of late in some parts of England. A gentleman of the embassy calculated that the saving of the seed alone in China by this drill husbandry, 775
which would be lost by that of broadcast, would be sufficient to maintain all the Euro-
pean subjects of Great Britain?"

In a communication to the Board of Agriculture, dated at Junacoundah, December 31, 1795, Captain Halcott says,—"The drill-plough, I find, is in general use here, and has been so long time immemorial, in the culture of all grain (except horse grain), and also of tobacco, cot-
ton, rice, and the castor-oil plant."

The first drill introduced into Europe seems to have been the invention of a German, who made it known to the Spanish court in 1647. (Horti's Essays on Husbandry.) The Roman farmers endeavoured to attain the advantages of row-culture by ploughing in the seeds.

It is useless to search in the works of Jethro Tull for any recommendation of the drill as a means of applying manure; for all Tull's arguments and experiments are directed to proving that the application of manure of any kind is utterly needless. And yet he had the discernment, when thus suffering his enthusi-
siasm to carry him too far, to make the observation, that "almost the only use of all manure is the same as of tillage, viz., the pul-
verisation, makes it more by fermentation, as tillage doth by attrition or combustion; and with these differences, that dung, which is the most com-
mmon manure, is apt to increase weeds, as much as tillage (of which hoeing is chief) destroys them." (New Husbandry, p. 166, 1st edit. 1721.)

The advantage, thus glanced at by Tull, of the manure keeping the ground light and porous, is much greater than the cultivator commonly suspects, and this benefit is mainly owing to the free access on which is thus secured of the watery vapour and gases of the atmosphere to the roots of the plants. Now, for the vapour of the atmosphere, all well-pulverised fertile earth has a strong attraction: the richer and the better divided the soil, the more copiously does it absorb vapour; but the power of the richest cultivated soils in this respect is very

much inferior to that of even the most ordinary manure. In my own experiments, I have never found, in a given space, say three hours, that 1000 parts of the richest soil, previously dried, absorbed more than from 14 to 20 parts of moisture; but in the same time, under similar circumstances, 1000 parts of horse-dung absorbed 145 parts; cow-dung, 130; pig-dung, 120; sheep-dung, 81; pigeons' dung, 50. (My Work "On Fertilizers," p. 41.)

It is evident, therefore, that for the mere purpose of with-
standing prolonged droughts, those plants whose roots have immediate access to organic manures will be much better enabled to absorb the necessary supplies of atmospheric moisture than those merely vegetating in the unmanured soil.

The merit of the introduction of the drill to general notice in England, is, however, to be ascribed, in a great measure, to Jethro Tull. Yet Jethro Tull certainly thought himself the inventor; for he tells us so very clearly, in the preface to the first edition of his Horsehoe Husbandry, published in 1731, and even whence he derived the hint for his drill; he says,—

"When I was young, my diversion was music; I also had the curiosity to acquaint myself

thoroughly with the fabric of every part of my organ; but as little thinking that I should ever take from thence the first rudiments of a drill, as that I should ever have occasion for such a machine, or practise agriculture; for 'twas accident, not choice, that made me a farmer."

But he was certainly not the originator of the idea of thus applying the seed; for, nearly a century before his time, John Worlidge, in 1669, laboured hard to draw the English farmers' attention not only to the drill, but to the manure-drill also. And little can be now added to what, 175 years since, honest John Worlidge urged in its favour, when he said, after describing the seed-drill,—"By the use of this instrument, also, you may cover your grain or pulse with any rich compost you shall prepare for that purpose, either with pigeons' dung, dry or granulated, or any other saline or lixivial substance, made dispensable, which may drop after the corn, and prove an excellent improvement; for we find, experimentally, that pigeons' dung, sown by the hand on wheat or barley, mightily advantageth it in the common way of husbandry: much more, then, might we expect this way, where the dung, or such like substance, is all in the same furrow with the corn; whereas, in the other vulgar way, a great part thereof comes not near it. It may either be done by having another hopper on the same frame behind that for the corn, wherein the compost may be put and made to drop successively after the corn; or it may be sown by another instrument to follow the former, which is the better way, and may both disperse the soil and cover the man-
ure and seed.""
petus which it will probably never lose, for with its use is now almost inseparably connected the cultivation of some of the most extensive districts of the poor light lands in the north of England; such as on the Wolds of Lincolnshire, and the sands of Nottinghamshire. See Bones.

The most recent improvement in the manure-drum is that of Mr. Grousell of Louth, for which the English Agricultural Society awarded him, in 1839, their silver medal. It is an attempt, and an excellent one too, to imitate the dibbling system, so as not only to save seed, but the manure also. And although, in all researches of this nature, it is especially necessary to proceed with great care, and to regard single experiments with caution, yet what has been yet experienced of its powers is certainly of a nature to induce farther and more extended trials; since it is evident that this drum can apply, and evenly too, as small a quantity of crushed raw bones ashes as six bushels per acre. In reply to some inquiries of mine, the inventor says,—"My drum will deposit from 6 to 100 bushels per acre of any kind of compost that may be prepared for drilling, from 10 inches to any greater distance apart in the rows, with turnips or grain, and either in a wet or dry condition; but I recommend, from experience, ashes to be applied in a wet state, especially in a dry turnip-seed season, for then the seed vegetate much sooner. Another equally excellent drop, and common drill, is that made by Mr. Hornsby of Grantham." See DRILL.

Admitting the truth of these experiments, that one-half the quantity of organic manures usually spread on the land is sufficient, when applied by the drum, in immediate contact with the seed, what a field is thus opened for the manuring of much larger breadths of land than has hitherto been deemed possible. The complaints of the deficiency of manures, which are now so prevalent with farmers, need then no longer be heard. Their crops will be properly nourished, and the manure applied with them will be not only bestowed in the most scientific manner, but it will lead to other improvements; it will enable the farmer to mix his manures, according to the nature of his soil and his crop, with much more facility than at present: he will then study, not merely the economy to be regarded in its distribution, but also its quality, or chemical composition, and to what soils the manure is best adapted.

There is one class of fertilizers, however, where the application of the drum requires great caution; I allude to the saline manures, for they are often much too powerful in their operation to be safely applicable in their pure state or in large proportions. Common salt has, in this way, carried great destruction by being drilled in with the seed, and I have witnessed equally disastrous effects from applying the lime of the gas-works (sulphuret of lime) in the same way. Yet when the seed-wheat is wetted with a nearly saturated solution of salt, and then rolled in lime, or the salt and lime are mixed and bones boiled being spread upon these for three months, and then sown on the land broadcast, or when the gas-lime is previously mixed with four or five times its bulk of sifted mould or ashes, then I have seen the most excellent effects produced by its being drilled with the turnip-seed: the same remarks apply to the chloride of lime of the calico-bleachers. Other salts, whose action is less energetic, or which are applied in very small proportions, are perhaps more readily utilized by the substance, saltpetre, which is rarely applied in larger proportion than 1½ cwt. per acre, may very likely be still further reduced in quantity, especially if mixed with other substances, such as three or four times its bulk of mould. Mr. Beadell of Witham, in Essex, a very excellent farmer, has found, that where saltpetre was applied to his turnips broadcast as a top-dressing, it did not succeed, but it did so very decidedly when it was drilled with the seed.

In those situations where night-soil, or sprats, or bones cannot be obtained at a sufficiently reasonable rate, very great effects may be produced by the careful collection of the excrements of domestic animals, and mixing them with merely a sufficient quantity of dry ashes, mould, saw-dust, or, what is best of all, recently prepared finely powdered charcoal, to render them sufficiently friable to pass the drill: this is very easily accomplished, by making the preparation under cover some months before it is used, and, if necessary, by causing it to be spread in the sun. By the adoption of these means, a very recent mixture will be found available by the farmer; the excrements of the horse, cow, and especially the sheep (still more so if fed with oil-cake), will be found excellent for this purpose. And in very small proportions the Peruvian farmers, according to Humboldt, employ the guano, or excrements of seabirds (which abound in phosphate of lime, or earthy salt of bones), which is brought in sailing vessels, from the rocky islands of the Pacific, expressly for the use of the cultivators of that republic. See Guano.

And that bones might be very profitably mixed with other fertilizers, so as to materially reduce the expense of the manure, is indicated by more than one successful experiment. To give another instance, which has recently been communicated to me, in the trials made by Daniel Dixon, Esq. of West Clandon, in Surrey. "On a poor chalk soil," observed an excellent and scientific friend of mine, "he has used a compost for a manure-drum for turnips with great advantage. He puts 8 bushels of ground bones with 24 bushels of any ashes he can get together in a dry place, and from time to time (as often as possible) he empties the liquid sewerage of the house upon it. In two or three months it is fit for use, working well out of the drum. The above is the quantity for an acre. The effect of drilling this mixture with the seed was very remarkable, and as bone-manure was drilled by the side of it, the contrast was at once visible; the difference was more than double. In fact, the bones by themselves seemed comparatively useless. The soil on which the mixture has been applied is poor, chalky, and flinty, abounding upon the sheep-walks and chalked race-course. Whenever the mixture is too wet for the drill, it is spread to dry for a day or two."
of Henry Dixon, Esq. to the Author, November, 1839, and March, 1840.

"A friend of ours, a farmer in Northumberland," says the excellent editor of the Quarterly Journal of Agriculture, "the late Mr. George Brown, Hetten Steads, mixed any quantity of coal-ashes, kept dry, and finely ridded, with a quarter of bone-dust per acre, and raised as good a crop of turnips (of course drilled) of all kinds, on a clayey soil, resting on a retentive bottom (but drained), as he could with two quarters of bone-dust." Mr. Turner of Tring, in Hertfordshire, drilled with his crushed bones an equal quantity per acre of manure, consisting for the express purpose, at an expense of 2½d. per bushel paid to the collectors: this he prepared in the winter, by laying the bone-dust in alternate layers with sheep-dung, and suffering them to remain fermenting some months until the turnip sowing. By this plan, by the fermentation of the mass, the two manures are thoroughly incorporated; and he considers that 35 bushels of the mixture are fully equal in effect to 25 bushels of the bones. So that, allowing 3½d. per acre for the expense of collecting the sheep-dung, there will be a clear saving of 12½d. per acre in bones, valuing these at 2s. per bushel. The mixed bones and sheep-dung are invariably drilled in with the turnip-seed.

The application of rape-cake powder by the drill has never been so common as it ought to be, for it is not only a very powerful, but a very easily manageable fertilizer; it has, moreover, the advantage of being moderate in price, and easily attainable at all seasons of the year. There is no doubt of the advantage of feeding stock with this food, the manure they produce when thus fed being exceedingly rich. Many farmers, however, owing to the want of cattle, or an unwillingness to lay out the requisite money in a long course of stall-feeding, are deterred from using oil-cake to the extent they would otherwise do. The use of the oil-cake powder conveys to the land all the enriching ingredients of this fertilizer at once, and to the exact extent the farmer requires; there is neither the waste, the risk, or the trouble of stall-feeding to be dreaded. The oil remaining in the cake certainly constitutes its most enriching portion; the oil abounding in sprats is an instance familiar to the farmer, and when this oil is imperfectly crushed out, the cake produced (as is well known to the Swedish cultivator in the case of herring-cake) is found to be exceedingly enriching. A very small quantity of oil left by the crushers in the cake will produce very great results; even three gallons of train-oil, as I have mentioned in another place, has been found amply sufficient per acre, when mixed with earth or ashes, to produce a capital crop of turnips. It has been found (and this is another illustration of the value of the manure-drill), that when rape-cake is drilled with the turnip-seed, 3½ cwt. per acre is sufficient, but if it is applied broadcast, then double the quantity is required. My friend Mr. Davis, of Spring Park, in Surrey, is well aware of the powers of oil-cake as a manure; he has found it even an advantageous plan to drill common coal, wood, or turf-ashes, at the rate of 40 bushels per acre, with his turnip-seed; and this he has successfully practised for some years, so much is he in favour of bringing the seed and the manure into immediate contact.

In proceeding to examine, as an instance of one of the least likely substances successfully applied by the drill, the properties of night-soil, and the modes which have been adopted to reduce its weight, without impairing its effect, many reflections will suggest themselves to the farmer. He will notice that such a process, by producing it in the state of powder, renders it capable of being readily drilled with the seed; and that the same remarks apply in a great measure to the excrements of the farm-yard, to whale-blubber, and to fish. The Essex farmers find, that when sprats are mixed with earth, finely divided, the mass, when these very oily fish are quite dissolved in the mould, forms a very powerful fertilizer, which is excellent as a drill-manure for turnips. They tell you, that the sprats lose none of their enriching powers, even when thus kept mixed with earth for some months.

Even earthy manures may be advantageously reduced in weight by exposure to the air, or by the application of artificial heat. Chalk, I have found by experiment, loses from 15 to 25 per cent. of its weight by being thus deprived of its water; and a cubic foot of calcareous sand, when thoroughly wet, contains, according to M. Schubler, more than 31 lbs. of water; the same measure of sandy clay, 38 lbs.; loamy clay, 41 lbs.; stiff clay or brick-earth, 45 lbs.; pure gray clay, 49 lbs.; garden-mould, 48 lbs.; and fine slaty marl, 53 lbs. By exposing the earths to an intense heat, their weight is still further reduced by the loss of their carbonic acid gas or fixed air; hence 100 parts of chalk, for instance, when thus treated, lose very commonly 24 parts of water and 34 parts of carbonic acid; so that 42 lbs. of lime, when well burnt, contain as much real earth as 180 parts of chalk. All these facts are such as the cultivator should be thoroughly acquainted with; for, in many cases, the earth which the farmer removes might be previously very advantageously dried, by exposure to the action of the atmosphere. Even the difference of labour to the men and horses, between carting them after continued dry weather and in wet periods, is much more material than the cultivator commonly believes.

My attention, however, will, in this place, be principally confined to fertilizers of an organic nature, and more especially to night-soil. Night-soil has not, in any form, been employed by the farmers of England to the same extent as on the Continent, although it is certainly by far the most powerful of the organic manures, and the most easily rendered applicable by the drill of any of the class. To this neglect many causes have contributed. Its disagreeable odour, certain vexatious fiscal regulations with regard to its removal, to which I have before alluded, and the erroneous modes of applying it, either in excessive quantities, or mixed with other composites in such proportions that its powers could not be distinguished in the mass; its semifluid nature requiring for its removal
MANURES.

Manures of a peculiar construction; the extent and completeness of the sewerage of our large cities, and several other minor obstacles, have rendered its use not nearly so extensive as, even in a national point of view, is desirable. (See Night-soil.) And yet the necessity for increasing the supplies of manures, in order to promote the fertility of the soil, will be self-evident to every one who remembers, not only the increasing population of the country, but the immense drains upon its organic fertilizing matters which are hourly pouring their contents into the sea. Thus, as I have elsewhere remarked, by carefully-conducted experiment it has been clearly ascertained that the principal London drains convey daily into the Thames 115,000 tons of mixed manure, consisting, on an average composition, of one part solid or mechanically suspended matter, and 25 parts absolutely fluid; but if we allow only 1 part in 30 of this immense mass to be composed of solid substances, than we have the large quantity of more than 1200 tons of manure daily wasted in the river from London alone.

What might not the farmers of England effect if this mass of fertilizing matter was preserved, at a reasonable rate, for their use! 15 tons of this solid manure—nay, 10 tons, would render fertile an acre of the poorest cultivated, or even common or heath land. But allow, for the sake of argument, that 20 tons were required, even then 3800 would give a daily allowance of manure sufficient for 150 acres of the poorest land in England; and if we give 300 days on an average, which is not more than the manure daily wasted in the river from London alone, we might afford an annual supply for fifty-four thousand of such acres, which land would not again need manuring for 4 years; and in this calculation nothing is allowed for the fluid portion of the drainage. It is the reckless waste of the drainage of our large cities and towns, which has alone prevented the cultivated lands of England from becoming increasingly fertile, because yearly more abounding in organic decomposing matters. For such is the enormous yearly import of foreign products into this country, that it must tend to rapidly increase the natural fertility of the soil of England, since all their ingredients ought and do, in some measure, eventually find their way as a manure upon the land; thus, in 1834, were imported into the United Kingdom, according to a parliamentary report, now before me, of—

So that, including corn, oil-cake, timber, &c., &c., at least 1,000,000 tons of vegetable matters alone are yearly imported from foreign countries into the United Kingdom, and added to the riches of the soil; thus our merchants are annually fertilizing, while the Commissioners of Sewers are in an equal ratio impoverishing the island. But against this great fertilizing import, we have at present to set off the large and ever-flowing drainage of the cities and towns of the United Kingdom; not only London, but Liverpool, Manchester, and a hundred others, are incessantly pouring the riches of the land into the sea; and to such an extent is this done at Bristol, that the Court of King's Bench was obliged, not long since, to interfere to protect the inhabitants from the nuisance created by the non-removal of the city drainage from the bed of the Avon.

On the Continent, the use of various manure powders made from night-soil is equally extensive and successful. An elaborate report upon these was made a short time since to the Directors of the Thames Improvement Company, by Dr. Granville, who had been commissioned to make the requisite inquiries and surveys; and from this we learn that the consumption of night-soil in Flanders is very large; but that the farmers, instead of transporting and using it in the dry and powdered state, rather prefer to mix it with water, and thus form a rich liquid manure. Of late years, the French farmers have adopted the same views with regard to night-soil; but the practice of their farmers, in this respect, is somewhat different. They prefer, for the sake of easy and convenient transport, to dry the stercoral substances to powder, which, bearing the name of poudrette, is sent into the country from the neighbourhood of the capital, and is sold at a high price. The success of the establishment for the manufacture of poudrette, first formed near Paris about 40 years since, by a person named Bridet, has been such that in almost every part of the kingdom similar manufactories have been erected, and nothing now is wasted. The Parisians have at present several such large works. M. Bridet obtained a patent for his process of manufacturing the poudre vegetatif. He proved, by experiments, that the poudrette is many times more valuable than the best sort of ordinary manure; that it was land, after repeated trials, that 240 lbs. of the poudrette would manure an acre of ground with greater effect than 8 cart-loads of the best stable manure.

Under the name of "Alkalino-vegetative Powder," another preparation of night-soil was ushered into notice in France, and gradually adopted, under the auspices of an agricultural lady, Madame Vivert Duboul, to whom, in consequence, the Royal Society of Agriculture, in 1814, awarded their gold medal. This lady obtained a patent of 15 years for her process, which consisted in promoting fermentation in the most liquid portion of the excrementitious substances, and treating them with slaked lime afterwards, so as to form a powder, which has been found to be very superior to the first-named poudrette upon cold, light, or moist soils. Its action is very powerful, and it extends its influence over the soil for several years without requiring, during that period, a repetition of the manuring process. This is not the case with the poudrette of Bridet, the influence of which over any soil is only annual. M. Hermstadt gave, in the Monthly Journal of the Economic Society of Petersham, for August, 1838, 779
as the result of his experiments instituted with the view of ascertaining the comparative fertilizing powers of farm-yard manure and poudrette, that poudrette is a complete substitute for common dung, whether with respect to price or quality."

In 1818 a company was formed near Paris (Messrs. Donat & Co.), for the manufacture of another kind of manure from night-soil. The name of "urate" (from the principal ingredient used) was given to it, and the Royal Society of Agriculture deemed it an object of sufficient importance to deserve being submitted to the examination of a joint committee of chemists and agriculturists, in which were included the names of Vanquelin, Dubois, &c. The report made by these distinguished men is full of interest to the agriculturist. Urine is the active ingredient, and plaster of Paris (gypsum), so common in the neighbourhood of that capital, the other constituent. This mixture is reported by the joint committee to have been one of the most powerful, if not the most powerful, manufactory to have been subjected to its effects upon the dullest soil, that they recommend that it should only be employed by skilful and discriminating farmers. For this discovery the inventor received a gold medal from the government. A powerful manure of the same name is now extensively prepared by the "London Manure Company," of 40 New Bridge street. It abounds with the salts of ammonia, phosphate of lime, and the animal matters of urine. It appears, also, from the fine, dry state of powder in which the "urate" is delivered, that it is admirably adapted for application by the drill with the seed. The quantity applied per acre is about 5 cwt.; and, as it is almost entirely composed of organic matters, phosphate of lime (earthy salt of bones), sulphate of lime (gypsum), and various salts of ammonia, it is evidently a most powerful fertilizer, as well adapted for turnips as for the grass and grain crops. I have had an opportunity of inspecting the manufactury of this company, and from the care displayed in its preparation, the "urate" will, I think, be rapidly and extensively employed by the farmer.

In some recent reports of trials with this manure upon turnips, I observe that Mr. Anderson, of Oakley, Bedfordshire, describes it as proving "itself quite equal, if not superior, to the farm-yard manure. The land I used it on was a sharp gravel, and was much out of condition previous to the present crop. The 6 tons were drilled with Swedish turnip-seed, 18 inches apart, on 18 acres."

Mr. Manning, of Elstow, says, "I drilled a ton of urate upon 8 acres, in rows 17 inches apart, upon a very hot, gravelly soil; each side abutting on this was manured in the usual way, with good farm-yard manure, about 14 loads per acre. The turnips on the urate were fit to hoe 7 days before the manured part; from their first appearance, a stranger could point out the spot where it commenced and ended; the difference is still evident, and in its favour. Both the manured and urate pieces were sown the same day, about the 14th of June. I certainly consider it a good artificial dressing, and its fertilizing properties great."

In 1820, another patent was granted to a M. Loques, by the French government, for a manure called "stercorat," consisting of a mixture of both the solid and liquid parts of the excrementitious matters, and some earthy substance. It is said to be particularly efficacious, and sells at a very high price.

M. Parmentier, a celebrated French agricultural writer, some years since expressed his surprise at the tardiness of his countrymen in adopting the practice of their Flemish neighbours, and in continuing so long to pay money for getting rid of that which other nations first, and the French themselves afterwards, found to be so productive of wealth. He quotes the case of an individual who in former times had amassed great wealth by the sale of a manuring powder, which he manufactured from the very soil he was annually paid by government to remove out of the extensive military barracks of Lisle.

There existed at one time much public prejudice against this mode of rendering the land more fertile; but it is now proved that it is a joint manufactory and of the most obvious principles of such a manure would form part of the plants raised by means of it; but the most accurate experiments have proved, that not the least vestige of such animal substances is to be detected either in the ascending sap, or in the more solid parts of the plants so cultivated. A great extent of the rich plains of Normandy are fertilized every year by the manure powder manufactured at present out of the cess-pools of Paris.

The poudrette sells for eight francs the entier on the premisses, and the whole is fetched away at that price as soon as ready, and principally distributed within 12 leagues of Paris. Now, as there are 73 sesters in a ton, it is evident that the value of the latter is 60 francs, or 2L 10s.; and yet the comparative agricultural value of this compost is not so great as that of the "Flemish manure." Messrs. Payen and Company, the patentees of the "engrais animalizé," or disinfected night-soil, sell their "poudrette" at 23 francs per ton under the market price of charcoal, and they have rarely any left on the premises.

The engrais animalizé, or disinfected night-soil, has recently been introduced into England by M. Poitevin, and a manufactory of it established in Whitechapel, near London. It is there produced by mixing the night-soil of the metropolis with a considerable quantity of recently prepared charcoal powder, and drying the mass in a very gentle heat. As thus prepared, its appearance somewhat resembles that of the friable, rich, vegetable mould of an old hothed; it is of very dark colour, and totally devoid of smell. Its introduction into England has been too recent for any very extensive trials to have been yet made with it; my own are only now carrying on; these, however, promise well. In some comparative experiments made last year with bones, they were found to answer very completely. These results have been confirmed by several communications with which I have been recently favoured, stating that, to use the words of Col. Challoner, "this manure, in its effects upon the turnip crop, was fully equal to bones." And Mr. Beach, of Oakley Hall, near Basing-
MANURES.

stoke, who had applied it by the drill with the seed, at the rate of 14 bushels per acre to a portion of a field of turnips; and, on another portion, drilled three sacks per acre of crushed bones, mixed with turf-ashes; and, on a third portion, with ordinary stable manure, says, in February last, "It is impossible to distinguish any difference between the three, some persons fancying one part, and some another, to be superior. In their early growth, the night-soil had a decided advantage. The seed came up as thick as rows of mustard-seed in a hot-bed, and the turnips were hoed out within a month." Mr. Beach adds a suggestion, which I think highly worthy of the attention of the turnip cultivators:—"I am so well satisfied with it for turnips, that I shall use a large quantity of the night-soil powder this season. I shall also mix 10 or 12 bushels with a quarter of crushed bones, which I am inclined to think will answer well." I have recently been shown a letter from Mr. Robert M'Crea, of Grange House, near Londonderry, in which he speaks of this manure in the highest terms, as a dressing for turnips; those thus treated having carried off last year the first prize offered by the Londonderry Farming Society.

A preparation of night-soil has been lately imported into Scotland and the north of England from Copenhagen, under the name of Owen's animalized carbon, which has answered, when applied by the manure drill, very well for turnips. Mr. James Waldie, in his recent prize communication to the Ayrshire Agricultural Society, describes it as a useful, auxiliary manure, and as likely, in a great measure, to supersede the use of bones, now that the latter have risen to the enormous rate of at least 3s. per bushel. He says, "One ton of carbon, the cost of which is 3l., is sufficient for an acre of land; and from experiments which I have made this year, conjoined with the accounts of numerous farmers in the neighbourhood, on a farm in this neighbourhood, where comparative trials were made with different manures, on a very extensive scale, it may be inferred, that one ton of carbon is equal to 25 bushels of crushed bones." These experiments are supported by the observations of Mr. M. Milburn, of Thorpefield, near Thirsk, when describing, in his report to the Yorkshire Agricultural Society, the various fertilizers advantageously employed on light lands in the cultivation of turnips; for, he observes, "Animalized carbon has been used advantageously; 16 bushels per acre, which is a sufficient quantity generally employed. Pigeons' dung is most valuable; rape-dust has been used successfully; malt-dust is useful as a top-dressing." There is a chemical "seed manure" prepared by Messrs. Hodgson and Simpson, near Wakefield, which is applied, mixed with water, as a liquid manure, or steep to the seed-corn, and seems, from a communication with which they favoured me in March, 1840, to be a kind of secret preparation, composed principally of saccharine matter, ammonium, common salt, and nitre. This seed manure is applied according to the following directions,—instructions which might be advantageously followed in the use of other fertilizers: "Dissolve 28 lbs. of this manure in a pail, by adding water in small quantities, stirring it at the same time, until the mixture is of the consistence of thick cream; it is then to be poured over the quantity of seed intended to be sown on an acre of land, and the whole repeatedly turned over, so that it appears one uniform mixture; it is then to be spread out thin on the floor to dry for 10 or 12 hours, and mixed with a sufficient quantity of sot, or any kind of dry ashes, to render it sufficiently friable to be sown by the hand or by the drill." The quantity thus directed to be applied per acre, is certainly very small, and yet, according to the testimonials which I have seen, the effect it produces is considerable. Mr. Milburn, of Thorpefield, in one of these, tells us: "A new principle in the application of manure has been developed in the use of the chemical seed manure, which, by applying a chemical composition to the seed itself, not only secures immediate effect in the precise situation required, but highly economizes the quantity necessary. I have great pleasure in detailing a very successful experiment with it on a barley crop. The field had grown a corn crop the preceding year—part of the field was dressed with a coating of fermented farm-yard dung—the remaining part with the chemical seed manure, at the rate of 28 lbs. per acre. The result was, that the barley sown with the chemical manure exhibited a decided superiority over the rest of the field, in colour, healthiness, and general appearance, and maintained that superiority to the time of cutting, so much so, that it lodged considerably more than the rest of the field."

Various modes besides those to which I have alluded, have, at different times, been suggested, by which night-soil might be rendered more concentrated and more portable. Simply drying it has been attempted with some success; but though by this means about 70 per cent. of water is obtained, yet the smell, and a considerable portion of ammoniacal and other gaseous matters are vaporized: thus the manure is impoverished, while the stench of the operation is intolerable. Then, again, it has been mixed with lime, in the way recommended by Davy; but judging by my own experiments, and those of my neighbours, I am fully persuaded that this is not the most economical way of using night-soil. The lime certainly dissolves, and partially decomposes it, but the fertilizing effect of a given weight of night-soil mixed with lime is clearly not so great as when similar quantities of it are used either by itself, or mixed with some merely drying odour-absorbing substance. There are several preparation of this kind made in large quantities in London, such as those of Mr. Clarke, and of Mr. Lance, the author of the Golden Farmer, all of which, I believe, are excellent manures; but I have not had an opportunity of examining any of their manufactures except those of the London Manure Company, and of the Messrs. Poitevin. The preparation of these gentlemen is the same as that so successfully carried into effect in France; it combines, and successfully so, the great object of driving off the water of urine and night-soil by a gentle heat, after all its gaseous matters have been
absorbed, by mixing with it a portion of newly prepared carbon, in the finest possible state of division, than which no known substance has such great powers of absorption of all gaseous matters like those which abound in and impart the disagreeable odour to night-soil. These purifying powers of coalhave been long known; the medical man applies it in purulent cases, the housewife rubs it powdered over her tainted meat, and the sailor chars the inside of his water-casks for a similar purpose. The presence of the carbon in the manure thus prepared is valuable in two ways; gradually it combines with the oxygen of the atmosphere, forming in the state of carbonic acid gas the food of plants; and, at the same time, all the gaseous matters of putrefaction with which it is saturated are thus preserved, stored up, as it were, for the service of the roots of the cultivator's crops; nothing is lost, the emission of the gases from the slowly dissolving charcoal being so gradual as to be almost, if not entirely, imperceptible to the senses.

Such, then, are the principal facts already ascertained with regard to the fertilizing uses of night-soil and other decomposing manures, in their ordinary form, and when reduced by various processes to such a state of dryness, so as to be easily applied in the state of powder to the soil by the drill. In thus investigating the advantages of rendering manures more concentrated, I have been induced chiefly to confine my attention to one only of the organic manures, night-soil, because, from its nature, cheapness, and powerful effects, it affords, perhaps, greater facilities for accomplishing this important object than any other excrement, and is, besides, more commonly wasted than any other fertilizer. I hardly deem it necessary to make any remarks upon the importance of all researches which tend to the better understanding of the powers and best mode of employing manures, for with such investigations is inseparably connected the gradual and steady increase of the productiveness of our country. Such improvements, too, are full of interest, not only to the cultivator, but to every one to whom the vegetable kingdom is an object of importance. And, as I have elsewhere had occasion to remark, it is hardly possible, in reflecting upon the essential use of organic fertilizers in the production of our food, to avoid being impressed with the wisdom and beneficence of the Creator, in thus making decomposing noxious organic substances the nutrient of vegetation, rendering the very animal substances which the grass once formed, its food when dead. This interchange of their elements, so essential to each, is equally incessant and remarkable, the death and decomposition of the one ever imparting fresh food and life to the other. Thus the same gases which are at one moment constituting the noxious products of putrefaction, are in the next existing in the exquisite aroma of the flower. These facts are, indeed, too apparent to escape our observation; and the rapidity with which the advantage of these magic vegetable combinations cannot but excite both our curiosity and our gratitude.

(Quart. Journ. of Agr. vol. x. p. 142.)

Manures. History of. See the heads Ashes, 782

Farm-yard Manure, Bones, Chalk, Lime, Green Sand, &c. The application of manures became one of the sustaining arts of life as soon as man was ordained to earn his bread by the sweat of his brow. From that time to the present, the art of manuring the soil has been steadily improving; and there is no doubt but that it will go on advancing, as long as mankind continue to increase.

The first manure used by man, as soon as he began to dwell in fixed habitations and till the land around him, would, of course, be that of his domesticated animals; but he is naturally averse to labour, and consequently this operation would be postponed until the rich alluvial soils, which would be certainly the first selected, were exhausted by over-cropping, and by the increase of population the poorer descriptions forced into cultivation; the occupier of the land would naturally avoid, if possible, the trouble of spreading the dung of his farm-yards over his fields. Instances of this kind have not been wanting in recent periods in the newly settled rich prairies of America, in which many cases have occurred where, in consequence of the enormous accumulation of dung around the farmer's sheds, he has been induced to remove his buildings to a new spot, rather than undertake the greater labour of removing the masses of fermenting manure which so deeply encumbered his old farm-yard. The first rude mode in which this was conveyed to the land, was naturally by hand-baskets, or by sledges or barrows; the use of beasts of burden was necessarily a later agricultural improvement; and, at first, there is no doubt but that manure was carried on their backs to the fields, as is even now practised in the mountainous districts of the Continent, and in some parts of the north of England, and in Devonshire. Dung-carts were a much later improvement; and the preparation of compost heaps, and the using of the manure in the form of manure by the use of the fork, has been a much more modern discovery than is usually believed.

Irrigation, which is a mode of applying the weakest of liquid manure, by the use of the waters of rivers, is of a very ancient date. It has been used from a very early period in Italy and the East; in fact, in many warm, sandy countries, as in China, a copious supply of water is an essential requisite for the successful cultivation of the earth. Water-meadows were first constructed in England, on a tolerably regular system, about the termination of the 17th century. Some of the most excellent of those in Wiltshire, such as those in the Wyley Bourne, were made between the years 1700 and 1705; and about half a century afterwards, the celebrated Craigintinny meadows were formed near Edinburgh, by which the town drainage is rendered available in the production of the most luxuriant crops of grass. These meadows were considerably enlarged towards the end of the 18th century, and again in 1821. These might be very advantageously imitated in the neighbourhood of other large towns.

Amongst the Egyptians and Israelites, whose climates were hot, a plentiful supply of moisture was necessary for a healthful vegetation;
and the simile of desolation, employed by Isaiah (chap. i. 30), is, "a garden that hath no water." In Egypt they irrigated their lands, and the water thus supplied was by an hydraulic machine, worked by men, in the same manner as the modern tread-wheel. To this practice Moses alludes, when he reminds the Israelites of their sowing their seed in Egypt, and watering it with their feet; a practice still pursued in Arabia. (Deut. xi. 10; Niebuhr's Voyage en Arabie, i. p. 121.)

Of their knowledge of manures we know little. Wood was so scarce that they conserved the dung of their animals for fuel. (Parkhurst, p. 764.) Perhaps it was this deficiency of carbonaceous matters for their lands, that makes an attention to following so strictly enjoined. (Levi, xix. 23; xxv. 3. Hosea x. 12.)

Agriculture was too important and beneficial an art not to demand, and the Greeks and Romans were nations too polished and discerning not to afford to it, a very plentiful series of preceding deities. They attributed to Ceres, as the Egyptians did to Isis, the invention of the art of tilling the soil. Superstition is a prolific weakness; and consequently, by degrees, every operation of agriculture, and every period of the growth of crops, obtained its presiding tutelary deity. The goddess Terra was the guardian of the soil; Sterculius presided over manures, &c.

Xenophon recommends green crops to be ploughed in, and leguminous plants to be raised for the purpose; "for such," he says, "enrich the soil as much as dung." He also recommends earth that has been long under water to be put upon land to enrich it. Theophrastus, who flourished in the 4th century B.C., is still more particular upon the subject of manures. He states his conviction that a proper mixture of soils, as clay with sand, and the contrary, would produce crops as luxuriant as could be effected by the agency of manures. He describes the properties that render dung beneficial to vegetation, and dwells upon composts. (Hist. Plant. ii. c. 8.) He also recommends the stubble at reap-time to be left long, if the straw is abundant; "and this," if burned, will enrich the soil, not only much, it may be, but much more, and mixed with dung."

From the outline which we can draw from ancient authorities of the agriculture of the Romans, we shall be surprised to find how little they differed from the methods we now employ. We are superior to them in our implements, and consequently in the facility of performing the operations of tillage; but of the fundamental practices of the art they were as fully aware as ourselves. No modern writer could lay down more correct and comprehensive axioms than Cato did, in the following words; and whoever strictly obeys them will never be ranked among the ignorant of the art. "What is good tillage?" says this oldest of the Roman teachers of agriculture. "To plough. What is the second? To plough. The third is to manure." (Cato, 61.) In his 4th chapter he thus expresses his conviction of the utility of manure: "Study to have a large dung-hill, keep your compost carefully; when you carry it out, scatter it and pulverize it; carry it out in the autumn. Lay dung round the roots of your olives in autumn." And in his 29th chapter: "Divide your manure; carry half of it to the field where you sow your provender, and if there are olive trees, put some dung to their roots." In his 37th chapter he advises the use of pigeons' dung for gardens, meadows, and corn lands, as well as *amrca, or dregs of oil: and recommends the farmer to preserve carefully the dung of all descriptions of animals. This was advice given 150 years before the Christian era; and now, after the lapse of 2000 years, the direction must be still the same. We learn from Columella (i. 6) and Pliny (xxvii. 9; xxv. 19) that they collected their manure and stored it in covered pits, so as to check the escape of the drainage; and sowed pulverized pigeons' dung, and the like, over their crops, and mixed it with the surface-soil by means of the sarelle or hoe. (Colum. i. 16; Cato, 36.) They were aware of the benefit of mixing together earths of opposite qualities, and sowing lupines, and ploughing them in while green. (Varro, i. 28.) Virgil is very particular in describing fertilizers. With common manure he mentions ashes (Georg. lib. i. 80), pumice-stone, and shells. (Lib. ii. v. 346, 50, and in v. 250, 8.) He advises the seeds of corn to be mixed with saltpetre and the dregs of olive oil, to make the grain swell. (Lib. i. 195.) Irrigation was employed in his days. (Lib. i. 106, 9.) The Italian farmers also fed down over-luxuriant crops (lib. i. 3), and burned the stubble. (Lib. i. v. 84, 8.)

Varro (lib. i. c. 38) mentions many kinds of animal manure, and is particularly minute in his enumeration of the dung of birds, and includes even that of blackbirds and thrushes kept in aviaries.

Columella (lib. ii. c. 5) advises the cultivator not to carry out to the field more dung than the labourers can cover with the soil the same day, as the exposure to the sun does it considerable injury; and he enumerates (lib. ii. c. 15), as well-known fertilizers, night-soil, the excrement of birds and urine, (especially for apple-trees and vines), dregs of oil, the excrements of cattle, the ass, the goat, the pigs, ashes, chopped stalks of the lupine (or hop), leaves of trees, brambles, &c. and mud from sewers or ditches. Pliny also mentions that lime was employed as a fertilizer in Gaul, and marl in the same country and Britain; but we can only surmise thence, that they were also probably employed by the Romans. (Pliny, xvii. 5.)

Liquid manure is not a mode of fertilizing the land altogether of modern origin. For a fermented mixture of water and night-soil has from a very early period been employed by the Chinese farmers. Those of Italy certainly practiced irrigation in the days of Virgil (Georgic. lib. i. v. 106, 9); and Cato adds, they employed a mixture of grape-stones and water to fertilize their olive trees. (Lib. xxxvii.) Columella praises very highly the use of stale, putrid urine for vines and apple-trees (lib. ii. c. xv.); commending also the lees of oil for the same purpose. More modern agricultural authors have united in praising various liquid preparations; thus Evelyn (whose ingredients most of
MANURES.

these authors recommend), in his Treatise on Earth (p. 123—160), gives several recipes, some of which have served as the bases for recent modes of preparing liquid manure; such as the dung of cattle, urine, salt, and lime, nitre.

The employment of crushed bones as a manure is but a very modern improvement; it is not one of the fertilizers even mentioned by the early agricultural writers; and to this neglect of bones several causes contributed. The necessary machinery for crushing them was, in the early ages of agricultural efforts, totally unknown; and bones when unbroken dissolve in the soil much too slowly to be of any apparent value as a fertilizer. The use of bones is an improvement, for which agriculture is entirely indebted to the enterprize of the English farmers. The refuse matters produced by the ivory and bone turners and cutters of Sheffield, which speedily accumulated in very considerable heaps around their manufacturies, first drew the attention of farmers to bones as a manure. The cultivators of the poor soils in the neighbourhood of that town, towards the conclusion of the last century, began to carry away these refuse matters with some readiness, and the turners were at first too glad to be relieved from this bone-rubbish, to think of charging them any thing for the valuable manure they had been the first to employ. As, however, the Yorkshire farmers soon began to scramble for these bone-turnings, the manufacturers of Sheffield speedily made a small charge for them, which has since gradually increased in amount. It required, however, some time to bring about this great and successful improvement. Mr. T. Ellin, late master cutler of Sheffield, well remembers, some fifty years since, the bone refuse carted into Sheffield Moor, and buried in pits as worthless rubbish; these old deposits, often found in digging foundations, are now carried off with much alacrity to the bone-crushing mills. The farmers at first gave sixpence a bushel for these parings and turnings; of these about 600 tons are annually sold in Sheffield. By the sole use of this fertilizer, great breadths of very poor land have been successfully brought into cultivation, and maintained in a state of the greatest fertility in the north and east of England and Scotland. Their effects upon the wolds of Lincolnshire has been magical. The first person, perhaps, who successfully used the roughly broken bones from the dog kennel as a manure was General St. Leger, in 1775. (Evelyn's Sylvae, by Dr. Hunter.)

Manuring with fish was necessarily an improvement of an advanced state of agriculture; we have no mention of them as thus used in the early agricultural authors; the immense shoals of sticklebacks, and other small fresh-water fish, which once tenanted the fen counties of England, first gave the farmers of Lincolnshire an opportunity of using this rich oily manure; they were towards the latter end of the eighteenth century sold by the fen fishermen at about sixpence a bushel; and Arthur Young tells us, that at one village on the borders of Cambridgeshire, 2800I. have been taken for these fish in one season. It is not often that a glut of herrings, pilchards, or other valuable fish, enables the farmer to obtain them at a rate sufficiently reasonable for his land, a purpose for which they have often, however, been employed with the most luxuriant effect on the coasts of Scotland and Cornwall. Sprats, and the fish called five-fingers, are used to a great extent by the Essex farmers; the demand for these has of late years been fully equal to the supply, although from the evidence given before a Committee of the House of Commons in 1833, it seems that during the season more than 400 boats are employed in catching these fish, for the purpose of selling them as manure.

Manuring with calcareous sand was practised very early in the middle ages by the English farmers. This they obtained not only from inland pits, but from the sea-shore, especially in Norfolk and Cornwall. The privilege of freely taking it from the sea-shore, the West of England farmers enjoyed under a grant from Edward the third to the cornwall, confirmed by another of 45th of Henry I. As this is expressed in the preamble of the act of the 6th James II. c. 18, A. D. 1609, which says, "Whereas, the sea-sand by long trial and experience hath been found to be very profitable for the bettering of land, and especially for the increase of corn and tillage within the counties of Cornwall and Devon, where the most part of the inhabitants have not commonly used any other worth for the bettering of their arable grounds and pastures." This act, which empowers the farmers to take this sand free from any toll, was, after being several times renewed, made perpetual by the 16th Charles L., c. 4. This wise encouragement of the use of manures by the legislature of England has not been confined to the sea-land of Padstow harbour; thus, uncruushed bones passing through a turnpike to be crushed for manure are exempt from toll; and carts loaded with common manure are equally free; or even when going empty to fetch it; but this exception does not extend to lime. And in authorizing the construction of railways, parliament has carefully provided, that the tolls levied upon the manures conveyed by them shall be much smaller than those demandable for any other description of goods: thus, in the Birmingham and Gloucester Railway Act, the authorized toll is, for manure of all kinds, only one penny per ton per mile; while coals, &c. are to pay three-halfpence, sugar twopence, cottons and other manufactured goods, threepence per mile. The same proportionate rate of tolls are authorized to be taken on several other railways, such as the Birmingham and Derby, the Midland Counties; and on the Eastern the difference in favour of the farmer is still greater; for while limestone, sand, and clay are to pay a penny, and all other manures three-halfpence, coals are to pay twopence, sugar, &c. fourpence, and manufactured goods sixpence per mile. Saltpetre is, perhaps, the most ancient of all the saline manures, and its introduction is not, as is commonly believed, a modern improvement. It is commended by Virgil as a steep with olive oil, to make the seed-grain swell. To this knowledge of the fertilizing powers of
MANURES.

...the early cultivators of the earth were probably assisted from noticing that those soils which naturally produce salt-petre are ever found to be of the most fertile description, and that all those rich and loamy soils which are so celebrated in Palestine for their fertility, abound in this salt. Three centuries since, according to Googe, it was employed by the German farmers. "Some saie colowrts prospereth best in salt grounde, and therefore they use to cast upon the grounde saltpetre or ashes." In 1676, Evelyn, in his Discourse on Earth, tells us, "rains and dews, cold and dry winters, with store of snow, which I reckon equal to the richest manures, impregnate as they are with celestial nitre," which, although an error, yet displays his opinion of the fertilizing power of nitre. "I firmly believe," he adds, "that were salt-petre, I mean fictitious nitre, to be obtained in plenty, we should need but little other com posts to meliorate our grounds." Evelyn recommends salt-petre to be used in solution, three pounds of this salt to fifteen gallons of water mixed with earth. And in this way Sir Kenelm Digby made some barley grow very luxuriantly by watering it with a very weak solution.

It must be, perhaps, difficult to name any other substance in the catalogue of modern fertilizers whose powers have been so often disputed as common salt. For this controversy many reasons may be assigned. It has been generally employed with little scientific accuracy, has been tried in a manner far too careless for any reliance to be placed upon the majority of the reports which have been furnished to us, and for many years a prohibitory duty rendered it inaccessible to the farmer; an impost which has not very long been removed, and which yet was the occasion of a great variety of blundering trials, miscalculated experiments. The duty on salt was indeed one of long continuance. It originated, as a war-tax, in the ninth year of the reign of William the Third, and was not removed until after an arduous debate at the end of that of George the Third. The price of salt, thus raised to more than 20s. a bushel, was in consequence too expensive a fertilizer to be employed by the English farmers. During that long period it was known only in their traditions. Through these they were told that it was formerly used to kill worms and to destroy weeds, that it cleansed fallows, increased the produce of light arable soils, and sweetened grass. These reported advantages were rendered more probable by certain facts that had been forced as it were upon their attention. Every gardener was aware that the brine of the pickling tubs, when poured over his heaps of weeds, not only killed those weeds and their attendant seeds and grubs, but that these heaps were then converted into so many parcels of the most fertilizing manure, whose good effects, especially upon potatoes and carrots, were universally admitted. It was well known, too, that a single grain of salt, placed upon an earth-worm, speedily destroyed it; that if brine was poured upon a lawn, from that spot all the earth-worms were immediately ejected; and that if it was sprinkled over a portion of the grass, on this salted portion all the deer, or sheep, or horses of the park constantly repaired, in preference to any other part of the field. Salt evidently therefore destroyed weeds and worms, and rendered grass more pruned and manure-field; and upon consulting the old agricultural writers, it was found that the notices of salt as a manure were many and important, and that salt had been employed in various agricultural operations from a very early period. Thus, it is referred to by St. Luke, chap. xiv. 34; Virgil reproubes a salt soil; Cato recommends it for cattle, hay, straw, &c.; as does Virgil (Lib. iii. v. 394). The early German farmers knew of its value for sheep; and for the same purpose, in Spain, it has been employed from the earliest ages. In 1750, Conrad Herebaseh commends it as a certain prevention of the "murrain or rotte." In 1653, Sir Hugh Platt speaks of salt as a fertilizer, in his usual visionary manner, and details the result of a very successful experiment on a "patch of ground" at Clapham, from which some late writers upon the uses of salt have led their readers into great blunders, by stating this experiment to have been performed upon an acre of land.

The use of salt by the cultivator, since the repeal of the duties in 1823, has been considerable, however, in many districts of England, in spite of these blundering instructions, ill-conceived experiments, and ignorant conclusions. If to this be added the natural difficulty of obtaining correct results in any experiments in which vegetable life is concerned, we need no longer be surprised that many contradictory statements have been made with regard not only to salt, but to all other fertilizers.

A mixture of salt and lime was recommended as a manure by the celebrated German chemist, Glauber, in his "Hints for the Prosperity of Agriculture," more than two centuries since. He at some length described the mode of preparing it, and characterized the compound of soda and chloride of calcium produced as "most fit for dunging lands, and to be used instead of the common beasts' dung." (Prosperity of Germany, vol. i. p. 417.) Christopher Packe, who, in 1688, published a huge folio translation of Glauber's works, enforces the value of this fertilizing compound with much earnestness in his preface, describing it as "the cheapest of all mixtures for the enriching of poor and barren land." The want of scientific knowledge amongst farmers, and the hindrance to the use of salt through the duties which were so long imposed upon it, naturally prevented any extensive use of this fertilizer; yet there have been many accidental or occasional notices of its value. Thus, for a great many years, it has been the practice of the farmers of Essex, and other English maritime counties, to steep their seed-wheat in sea-water, strengthened with salt, until it is of a sufficient gravity to float an egg; and then roll the brined seed in lime. This treatment not only causes the smut to fall off, but promotes the general health and vigour of the plant. The Essex farmers have a tradition that this plan was discovered by the accident of a farmer's labourer dropping a sack of seed-wheat from the boat in which he was crossing the mouth of the River
Crouch. It was long, however, the superstitious belief of the district, that the salt-water wetting must be the result of accident to produce a good effect. The Cornish farmers have for centuries used the saline calcareous sand of the coasts of Devon, which contains 64 per cent. of lime, fetching it for some miles from the shore, in preference, says Dr. Paris, to the unsalted sand, which they can procure at their own doors. The very mixture of salt and lime was successfully employed in Ayrshire many years since. And George Sinclair, in 1818, very nearly demonstrated at Woburn the value of this application. He unfortunately, however, applied the salt and the lime separately, yet still with considerable benefit. (C. H. Johnson’s Essay on Salt, p. 40.)

The use of salt and lime was noticed in the year 1800, by Mr. Holingshead, of Chorley, in Lancashire, who observes, “Lime prepared for manure should be slacked with salt springs or salt-water; lime so slacked will have a double effect.” In 1804, in the experiments of the late Rev. Edmund Cartwright, upon potatoes, of 25 manures, or mixtures of manures, salt and lime were found superior, in their product of potatoes, to 19 others. And in 1816, Mr. James Manley, of Anderton, in Cheshire, when giving his evidence before a committee of the House of Commons, on the salt duties, mentioned that in getting marl (which is a mixture of carbonate of lime, alumina, and silica), he had found that, by mixing it with brine instead of water, the portion of the field on which the brined marl was used yielded 5 bushels of wheat per acre more than that portion on which the watered marl was employed.

The use of ashes as manure may be traced to a very early age. The Roman farmers were well acquainted with paring and burning. Cato recommends the burning of the twigs and branches of trees, and spreading them on the land. Palladius says, that soils thus treated would yield in any other culture for years. They also burnt their stubbles—a practice common amongst the Jews in Palestine. The ancient Britons, according to Pliny, were used to burn their wheat-straw and stubble. and spread the ashes over the soil; and Conrad Herebach, a German counsellor, in his Treatise on Husbandry, published in 1575, which was translated by Googe, tells us (p. 20), “In Lombardie they like so well the use of ashes, as they esteem it far above doeing, thinking doeing not meete to be used for the unwolesomness thereof.”

_Gypsum, or sulphate of lime, when employed as it exists in an impure state in ashes, which owe all their virtues to the gypsum they contain, was used by the early Italian farmers. Virgil (Georg. l. i. 80) gives the following injunction:—

—_Neve

Effectus cinerum immundam lacte per agros._

“Nor hesitate to scatter the dirty ashes over the exhausted soils.” And he also recommends, in addition to ashes, two other remedies (lime, and marl), and gelbarum cum stipulis incisum (the turning up and burning the stubble). Robert Ainslie, steward to the celebrated John, Earl of Stair, at Culhorn, in Wigtownshire, had very nearly discovered the agricultural advantages of gypsum in 1728; for in that year the Earl sent from London several hogheads of peat-ashes, which abound in sulphate of lime, with directions for their use, describing them to Ainslie as being much employed in the south of England as an admirable top-dressing for the grass and root crops of tillage lands, which were used, according to his lordship’s directions, with great success, on both barley and grass lands. Ainslie, convinced of their fertilizing properties, immediately began to burn turf, moss, and peat, for the use of the farm under his care, in considerable quantities; he, moreover, submitted these ashes to what he very ludicrously calls an analysis, and gravely tells us, that “with a great proportion of earthy substances, they contained many particles of lime or shelly matter.” This was most probably the gypsum.

The use of the mineral gypsum as a manure was discovered in 1768, according to Kirwan, by M. Meyer, a German clergyman of great talents; but as in those days the chemical composition of gypsum was totally unknown, he naturally confounded it with other calcareous earths which it resembled in appearance. His merit consisted in discovering the use of a certain mineral substance existing in his own neighbourhood, which was long afterwards shown to be sulphate of lime, but of which fact Meyer was entirely ignorant. Even as early as 1792 gypsum was tried very successfully by Mr. H. Smith, of Highstead, near Sittingbourne, who first noticed, what has since been confirmed by numerous observations, that clover manured with gypsum is always preferred by horses and cattle to all other clover.

Sir Joseph Banks recommended this substance as a fertilizer to Lord Leicesteer, and, at his suggestion, it was tried at Holkham many years since, which owing to management in its application, it did not then appear to answer the intended purpose. Some years afterwards, owing to the warm recommendation of Mr. Grisenthwaite, it was again employed pretty extensively by the same nobleman, and with great success; and so satisfied was this great friend of agriculture with the result, that he presented Mr. Grisenthwaite with a piece of plate for his exertions in its introduction. In a letter with which I was favoured from the Rev. R. Collyer, dated Holkham, October 17th, 1837, that gentleman tells me, “Lord Leicester wishes me to say, in regard to gypsum, that its effects, when applied to clover and sainfoin, have been invariably such as to induce him to speak from his own experience in favourable terms of that fertilizer.” It has since been gradually creeping into use in the east and south of England. Mills have been erected for grinding it, and considerable quantities have been brought from the northern counties; but still not one-thousandth part of the quantity is employed in agriculture that would be used if its advantages were more generally known; since, from the small quantity used per acre, and the low price of the article, it constitutes one of the cheapest of the artificial manures.
MANURES.

From this sketch of the history of the chief manures, and of the steady improvement in the mode of applying them, we may safely conclude that, as regards the cultivation of even the most barren soils, the drifting lands of Norfolk, the heath-lands of the north of England and Scotland, and even the shingle of its sea-coast, much will yet be effected by improved modes of applying manures. Let such improvements proceed; let science go hand in hand with practice; let the naturalist discover new cultivable vegetables, or new varieties of those already known; let the chemist yield his magic aid to demonstrate the best mode of promoting their growth, and increasing the fertility of the soil; and then I fearlessly assert that many more than the present inhabitants of Britain may be amply supported by the produce of the land of our birth. "Nature," said Davy, "amidst all her changes, is continually directing her resources towards the production and multiplication of life; and in the wise and grand economy of the whole system, even the agents that appear injurious to the hopes and destructive to the comforts of man are, in fact, ultimately connected with a more exalted state of his powers and his condition. His industry is awakened, his activity kept alive, even by the defects of climates and seasons. By the accidents which interfere with his efforts he is made to exert his talents to look farther into futurity, and to consider the vegetable kingdom, not as a secure and unalterable inheritance, spontaneously providing for his wants, but as a doubtful and insecure possession, to be preserved only by labour, and extended and perfected by ingenuity." (Lectures, p. 267.)

Manure, Law with regard to.—In most English farm-leases there are covenants introduced with regard to manure, which are often worse than useless; encumbering the efforts of the skilful cultivator, and rarely improving the prospect of the ignorant, lazy, and unprincipled. Thus, by some leases the farmer is allowed, on certain conditions, to sell his straw and hay, and bring on to the farm in its stead a given weight of manure (commonly 2 tons of stable-dung for a load of straw, and 3 tons for a load of hay); in others he is restrained from selling either; in others, from liming or chucking his land. In most leases he covenants to spread the manure on the farm, and to leave it, in the concluding year of his term, properly laid in heaps, if it is not already employed on the land.

The mere relation of landlord and tenant is a sufficient consideration for the tenant’s promise to manage a farm in a husbandlike manner, and not to carry away any straw, dung, compost, &c.; but to promise to spend 60l. worth of manure every year, is not in law an obligation arising out of the bare relation of landlord and tenant. A tenant from year to year, under a notice to quit, cannot remove manure, except according to the custom of the country; and, if necessary, he may be restrained by force. The custom of the country is usually followed with regard to the management and sale of manure; but in case there is a written agreement, no inquiry can be made as to the custom of the country; and when an express stipulation is made, the custom of the country is excluded entirely. In this case Lord Lyndhurst said, "The outgoing tenant was bound by the custom of the country to leave the manure on the premises, and was entitled to be paid for it by the landlord, or the succeeding tenant; but in the case they did not rely on the custom. The lease contained a covenant that the tenant, on quitting the farm, should not sell or take away the manure which should be in the fold, but should leave it to be expended on the land by the landlord or his succeeding tenant. It is to be left for their use, and there is no provision as to any payment in respect of it. We are of opinion, therefore, that the plaintiff is not entitled to be paid for the manure." But where an agreement is silent as to the question of manures, then the custom of the country is valid in law. If the outgoing tenant has covenanted with his landlord to sell the manure to the incoming tenant at a valuation, and to leave it on the farm, the outgoing tenant has a right of on-stand on the farm; and if the incoming tenant remove the manure before such valuation, he is answerable to the outgoing tenant in an action of trespass. A tenant may sell or assign over manure to an assignee, although he thereby subjects himself to an action of covenant. And it is a reasonable custom for the landlord to pay the outgoing tenant the expense of manuring. If a tenant, during his tenancy, removes a dunghill, and at the same time digs into and removes virgin soil that is beneath it, his landlord may maintain either trespass de bonas asportatis, or trover, for the removal of the virgin soil. But if a tenant covenants to sufficiently muck and manure the land, with two sufficient sets of muck, within the last six years of his tenancy, the last mucking to be within the last three years, this covenant is satisfied by the tenant laying on two sets of manure within the last three years of his term, if he shall think fit to do so.

In valuing manure to an incoming tenant, much depends upon the custom of the country, which is usually followed in these cases. Land which has been rendered perfectly clean by a year’s fallowing, is denominated a full tillage, and by tillages the valuation is commonly made.

In estimating the value of manure in arable land, it is done by allowing a full tillage after a fallow or crop of turnips fed off; after a white crop, half a tillage; but after two white crops no allowance at all.

For bones one tillage more is valued than for dung, on arable soils; two-thirds of the value of the bones, and labour of procuring and spreading them, being allowed after one white crop, and one-third of the value after two white crops. Soot, rape-cake, oil, sprats, &c., which are quickly exhausted in the soil, are allowed for as one full tillage before a crop grown, or after turnips, &c., eaten off; but if the turnips, &c., have been carried off, then only one-third of the cost of procuring, carrying, and spreading is allowed.

For early manures more is allowed in a valuation than for those of a perishable nature. Thus, on pasture land, lime, chalk, or
MANURES, ARTIFICIAL.

MAPLE.

Acer, from the Celtic ac, a point, the wood having formerly been much sought after for manufactures requiring in texture, hard, and strong fibres and lances). The maples are for the most part beautiful trees, of considerable size, generally employed in forming avenues or the back of shrubberies. The soil they delight most to grow in is open sandy loam, in which also cuttings will strike freely in the open air; or they may be increased by layers put down in the autumn: but all the best plants are obtained from seed, which should be sown soon after gathering. There are a great many species of maple; but two only, with some varieties, are common to Britain:

1. The greater maple or sycamore (A. pseudo-platanus), which grows in hedges and about houses, common, but not truly wild. It is a large, handsome tree, of quick growth, with a smooth ash-coloured bark, and round spreading branches. The wood is white and soft, useful for many purposes, such as making musical instruments, cheese and cider presses, tables, mangles, and some parts of machinery; but is chiefly employed by coopers. The sap is said to yield some portion of sugar, and to be made into wine in the Highlands of Scotland.

The sycamore is propagated entirely by seed. The principal cultivated varieties are, the yellow variegated sycamore, or Costophine plane (Ae. p. flava-variegata, London), the white variegated leaved sycamore (A. p. varie-gata, London), and the purple-leaved variety.

2. The common or field maple (A. compesvtra). This is a common tree in hedges and thicketes, but is rather rare in Scotland and the north of England. It is of much more humble growth than the preceding, with more spreading branches; the bark corky and full of fissures; that of the branches smooth. The wood is compact, of a fine grain, sometimes beautifully veined, celebrated among the ancient Romans for tables, though now superseded by mahogany, and even by our native oak.

The Norwegian maple (A. platano-sideae) has latterly been classed among British forest trees. It is a tree of the first rank, thrives well in England, and attains a height equal to that of the sycamore within a like period of years, it is a decided acquisition to park and woodland scenery, and its wood appears to be of more value, and adapted for a greater variety of purposes, than that of the sycamore, being white, close-grained, firm, susceptible of a fine polish, and frequently exhibiting the beautiful appearance in the direction and disposition of the fibre, for which the bird's-eye maple of America is so highly prized and sought after. The foliage, though not so heavy and massive as that of the sycamore, is unbranched; the leaves, which in shape bear a striking resemblance to those of the Platanus occidentalis, are large, the slender petals, and, when fully expanded, of a fine, shining light-green; in an early or half-expanded state, they are of a delicate yellowish-green, and in autumn, before they fall, become of a rich, warm yellow.

MAPLE.

Trimmer's Compost for Turnips, per cwt., 8s. Urate, per ton, 51.

Watson's Compost, per cwt., 10s., in quantity, 91. per ton.

A. MAPLE.

Are commonly valued for six years after they have been spread on the land. This includes prime cost, carriage, and labour in spreading in full, when laid on not more than a year; two-thirds of the value if spread within two years; one-half in three years; one-fourth in four years; and one-sixth in five years: but when lime is used on arable lands, it is commonly valued in the same way as farm-yard manure.

When compost is in the heap, it is usually valued in cubic yards, the value of which necessarily varies; it may be estimated, however, commonly as of the same value as half a bushel of wheat. (Woodfall, by Harrison, p. 529; Bayldon on Reints; Gratner and Kennedy on Tillage.)

The custom of the incoming tenant paying for the dung varies in different counties. In the following counties he wholly pays for all dung on the farm: viz. Essex, Kent, Northumberland, Nottingham (artificial manure), Rutland, Stafford, Suffolk, Surrey, Sussex, Wrexmorland, and the West Riding of York. In the other English counties the dung is usually left free of charge to the incoming tenant. This, in Scotland, is called holding in steel-bow.

See Customs of Counties.

MANURES, ARTIFICIAL. A great many fertilizing compounds are now prepared in large manufacturing establishments specially devoted to the purpose; and these are extensively used upon the various field crops to which they have been found best adapted. The basis of many of these is night-soil, such as poudrette, &c. The virtues of others depend upon various salts of potash and soda. The following list of the leading articles of this kind now prepared and extensively used by the English farmers, with the prices at which they are vended, cannot but be interesting to the American agriculturist. It forms an ordinary advertisement in a London newspaper:

- Agricultural Salt, per ton, 30s. to 22s.
- -- -- fine, per ton, 31s.
- Alexander's Compost, per bushel, 1s. 10d.
- Bleaching Powder, per cwt., 30s.
- Bone-dust and half-inch Bone, per quarter, 15s.
- Brimstone, per ton, 11l.
- Clarke's desiccated Compost, per bbl., 31s. 12d.
- Darnell's Bristol Manure, according to quantity, per bushel, 10d.
- Guano (foreign), per cwt., 10s. to 12d.
- Potter's English, according to quantity, per cwt., 15s. to 14s.
- Gypsum, according to quantity, per ton, 30s. to 42s.
- Hart's New Fertilizer, per bushel, 1s. 5d.
- Moriate of Ammonia, per cwt., 21s. to 26s.
- Lime, per cwt., 12s.
- Nitrate of Soda, according to quantity, duty paid, per cwt., 17s. 6d. to 18s. 5d.
- Petre Salt, per ton, 31s. 16s. to 5l.
- Phosphate of Ammonia, per lb., 1s. 9d. to 2s. 3d.
- Phosphate of Soda.
- Policey's disinfected Manure, per quarter, 13s. 6d.
- Potassium and Concentrated Manure, per cwt., 22s. 6d.
- Rape-dust, according to quantity, per ton, 71s. 10d.
- Rock Salt, per ton, 51., in quantity, 31.
- Sulphate, per cwt., 22s. 6d.
- Silicate of Potash (pure), per cwt., 65s.
- Soda Ash, per cwt., 14s.
- Sulphate of Ammonia, per cwt., 13s.
- -- of iron, per ton, 1s.
- -- of soda, per ton, 7l.
- Sulphur, per cwt., 16s.
- Sulphuric Acid, according to strength, per lb., 14d. to 21d.
- Trimmer's Composition for Clover, per cwt., 8s.
- Urate, per ton, 51.
- Urine, per cwt., 31s.

Potash, per cwt., 31s.
There are many species of maple found in the North American forests, which are generally lofty and beautiful trees. They are capable of enduring the most intense cold, and therefore form in the north of the new continent, as they do of the old, extensive forests, which, with those of the beech, appear to succeed the spruce, the larch, the pine, and to precede the chestnut and oak. Michaux gives 7 species of maple to Europe, and 7 to America, exclusive of the dwarf red maple of the Northeastern States, and the species found in the Northwestern territories.

The wood of the maples differs so widely in quality in different species, that it becomes difficult to characterize it by general observations. It may be remarked that it speedily decomposes and decays when exposed to the weather, that it is liable to be injured by worms, and that hence it is unfit for building. It possesses properties, however, which compensate in part for these defects, and which render it useful in the arts and domestic economy.

The American maple is not only flower but mature their seed during the spring months. These are—the white maple (Acer griseum) and the red-flowering maple (A. rubrum). In the other kinds, the fructification is autummal, namely— the sugar maple (A. saccharinum), black sugar maple (A. nigrum), moose wood, or striped maple (A. striatum), box elder, or ash-leaved maple (A. negundo), mountain maple (A. montana).

Some of the inhabitants of the Western States make sugar by boiling down the sap of the white maple, which, however, like that of the red maple, yields only half the proportion of sugar obtained from the juice of the sugar maple. The sap is in motion even earlier in the white than in the sugar maple, beginning to ascend about the middle of January.

The red-flowering maple is the earliest tree whose bloom announces the return of spring, the beautiful purple blossoms unfolding more than a fortnight before the leaves. It never attains its full size except in swamps where the bottom is composed of fertile soil, and it affords the wood commonly used in the manufacture of Windsor chairs.

The moose wood maple of the Eastern States was so called by the first settlers, from observing that the moose fed upon its twigs during the latter part of winter and beginning of spring. Although it fills the forests in Nova Scotia and Maine, it becomes rare on approaching the Hudson, to the west and south of which river it is confined to the mountainous tracts of the Alleghanies, on the cold and most shaded sides of which mountains it extends to their termination in Georgia. Where it mostly abounds, its principal advantage to the inhabitants consists in furnishing them, at the close of winter, when their forage is exhausted, a resource for sustaining their cattle, till the advancing season has renewed the herbage. As soon as the buds begin to swell, the famished horses and neat cattle are turned loose into the woods, to browse on the young shoots, which they consume with avidity. Poor as this resource may appear, it is not wholly inadequate, since the twigs are tender, and full of sweet juice. This species of maple is much admired in European parks and gardens, particularly on account of its variegated trunk. When grafted on the Sycamore, as is commonly the case, the striped maple grows to nearly four times its ordinary size.

The box elder, or ash-leaved maple, is common in the states west of the Alleghanies, and rare to the eastward of these mountains. It is the species which ventures least to the north, not being seen on the Delaware higher than the neighboring state of Philadelphia. It is chiefly found in low bottoms where the soil is deep, fertile, and constantly wet. Even in such situations it seldom attains more than 50 feet in height, and 20 inches in diameter.

The mountain maple abounds in Canada, Nova Scotia, and along the whole range of the Alleghany mountains, preferring the northern sides, and the moist, coolest, and most shady situations, on the abrupt and rocky banks of torrents and rivers. It seldom is more than 6 or 8 feet high, and is most frequently in the form of a shrub, with a single, straight stock. Like the moose wood, this maple is frequently grafted on the sycamore (A. pseudo-platanus), by which means it is increased to nearly twice its natural size. This surprising development proves how great are the advantages which may be derived from this process, and from continued cultivation, in improving inferior vegetables.

But by far the most interesting tree of this family to the American is the sugar maple, which in the north begins to appear a little north of lake St. John, in Canada, and within the 48° of latitude, which in the intensity of its winter cold corresponds to the 68° in Europe. It is nowhere more abundant than between the 46° and 43°, which comprise Canada. New Brunswick, Nova Scotia, the states of Maine, New Hampshire, and Vermont, where it enters largely into the composition of the wide-extending forests. Farther south, it is common only in Genesee, in the state of New York, and in the northern highlands of Pennsylvania. Dr. Rush estimated that in the northern parts of these two states there are 10,000,000 of acres which produce these trees in the proportion of 30 to an acre. In some places large masses of woods are formed of them almost exclusively. In Virginia and other Southern States, the tree is comparatively rare, and only to be found in mountainous situations. In those sections of country where the sugar maple most abounds, they distinguish the kinds of soil into what are called black, or soft wood lands, comprising the pines and spruces covering the low grounds and valleys, and the hard wood lands, consisting of leaf-shedding trees, such as the sugar maple, the white and red beech, the birch, and the ash. These last occupy the level grounds. Above the 46° of latitude, the maple and other trees of the hard wood class begin to be rare, and the pines and other resinous trees take their place. Below 43°, the spruce and other soft wood trees are less common, and lose their preponderance in the forests, where they become mingled with the numerous species of oaks and beech.

Black sugar maple. In the Western States,
and in the parts of Pennsylvania which lie between the mountains and the Ohio, this species of maple is called the black sugar tree, probably on account of the colour of its leaves being darker than those of the genuine sugar maple. In the Genesee country of New York, both species are indiscriminately called sugar maple, and the trees have also been confounded by botanists. In the Northern States, the black sugar maple is inferior in size and also more rare than the true sugar maple. A few degrees farther south, it forms a large part of the forests of Genesee, where it is one of the most common and most lofty trees. The wood is much like that of the other species, but coarser grained and less brilliant when polished. It is comparatively but little used, because, wherever it abounds, other trees are found, such as oak, the walnut, cherry, and mulberry, more esteemed for building and cabinet work. It is, however, preferred for the frames of Windsor chairs, and, after hickory, considered the best of fuel. It forms one of the finest shade trees, assuming, when standing alone, a regular and beautiful form. (Michaux.)

The sugar maple covers a greater extent of the American soil than any other species of this genus, flourishing most in mountainous places, where the soil, though fertile, is cold and humid. Under such favourable circumstances it is often found 70 or 80 feet high, and proportionally large in diameter. It is one of the most beautiful native trees, and distinguishable by the external whiteness of its bark. The grain of the wood is fine and close, and when polished it has a silky lustre. It is very heavy and strong, but wants the property of durability for which the chestnut and the oak are so highly esteemed. Exposed to moisture it soon decays. The different forms of this wood furnish the most admired nudulated or curly maple, and the highly esteemed and still more beautiful spotted variety called bird’s eye maple.

The wood of the sugar maple makes good fuel, for which purpose it is extensively used in Boston and other northern cities. The ashes afford a large proportion of the alkaline principles, and, it is asserted, furnish four-fifths of the potash exported in such abundance from Boston and New York to Europe. The extraction of sugar from the maple is a valuable resource in a country where all classes of society daily make use of tea and coffee. The process by which it is obtained is very simple, and everywhere nearly the same. Though not essentially defective, it might be rendered still more perfect and profitable than is commonly the case.

The work of sugar-making commonly begins in the month of February, or early in March, whilst the cold still continues intense and preserves the ground firm. Thus the sap begins to move nearly two months before the general revival of vegetation.

In a central situation, lying convenient to the trees from which the sap is drawn, a shed is constructed, called a sugar-camp, which is designed to shelter the boilers and the persons who tend them, from the weather. A auger three-fourths of an inch in diameter, small troughs to receive the sap, tubes of elder or sumac, 8 or 10 inches long, corresponding in size to the auger, and laid open for a part of their length, buckets for emptying the troughs and conveying the sap to the camp, boilers of 15 or 18 gallons capacity, moulds to receive the syrup when reduced to a proper consistency for being formed into cakes, and, lastly, axes to cut and split the fuel, are the principal utensils employed in the operation. The trees are perforated in an obliquely ascending direction, 18 or 20 inches from the ground, with two holes 4 or 5 inches apart. Care should be taken that the augers do not enter more than half an inch within the wood, as experience has shown the most abundant flow of sap to take place at this depth. It is also recommended to insert the tubes on the south side of the tree; but this useful hint is not always attended to.

A trough is placed on the ground at the foot of each tree, and the sap is every day collected and temporarily poured into casks, from which it is drawn out to fill the boilers. The evaporation is kept up by a brisk fire, and the scum is carefully taken off during this part of the process. Fresh sap is added from time to time, and the heat is maintained till the liquid is reduced to a syrup, after which it is left to cool, and then strained through a blanket or other woollen stuff, to separate the remaining impurities.

Some persons recommend leaving the syrup twelve hours before boiling it for the last time; others proceed with it immediately. In either case the boilers are only half-filled, and by an active, steady heat, the liquor is rapidly reduced to the proper consistency for being poured into the moulds. The evaporation is known to have proceeded far enough, when, upon rubbing a drop of the syrup between the fingers, it is perceived to be granular. If it is in danger of boiling over, a bit of lard or of butter is thrown into it, which instantly calms the ebullition. The molasses being drained off from the moulds, the sugar is no longer discoloured, like the raw sugar of the West Indies.

Maple sugar manufactured in this way, is lighter coloured, in proportion to the care with which it is made and the judgment with which the evaporation is conducted. It is superior to the brown sugar of the colonies, at least, such as is generally used in the United States; its taste is as pleasant, and it is as good for culinary purposes. When refined, it equals in beauty the finest sugar consumed in Europe. It is made use of, however, only in the districts where it is made, and there, only in the country: from prejudice or taste, imported sugar is used in all the small towns, and in the inns.

The sap continues to flow for six weeks; after which, it becomes less abundant, less rich in saccharine matter, and sometimes even incapable of crystallization. In this case, it is consumed in the state of molasses, which is superior to that of the islands. After three or four days’ exposure to the sun, maple sap is converted into vinegar, by the acetous fermentation. The amount of sugar manufactured in a year varies from different causes. A cold
and dry winter renders the trees more productive than a changeable and humid season. It is observed, that when a frosty night is followed by a dry and brilliant day, the sap flows abundantly; and 2 or 3 gallons are sometimes yielded by a single tree, in 24 hours. Three persons are found sufficient to tend 250 trees, which give 1000 pounds of sugar, or 4 pounds from each tree. But this product is not uniform, for many farmers on the Ohio do not commonly obtain more than 2 pounds from a tree. Trees which grow in low and moist places afford a greater quantity of sap than those which occupy rising grounds, but it is less rich in the saccharine principle. That of insulated trees, left standing in the middle of fields or by the side of fences, is the best. It is also remarked, that in districts which have been cleared of other trees, and even of the less vigorous sugar maples, the product of the remainder is, proportionally, most considerable.

"Having introduced," says a writer, "twenty tubes into a sugar maple, I drew from it the same day, 23 gallons and 3 quarts of sap, which gave 7½ pounds of sugar; 33 pounds have been made this season from the same tree; which supposes 100 gallons of sap. It appears here, that only a little more than 3 gallons was required for a pound, though 4 are commonly allowed.

It has been advanced, and doubtless correctly, that the Northern parts of New York and Pennsylvania contain maples enough to supply the whole consumption of the United States. But the annual produce by no means answers to this patriotic calculation. The trees grow upon excellent lands, which by the influx of emigrants from the older settlements, and by the surprising increase of the population already established, are rapidly clearing; so that in less perhaps than half a century, the maples will be confined to exposures too steep for cultivation, and will afford no resource, except to the proprietor on whose domain they grow. At any rate, also, the wood will probably produce a greater and more ready profit than the sugar. Wild and domestic animals are inordinately fond of maple juice, and break through their enclosures to sate themselves with it.

MARC. The matter which remains after the pressure of fruit; or any substance which yields oil; or, in fact, any fluid matter for the separation of which the action of the press is required. What remains in the press is the marc.

MARCESCENT. In botany, a term applied to leaves, &c., which are permanent, and when withered do not fall off.

MARCHES. The name given to the borders or frontiers of any district, but more especially applied to the boundaries between England and Wales, and England and Scotland.

MARE. The female of the horse. See Horse.

MARE'S-TAIL. (Hippuris vulgaris). A curious indigenous aquatic, growing in marshy situations and in ditches, pools, and the borders of slow streams.

MARGARIC ACID. An acid obtained from animal fat. Its derives its name from its resemblance to pearl. Its appearance and properties very much resemble those of stearic acid, another product of animal fat, the chief difference being in the greater fusibility of the margaric, which melts at 140° Fahr. See Acids, Animal.

MARGOL (Calendula, named from calendae, the first day of the month; there being flowers almost any month in the year). A genus of showy plants, among which is the old and well-known common marigold (C. officinalis). This species was formerly used in soups and broths, but is now little regarded. There are several varieties of the common marigold, among which are—

MARIgold, CORN. See CORN MARIgold. MARIgold, AFRICAN. See AFRICAN MARIgold.

MARIGOLD, THE MARSH. See MARSH MARIGOLD.

MARINE ACID. See MURIATIC ACID.

MARINE SALT. Common sea-salt, or mu-riate of soda.

MARJORAM (Origanum, from eros, a mountain, and ganoS, joy; the delight of the mountain, in allusion to the habituation of the plants). A genus of well-known, pungent, and gratefully aromatic herbs. The plants are all of easy cultivation; the shrubby kinds are increased by cuttings or slips; the herbaceous species by dividing at the roots. There are as many as 8 species, besides numerous varieties. The species generally cultivated are the common or pot marjoram (O. vulgarE), and sweet or summer marjoram (O. majorana), and bastard or winter marjoram (O. heracleoEum).

A light, dry, and moderately fertile soil is required for their healthy growth; and if it is one that has not been cropped for a considerable time, it is the more favourable for them. If the soil is wet or rich, they are deficient in their essential qualities, and are unable to withstand severe weather. The situation cannot be too open. The sweet marjoram is propagated solely by seeds; the perennial by seed, as well as by parting their roots, offsets, and slips of their branches. Sowing may be performed of all the species, from the conclusion of February, if open weather, to the commencement of June; but the early part of April is the usual time for performing it. Portions of the rooted plants, slips, &c., may be planted from February until May, and during September and October.

The soil is performed either in drills, 6 inches apart, or broadcast; in either case the seed being buried not more than half an inch deep.

The tops and leaves of all the species are gathered when green, in summer and autumn, for use in soups, &c.; and a store of the branches are cut and dried in July or August, just before the flowers open, for winter's supply.

MARK. A term applied to a horse, which is said to mark when he shows his age by a black spot like the eye of a common bean, which appears at about 53 years old in the cavities of the corner teeth, and is gone when
he is 8 years old. When he ceases to mark, it is said he has raised. See Age of Animals.

The term is also applied to a common mode of marking hogs, &c., in those parts of the United States where they are allowed to run at large, and where the owner fixes a mark upon his property by cropping more or less of the ears, slitting these into swallow-forks and every other shape of mutilation.

MARKET. In English law the liberty or franchise, whereby a town is enabled to set up and open shops, &c., at a certain place within its limits for buying and selling, and better provision of such victuals as the subject wanteth. The establishment of a market, with the grant of the tolls thereunto belonging, is one of the king's prerogatives, and can only be effected by virtue of the king's grant, or supported on long and immemorial usage and prescription, which presuppose such grant.

The general rule of law is, that all sales and contracts of any thing vendible in fairs or markets overt (i.e. open), shall not only be good between the parties, but valid against all claim by others having any right or property in the subject. See Fairs.

MARL. Marl implies, properly speaking, a natural mixture of chalk, shells, or carbonate of lime, with some of its forms, with clay or sand, or both. Its application to land, as a fertilizer, is of very ancient date, as it was much used by our English forefathers as a manure; and no one can read the account given by Pliny of the agricultural operations of the early Britons, without being struck with the minute discrimination, the evident result of long, attentive practice, which was displayed by them in the application of marl to particular soils; and from a very early period the Cornish farmers have been used to employ extensively the sea sand of Padstow harbour (which contains 64 per cent. of carbonate of lime), for the same purpose, carrying it from the sea-shore either in carts, or even on horses' backs, some miles up the country.

Marl was certainly used by the early Italian cultivators as a valuable addition to the soil of their fields. It is thus spoken of by Columella:——“If, nevertheless, you are provided with no kind of dung, it will be of great advantage to it to do what I remember Marcus Columella, my uncle, a most learned and diligent husbandman, was frequently wont to do, viz., to throw chalk or marl upon such places as abound in gravel, and to lay gravel upon such as are chalky, and too dense and stiiff; and thus he not only raised great plenty of excellent corn, but made most beautiful vineyards; for this most skilful husbandman denied that dung ought to be applied to vines, because it would spoil the taste of the wine; and thought that stuff gathered together out of thicketts, and from among briers and thorns, or, in a word, any other sort of earth fetched from any other place, and carried to them, was much better for making a plentiful vintage.”

The mixture of soils, we find from Theophrastus, was a practice common in his days: “they found, it seems, the advantage of uniting the light with the heavy, the fat with the lean, and, in fact, any that were of a contrary nature. This mixture, he tells us, not only supplies what shallow soils need in depth, but adds to the power of both; so that a worn-out soil, thus treated, begins again to bear crops with renewed energy; thus barren clays, when thus fertilized, again become fruitful; in truth, this mode of cultivation he deemed a complete substitute for manure. The inhabitants of Megara, besides practising this system, were used every 5th or 6th year to trench their land, digging as deep as they imagined the rain to penetrate, and bringing the under soil to the top; for it was an axiom with the Megarian cultivators, that the lighter portions of earth proper for the nourishment of plants are always washed downward as far as the influence of the surface water extends; so that we see from this that the advantages of deep ploughing, or subsoiling, is not a very modern discovery. (Col. lib. xi. c. 16; Theop. l. ii. c. 25.)

The right of sinking marl-pits is mentioned in the Charta Foresta, A. D. 1235; and in the Statuta Walliae, 12 Edward I., marl-pits are mentioned as being dug close to common roads. “It is one of the duties of the sheriff and coroner,” says Daines Barrington, “to inquire de fossatis et marlieris levatis juxta iter publicum,” which shows that this kind of manure was very commonly used. When a marl-pit was sunk in ground that did not belong to the king, but which happened to be in the purlieus or neighbourhood of a forest, prosecutions were instituted in the forest, which imposed heavy fines for the offence, as the pit occasioned both inconvenience and danger to the hunter.

Marl is found in many parts of England; and any earthy substance in which the proportion of calcareous matter is apparent, mixed with sand or clay, is styled, in popular language, a marl. Of this there are 3 principal varieties: 1. Clay marl; 2. Sand marl; 3. Slate or stony marl; 4. Shell marl. Of these the last is commonly the richest in calcareous matter. In some shell marl examined by Sir George Mackenzie, he found——

</table>

Clay marl usually contains from 68 to 80 per cent. of clay, and from 32 to 20 per cent. of calcareous matter. Silicious sand often contains 75 per cent. of sand (Kirwin on Manures, p. 13). Thus, M. Thaer found in that of Oldenburgh——

The quantity of marl applied per acre necessarily varies with the kind of soil and the quality of the marl; it is usual to employ it in
very considerable quantities, and it is often some years before it is sufficiently incorpo-
rateed with the soil to produce an evident im-
provement; but then that advantage is almost always, sooner or later, not only decided, but permanent.

The clay marls render light sandy soils more tenacious; the sandy marls materially
improve the friability of the heavy clays. In
Cheshire, they often apply 188 cubic yards of
clay marl per acre to light sandy soils, and
about half that quantity to their heavy lands.

In many parts of Scotland it is spread on grass
lands, and suffered to remain for two or three
winters exposed to the frost, before it is
ploughed in, in about the same proportions per
acre.

The beginning of all improvements in Ger-
manny," says Mr. S. S. Carr, in his Prize Essay,
"is, to give a dressing of marl (containing, on
an average, 60 per cent. of carbonate of lime),
at the rate of 164 cubic feet per acre, as by
this means land, not worth cultivation previously,
yields excellent crops for 8 or 10 years; and
if the straw produced during that time is care-
fully converted into manure, the productiv-
ness does not materially decrease. Should
that, however, be the case, the deposits of
ponds, and even plots of peat-moss, which not
unfrequently occur, are carried upon the fal-
loows in winter, where these substances, when
broken down by the frost, prove a valuable al-
ternative to the texture of the soil, especially
where the pulse, rape, and clover crops are

The heathy sands of Norfolk much im-
provement might be effected by the application
of marl. Mr. Kiddle, of Marsham, in that
county, made many experiments with marl;
he preferred, from long experience, the variety
denominated "clayey marl," which he thought
the best for sandy lands, even if it brought from a
considerable distance. "A few years since,"
said General Vavasour, "I purchased, with
other lands, a field of 10 acres; it had been
part of a common enclosed about 15 years be-
fore, and was thistle-free, the soil sandy, mixed
with moony earth. I ploughed and sowed it in
divisions with various crops, most of which failed.
Having discovered a stratum of rich
clay marl, within 400 yards of the field, I carted
on 75 cubic yards per acre, at 10d. per yard,
or 3l. per acre." The result was, that the
value of the land increased from 6s. to 1l. 1s.
per acre.

In Europe, the term marl is applied to vari-
ous mixtures of calcareous marl, with clay,
sand, &c., and the common test is to effervence
on the addition of vinegar, or other acid. But,
in the United States, those at least on the At-
tantic coast, where this fertilizer is met with in
great abundance, two kinds of marl are ex-
tensively used, one of which has been already
described under the head of Green Sand.
This is often so free from lime, as scarcely to
retain a trace, and, consequently, the addition
to it of vinegar, or other acid, would not pro-
duce that effervescence necessary to constitute
it a marl, in accordance with the common test.

What, in the states of New Jersey, Delaware,
Maryland, and Virginia, is usually called green

sand marl, instead of containing lime, abounds in
potash. See Green Sand.

The calcareous marl found in the states
named, generally contains more or less of the
green sand; and this combination of lime and
potash forms a natural fertilizing mixture, the
value of which is scarcely yet appreciated as
it deserves to be. Its great weight makes it an
expensive application to land, wherever much
hauling is required, and consequently it yields
to burned lime under such circumstances.

The admirable treatise upon the subject of
"Calcareous Manures," by E. Ruffin, of Virginia,
has been extensively circulated throughout the
United States, and may be referred to as contain-
ing the most useful body of information upon
the subject of marl ever brought together, embrac-
ing every detail in relation to hiring, transport-
ing, application, and effects, that can be de-
sired by the farmer or general reader. See
Mixture of Soils, Lime, Chalk, Earths, &c.

MARSH.

Of the common names of the marsh-plant (Arundo arenaria).

MARSH (Sax. mere, a fen). A flat surface, the soil of which is so far saturated with water
throughout the year as to be unfit for culture
by the spade or plough; but not so much as to
prevent it from producing coarse grasses, and
other kinds of herbage. Marshes are generally
situated in bottom, where they are kept moist
by the water which descends from the sur-
rounding lands; or along the banks of rivers
or lakes, where their humidity arises from
their being nearly on the same level with the
adjoining water. Where a marsh is situated
so as to be occasionally overflowed by the sea,
or by a river, up which the tide flows, it is
called a salt marsh; and the herbage produced
by such lands is found highly conducive to the
health of animals which pasture on them for a
certain portion of the year, from the alterative
effect of its saline properties.

Salt marshes abound along the shores of the
bays and sounds of the southern states of the
United States. The natural grasses which
grow so luxuriantly are extensively mown,
and furnish an inferior, and generally a coarse
description of hay, which, however, is much re-
lished by cattle in consequence of its saltiness.
It furnishes excellent litter, and thus contri-
butes greatly to swell the manure-heap. On
the Delaware bay it sells for about $2 to $4
per ton.

Salt marshes are often reclaimed by em-
bankments, which keep off the tide-water. The
best mode of managing land thus reclaimed, is
well worth knowing; and the following direc-
tions from Mr. T. F. Lambs, of Salem, New
Jersey, contain valuable information, the result
of much experience and expense:—"1st. The
marsh should be secured from the tide by a
permanent bank. 2d. A sluice or sluices of
sufficient capacity must be laid to discharge
the rain-water and back-waters which exceed
from adjacent uplands, so that at no time
the water-courses and ditches will be filled to
overflowing. The sluices should be laid deep
enough to draw the water through them, and
the lowest part of the marsh should be kept
at a height, so as to

100

3 X 793
MARSH-LANDERS.

Marsh-landers (Althea, derived from altheo, to cure; from the medicinal qualities of some of the species). This is a genus of tall, free-flowering plants: the biennial and annual kinds should be sown in the open border in spring, and transplanted when sufficiently strong. The herbaceous kinds may be increased by dividing the roots or by seeds. A. rosea, the parent of the many beautiful varieties of holly-hock, yields a blue colouring matter equal to indigo. (Paxton's Bot. Dict.)

The common marsh-landers (A. officinalis) is in England an indigenous perennial, growing abundantly in marshes, especially towards the sea. The root is perennial, tap-shaped, rather woody. The herbage of a hoary green, peculiarly soft and downy, with a fine starry pubescence. Stems several, about a yard high, simple, round, leafy, tough, and pliant. Leaves ovate or heart-shaped at the base, various in breadth, soft and pliable, slightly five-lobed. Flowers (which blow from July to September) are very short, dense, axillary panicles, rarely solitary, of a delicate uniform blush-colour, not inessential. Bees are very fond of its melliferous flowers. The whole plant, especially the root, yields in decoction a plentiful, tasteless, colourless mucilage, besides a fatty oil, uncrystallizable sugar, starch, and phosphate of lime. It is emollient, and salutary in cases of internal irritation. A syrup made with the root, as well as the decoction, is an official preparation of the Pharmacopoeias. It is used in the coughs of children. See Mallow.

MARSH-MARIGOLD (Caltha, a synonyme of kalathos, a goblet; in allusion to the likeness of the form of the carolla to a golden cup). The species of this genus are showy, and do best in a moist situation, but will grow and flower in a common border. They may be increased by seeds or divisions. The British indigenous species are two in number, viz:—

1. The common marsh-marigold (C. palustris), which grows in marshy meadows, and about the margins of ponds, lakes, and brooks, almost everywhere. It is perennial in habit, blooming in March and April. The root is thick and somewhat tuberous, with many simple fibres. Stem 12 or 18 inches high, round, hollow, leafy, branched, furrowed. Leaves variously heart-shaped, rounded. Flowers from 3 to 5, large, bright yellow, on alternate solitary stalks. The flower-buds pickled serve for capers, which they resemble, except in having numerous germens. A double variety is frequent in gardens.

2. Creeping marsh-marigold (C. radicans). This species is found by the sides of lakes and rivulets in Scotland, and is scarcely half the size of the common C. palustris. A double variety of this is cultivated near London.

MARSH-MUD. This substance, which forms such an excellent manure, is not so well appreciated or so generally employed in the United States as it deserves to be. An intelligent correspondent of the Farmers' Register (for July, 1834) states, that he deemed it more valuable than barn-yard manure, and that it never failed in any application he had made of it. He even prefers it to marl, because its effects are more quickly manifested, and, when readily accessible, much more improvement can be effected for the same money than by applying marl. He, however, confesses that the permanent advantages of marling are much greater, and thinks that marl and marsh-mud will both be improved by combination. This result may certainly be expected in most cases, but must depend much upon the prevailing constitutions of the mud. The alluvial deposits found in marshes, must of course contain more or less of the ingredients of the soils of the neighbouring uplands. When these contain lime, magnesia, silex, iron, &c., so will the marsh-mud. This is clearly shown in the following tabular statements, giving the results of Dr. Dana's chemical examinations of a few specimens of marsh-mud taken from the rocky coast of New England.

"A substance," says Professor Hitchcock, "so rich in geese or salts of lime and soda, or in both, as the above analyses show, cannot but prove a fertilizer of the soil if spread upon it. If a soil be quite poor, those varieties should probably be chosen that contain the most geese; and this can be judged of by their comparative lightness when dry; the lightest abounding most in organic matter. But if the soil already contain a good deal of inactive vegetable matter, the varieties that abound most in salts will probably be most efficacious; though an additional quantity of geese can do no harm, and may do much good. If marsh-mud be applied at random, it is not strange that varieties of it, almost destitute of geese, should be sometimes put upon exhausted soil, and that no good effects should follow. Hence the necessity of some fixed principles to guide the farmer. And since Massachusetts contains so much sea-board, and so much land near the coast that may be benefited by this substance, a correct mode of applying it is of great importance. (Geological Report.)

The abundant deposit called marsh-mud found along the extensive marshes which border many of the shores of the bays and rivers of the Middle States, is variously constituted, being sometimes a black, unctuous substance, made up of vegetable and mineral matter, in which sometimes no trace of vegetable fibre can be traced, whilst at others it contains not only a perceptible portion, but consists mainly of the fibres of grass-roots and leaves, in a state of greater or less decay. Professor Booth, who has treated of the subject in his Geological Survey of Delaware, says, that the first of these is the most valuable, and may sometimes be directly applied to land without admixture; but it is advisable to adopt a uniform method of using it, which may be done in two ways, by mingling it with lime, better after exposure to the air for some time, or by drawing it into the barn-yard to bring it into an incipient fermentation by contact with stable-manure. In either case it will more than repay its expense; and if lime be employed on the land at the same time, a more powerful and durable influence will be derived from it.

Blue mud. The fertility of those lands of which blue mud forms the upper surface, and its beneficial effects in the few instances in which it has been employed on the upland, are a warrant of its fertilizing powers, but it is a matter of some doubt to what substances its effects are mainly to be attributed. Its basis is a fat clay, both lead-coloured and yellowish, with a quantity of organic matter, which appears to be chiefly in the state of crenic and aporicene acids, combined with the oxide of iron. There is no doubt that it would be advantageous if applied directly to the soil, but its tenacity is an objection to such a mode of using it, and hence it is more advisable either to draw it into the barn-yard, where it will be broken down by mingling it with lime, or to mix it with lime, and expose it for some time to the air, adding, at the same time, the black marsh-soil, which is generally to be obtained in its vicinity.

The blue mud is wholly unlike a peaty soil, but being deposited on the river-marshes, it soon becomes a marshy soil, and many of the creek and western marsh deposits are far from being peaty, although they contain much organic matter. Its value, as a manure, rests not on a mere theoretic assertion, but it has received the test and sanction of experience, and such experience, both in Delaware and elsewhere, as may not be contradicted. As it would be a matter of nicety to discriminate between such varieties as are not sufficiently decomposed, and require some preparation prior to their application, and those which might be directly employed, it would be better to adopt a general rule relative to the mode of using it, viz., either to draw it into the barn-yard, or to form a compost with lime, or with ashes. In either case it will form an excellent manure, and with lime or ashes a durable one.

**MARSH-THISTLE, or RED THISTLE** (Carduus palustris). See THISTLE.

**MARSH-TREFOIL.** See BUCK-BRAN.

**MARUM.** Bitter. In botany, the term is used to signify an herb with a strong smell.

**MASH.** A soft sort of diet occasionally given to horses. It is prepared by pouring boiling water upon a small quantity of ground malt, bran, or other similar substance, in a pail, so as just to wet it well. After this has been done, it should be well stirred about, till it is thoroughly mixed and sweetish to the taste, when, after becoming lukewarm, it is in a proper state to be given to the animal. It is frequently used after purges to increase their operation, as well as after hard labour, and in the time of disease. Mashes are very useful for restoring animals in these circumstances.

**MAST.** The nus or seeds of the beech, oak, and chestnut-trees, which are the food of hogs, squirrels, &c.

**MASTICATION.** The process of grinding or chewing the solid parts of food between the teeth, by the united motion of the jaws, tongue,
and lips, in consequence of which it is broken into small pieces, mixed with the saliva, and thus adapted for deglutition as well as more easy digestion; although it is, perhaps, not more essential for the latter purpose than water. Leuchs and Schwan, two German physiologists, have, however, proved that saliva has the property of changing starch into sugar; and it is a well-known fact that the process of digestion in the stomach converts starch into gum, and gradually into sugar. Mastication, in the animal economy, is so essential to the prosperity of the individual, that old horses, &c., whose teeth are impaired, always require to have their food broken, chopped, or crushed for them. See Mastication.

MAT-GRASS, or HEATH MAT-WEED (Nardus stricta). An insignificant species of grass growing on barren, sandy, moist heaths and moors, in many parts of Britain. The root consists of numerous very strong, downy fibres. Stems and leaves furrowed, roughish with minute and rigid hairs, four or five inches high, remaining bleached through the winter. Spikes solitary, purplish, bristle-shaped, straight, of many slender flowers. Schrak celebrates this deep-rooted grass as a safe support to the hands of the Alpine botanist, in precipitous situations, though it renders his path very slippery. The hard and wiry foliage of the mat-grass is eaten by horses and goats, but disliked by cattle and sheep. The species is often a troublesome weed on arable lands and pastures, where it affords but coarse food to cattle. As it, however, forms large and thick tufts, which resist the action of the scythe, it may be usefully transplanted to loose, sandy lands, where its spreading, horizontal roots will tend to consolidate the soil, and increase the stratum of vegetable mould, for the reception of more useful plants.

MATH. An old term for crop; hence latter-math is the last mown crop of grass.

MATRIX. The womb, or place where any thing is generated or formed. In mineralogy, it means the earth or stone in which the mineral is imbedded.

MATWHEED, THE SEA. One of the names of the sea-reed (Arduntia arenaria). See Reed.

MAULDIN-WORT. See Ox-eye Daisy.

MAUL. A provincial word, variously applied to a beetle, a mallet, and the mallow, in different localities.

MAW-SKIN. A word used in some places to signify the stomach of the calf prepared for cheese-making. See Rennet.

MAY-APPLE. An American plant, so called from its flowers being very abundant in the month of May. Its botanical name is Podophyllum peltatum, and it has also the common names of Wild Mandrake, and Hog Apple; the last name must be regarded as inappropriate, since hogs seldom, if ever, eat them. The plant grows very abundantly in all moist and shaded places in woods, almost from one end of the Union to the other. It has usually a simple stem, terminating in a single broad leaf, 4 to 6 inches in diameter, and deeply divided into 5 or 7 lobes. The root of the plant is biennial, and is frequently used as a medicine, being active both as an emetic and cathartic, when taken in powder, in small quantities. The fruit consists of a single large, long, and flatish apple, yellow when mature, and varying in size from 1 to 3 or 4 inches long by 1 or 2 broad. The soft pulp contained within the rind has a very peculiar musky taste, which is relished by many persons. The fruit is by no means unwholesome, and has been introduced with the dessert, in which case the pulp may be squeezed into a wine-glass, and, with the addition of a little old Madeira and sugar, is said to be equal to the jujubes, and is said to resemble in appearance. (Am. Farm. vol. 14.)

MAY-DAY. The first day of May.

MAY TREE. See Hawthorn.

MAY-WEEP, THE STINKING, or MATH-ER. Called in Pennsylvania, Stinking Chamomile, Dog's Fennel, &c. (Pl. 10, t. v.) It is frequent in the farm-yards, lanes, &c., in the Middle States, and is a disagreeable foreign weed, now extensively naturalized. It is readily distinguished from the preceding by its fetid odor,—as well as by its botanical characters,—on which it has been generically separated from Anthemis, by Cassini, Lessing, &c. There are no native species in the United States.

MEAD (Dutch, meede). An agreeable vinous liquor made from honey. The use of this substance as one of the ingredients in drink is of very ancient date. When fermented, honey-water obtains the name of mead, which is, in fact, honey-wine: indeed the Germans call it by that name (Honigwein). Mead is said to have been the principal beverage of the Britons before the use of malt liquor among them; and long after the introduction of the latter beverage, mead was a favourite drink. Under the name of mehethlin, it was frequently alluded to by old writers. Mead formed the ancient, and for centuries the favourite beverage of the northern nations. It is frequently mentioned in Ossian. Dryden has a couplet:—

"T' alloy the strength and hardness of the wine, Let with old Beccius new Methhelin join."—Queen Elizabeth was so fond of mead, as to have had it made every year for her. Her receipt for it has been preserved, and is given by Dr. Bevan, in his interesting little volume on the Honey Bee:—Take of sweet-briar leaves and thyme each one bushel, rosemary half a bushel, bay leaves one peck. See these ingredients in a furnace full of water (containing probably not less than 120 gallons): boil for half an hour; pour the whole into a vat, and when cooled to a proper temperature (about 75° Fahr.), strain. Add to every six gallons of the strained liquor a gallon of fine honey, and work the mixture together for half an hour. Repeat the stirring occasionally for two days; then boil the liquor afresh, skim it till it becomes clear, and return it to the vat to cool: when reduced to a proper temperature, pour it into a vessel from which fresh ale or beer has just been emptied; work it for three days and turn. When fit to be stopped down, tie up a bag of beaten cloves and mace (about half an ounce of each), and suspend it in the liquor from thebung-hole. When it has stood...
MEADOW.

for half a year, it will be fit for use. Such was the receipt.

In Wales, in ancient times, mead was held in very high repute; as appears from an ancient law, which has been given by Dr. Bevan, that—

"There are the meadows which must be communicated to the king before they are made known to any other person: 1st, every sentence of the judge; 2d, every new song; 3d, every cask of mead." The mead-maker was the eleventh person in dignity at court, and took precedence of the physician. Besides the preparation of mead, our forefathers were accustomed to flavour their usual grape wines with honey and other ingredients. There were two kinds of spiced wines in use in England in the thirteenth century, called Hippocras and Clary. The first consisted either of white or red wine, and the latter of claret, both mingled with honey and spices. Dr. Henderson, in his History of Wines, speaks of a receipt still existing, which gives directions how "to make insiprice for lords with gynger, syuamon, and graynes, sugour, and turscel; and for comyn pepull, gynger, canell, longe peper, and clarified honey." Meadow formed the nectar of the Scandinavian nations, and was celebrated by their bards: it was the drink which they expected to quaff in heaven out of the skulls of their enemies; and was, as might be expected, liberally patronized on earth. The Scandinavian mead is flavoured with primrose blossoms. (Penny Magazine.)

MEADOW. A field under grass cultivation, generally situated on the banks of a river or lake; but so far above the surface of the water as to be considerably drier than marsh land, and, consequently, producing grass and herbage of a superior quality. The soil of meadow lands is generally alluvial, and more or less mixed with sand; and it is kept in a state of fertility by the deposition made on its surface, in consequence of being occasionly overflowed by the adjoining waters. The produce of meadows is generally made into hay, which, though not equal in quality to that produced on drier grass lands, is yet superior to what is obtained from marshes. See Grass, Hay, Irrigation, and Marsh.

In England some meadows of great extent, belonging to a community or district in which every inhabitant has a right to send his cattle to graze under certain regulations, are never mown. When the number of those who have a right to common pasture is not very great, they frequently agree among themselves to abstain from depasturing the meadows in spring, and, dividing them into portions, each makes hay of his share; after which the cattle are admitted in common for the remainder of the season. Thus a common meadow is converted into a Lammas meadow, that is, a meadow which becomes a common meadow after the 1st of August, this being the time when it is supposed that all the hay has been made and secured. Low alluvial land, or that which can be irrigated at pleasure, is usually left for the meadow, either from its productiveness from mead. The rich deposits which are periodically laid upon it, or from its being too wet for cattle to graze on it in winter without poaching the surface. In a proper rotation system, upland is also occasionally devoted to the production of grass for the mow. In upland situations meadows are either alternately mown and pastured, or broken up for oats or wheat, after they have yielded a crop of hay, and been grazed during the preceding year. The practice of leaving young leys in pasture one year after the first mowing, and then ploughing them up, is very general in England and Ireland. Grass land kept constantly for meadow, ought never to be depastured except in dry weather, as the breaking of the surface by the feet of the cattle, not only injures the grasses of the sward, but, by causing the stagnation of water in the holes, promotes the growth of rushes and other coarse aquatic plants, besides killing the finer grasses, and rendering the surface uneven for the mow. A dressing of sand, even of the worst kind, and the use of calcareous manures, or salt, will be found excellent for coarse, rushy meadows, by tending to render the texture of the grasses finer; but as the rankness and inferiority of the herbage proceeds from a superabundance of water, draining will be found the most certain remedy, and effectual means of improvement. The meadows which are to be mown should be shut up early in spring, and those which are soft and wet should have nothing larger than a sheep admitted into them from November till after hay-making time the next year.

Of late years the practice of soiling has been extensively adopted. By this means all the advantages of mowing for hay are obtained, besides an abundant supply of rich manure, which can be applied to the land in a liquid and diluted state, when its effect is powerful and certain. So much more fodder is produced from the land by the system of soiling, that arable fields are converted into artificial and temporary meadows, in which the different species and varieties of grasses are sown, to be green or made into hay; and when, from the nature of the soil, the herbage degenerates, the field is ploughed up again, greatly improved by this change of cultivation.

When a natural meadow has been neglected, and the grass is of an inferior quality, and mixed with rank weeds and moss, it requires much care to restore it to its original fertility. In most cases (says a writer in the Penny Cyclopedia), the shortest method and the best is to plough it up, clean and manure it during a course of tilage, without taking very exhausting crops from it, and then to lay it down, again, in a clean and enriched state, by sowing the best sort of grass-seeds; or, which is preferable, by inoculating or planting in it small tufts of grass from some rich meadow, which will soon increase, and produce a new and improved sward. But when the soil is a very stiff clay, with only a small depth of good mould over it, there is some danger in breaking the old sward, for it will take a long time and much manure to reproduce a proper covering of sward. In this case it is a preferable practice to scarify the meadow, by means of instruments which do not go deep, but only tear up the surface. If this is done in early spring, when the ground is moist, and the whole surface is

\[\text{3 x 2} \quad \text{797}\]
MEAT.

brought to resemble a fallow field, good grassseed may be immediately sown. If rich manure, mixed with lime or chalk, is then evenly spread over the land, and the whole well harrowed and rolled, the old and young grass will spring up together, and show a wonderful improvement in a very few months. Great Britain and Ireland are reputed to possess the most verdant pastures and the finest natural grasses in the vegetable creation.

In extent of meadow and pasture-land, as well as in flocks, Great Britain and Ireland (says a French statistical account) are the most favoured countries in Europe. They contain 5572 square leagues (more than two-thirds of their territory), in meadow and pasture-land. Germany comes next, having one-quarter of its surface in this description of land. Prussia, Holland, and Belgium have a fifth; Austria and Switzerland a sixth. France does not reckon in this respect more than a seventh part, namely, 4000 square leagues. Italy, Naples, Sicily, and Portugal have only a tenth.

MEADOW FOXTAIL. See Alopecurus and Grass.

MEADOW-GRASS. See Poa, Couch, Holcus, and Grasses.

MEADOW OAT-GRASS. See Avena.

MEADOW-SAFFRON (Colchicum). An ornamental genus of bulbs, growing best in a light loamy soil, and increased by offsets, or from seeds. One species only is indigenous. See Colchicum.

MEADOW-SWEET, or QUEEN OF THE MEADOWS (Sp irrigus umbratica). In England an indigenous perennial plant, growing in moist meadows, and about the banks of rivers and ditches; flowering in June and July. The root is fibrous, without knobs; the stems are herbaceous, 3 or 4 feet high, leafy, branched, furrowed, angular, smooth. Leaves interruptedly pinnate; downy beneath; the terminal leaflets largest, and lobed. Flowers extremely numerous, cream-coloured, with a sweet but oppressive, hawthorn-like scent, in dense, compound, cymose panicles, with many styles. The taste of the honey, like the scent of the flowers, is aromatic, not unlike the flavour of orange-flower water. The distilled water is said to be used by wine merchants to improve the flavour of made wines. Hogs devour the roots with avidity; goats and sheep also relish the herb; but horses and cattle refuse it.

MEAL (Dutch, mel). The edible part of wheat, oats, rye, barley, and pulse of different kinds, ground into a species of coarse flour. See Flour.

MEASURES. See Weights and Measures.

MEAT (Sax. mete, food). A general appellation for the flesh of animals when prepared for human food. See Beef, Bacon, Cattle, Mutton, Pork, Sheep, Swine, &c.

"In whatever manner meat is cooked," observes Mr. Donovan, "there is a considerable diminution of substance, the loss consisting chiefly of water, juices, soluble matter, and fat. In an economical point of view, a comparison of the loss incurred in the two most usually employed processes, roasting and boiling, is interesting, yet it has not occupied the attention of the public so much as the importance of the subject seems to demand. Professor Wallace, of Edinburgh, has given us the results of some experiments made to determine the loss which meat undergoes in cooking. It is to be regretted that it is not more in detail, and that the weight of the bone in each joint was not ascertained; but still it is of great value. The results, reduced to 100 pounds of meat, are as follows:

<table>
<thead>

<td>23 lbs.</td>
</tr>
</tbody>
</table>

Thus, the loss in boiling beef or mutton was less than in roasting. And it appears that meat loses by the cooking about one-fifth to one-third. A few years since, I undertook the superintendence of some experiments of the same tendency, with the view of verifying the results in this volume. These trials were made on several parts of the different animals, with as much attention to accuracy as the nature of the subject permitted. They were made on different qualities of the same kind of meat, at various seasons, both in England and Ireland. Such experiments are exceedingly troublesome, and occasion no small inconvenience; it is, therefore, the less surprising that the subject has so little investigated; and the following results, in the absence of any others so particularly detailed, will, perhaps, prove interesting. Allowance must be made for the nature of such processes, as the difficulty of fixing an average price of meat, fish, and poultry, owing to variations occasioned by the supply and the season, the want of uniformity in the prices of the city, and by the exorbitant demands of some vendors of these articles. The degree of fattness was in all cases brought to a standard by cutting off all excess, and leaving the meat in a proper state for housekeepers' use. The meat was in all cases cooked as nearly as possible to the same degree, and the weights were determined with exactness; avoirdupois weight throughout is intended. The bones were entirely stripped of their meat previously to their being weighed. The only cost taken into account is that of meat, leaving out fuel, &c.

"Experiment 1.—A piece of beef, roasted. It consisted of four of the largest ribs, and was not remarkably fat: its weight was 11 1/2 lbs. During the process of roasting it lost 2 lbs 6 oz., of which 10 oz. were fat, and 28 oz. were water dissipated by evaporation. When the meat was disseted off with the utmost care, the bones weighed 16 oz. Hence, the weight of meat, properly roasted and fit for the table, was but 7 lbs 11 oz., out of 11 1/2 lbs. originally submitted to experiment. This beef would cost in London 8s. per lb. The roasted beef cost, therefore, 12½ d. per pound. In another trial, a piece of beef of the same description, the tops of the ribs having been rejected with their meat, was submitted to the same mode of trial; the weight of bone in 10½ lbs. was 16 oz. and

798
MEAT.

the fat 11 oz., which agrees with the former estimate."

Other parts of mutton, submitted to similar tests, gave the following results.

"Experiment 17.—A leg of mutton, weighing 9 lbs., when boiled gave 1 lb. of bone, shank included; it lost in the boiling 1 lb. 2 oz.: the meat weighed 7 lbs. 2 oz. If the butcher's price was 8d. per lb., the meat cost about 104d. per lb.

"Experiment 18.—A similar leg, weighing 9 lbs. 6 oz., afforded 15 oz. of bone, and lost 1 1/2 lb. in the roasting; the meat weighed 6 lbs. If the butcher's price be 8½d. per lb., the roasted meat costs 12½d. per lb.

"Experiment 19.—A leg of small Scotch mutton, weighing 6 lbs., afforded 10 1/4 oz. of bone, lost 5 1/2 oz. in the boiling, and the meat weighed 5 lbs.: cost 9½d. per lb., if butcher's price be 8½d."

The following are miscellaneous:

"Experiment 20.—A fore-quarter of lamb, weighing 9 lbs., when boiled, lost 2 oz. of bone, and 1 1/4 lb. in the roasting: the meat weighed 6 lbs. If the butcher's price be 8½d. per lb., the lamb costs 13½d. per lb.

"Experiment 21.—A hand of salt pork weighing 4 lbs. 5 oz.: lost in boiling 11 oz. The bone weighed 9 oz.; the meat was 8 lbs. 1 oz. If the first cost of the pork was 7½d. per lb., the meat, when duly boiled, cost 10½d. per lb.

"Experiment 22.—A knuckle of veal weighing 6 lbs., when duly boiled, lost half a pound. Its bones, perfectly cleared of meat, weighed 2 lbs. 6 oz.; the meat weighed 3 lbs. 2 oz. Hence, if the butcher's price was 5½d., the boiled meat cost 10½d. per lb.

"Experiment 23.—A goose properly trussed, weighed 4 lbs. 1 oz.: in this state it was roasted, and when sufficiently done, was found to have lost 18 oz. The skeleton weighed 12 oz.: the meat weighed 3 lbs. This goose would cost, in London, 4s. 6d. Hence the roasted meat amounted to 1s. 8½d. per lb.

"Experiment 24.—A turkey, with its liver and gizzard, weighing 4 lbs. 14 oz., was boiled: it lost 12 oz. The skeleton weighed 13½ oz.; the meat, 3 lbs. 4½ oz. If this turkey cost 3s. 6d., the boiled meat amounted to 1s. 1d. per lb.

"Experiment 25.—A young duck, weighing 20 oz., lost 5½ oz. in roasting. Its bones weighed 2½ oz.: the meat was 12½ oz. It cost 2s. 6d.: hence the flesh amounted to 3½d. per lb.

"Experiment 26.—A fowl, with its liver and gizzard, weighing 14 lb., was roasted. It lost 3 oz.: the skeleton weighed 4½ oz., and the flesh 16½ oz. If such a fowl cost 2s. 6d., its meat, when roasted, would cost 2s. 4½d. per lb.

"Experiment 27.—A chicken, weighing 1 lb. 4½ oz., when roasted lost 3½ oz. The bones weighed 3 oz., the flesh, 13½ oz. If the chicken cost 2½d., the meat, roasted, was worth 2s. 8½d. per lb.

"Experiment 28.—A fine mackerel, when trimmed, and ready for boiling, weighed 2½ oz. (including the weight of the roe, 3½ oz.) It cost 1½d. It lost 1½ oz. in the boiling. The skeleton, carefully collected, along with gills, fins, and tail, weighed 4½ oz. Hence, the cost of the eatable parts of the boiled fish was 9½d. per lb."

It will now be necessary to collect the results of all these experiments into a kind of con- spectus, for the sake of more easy comparison; and it is to be understood, that, in the following estimates, the butcher's price is mentioned, of course comprising all expense in the usual manner. But, when the ultimate cost of the cooked meat is specified, it refers to the price cost of the meat only, the bone being considered valueless: and it is supposed that the fatness of the meat was such as good meat is expected to have, without any redundancy being left on it. From an average of five experiments, it appears that, when the butcher's price of ribs of beef is 8½d. per lb., the cost of the meat, when duly roasted and fit for the table, is 11½d. per lb. and that the average weight arising from the liquefaction of the fat, and the evaporation of water from the juices, is 18 per cent. From an average of six experiments, it appears that, when the butcher's price of salted briskets of beef is 6d. per lb., the cost of the meat, when duly boiled and fit for the table, 1s. 1½d. per lb., and that the average weight lost during the boiling is 20½ per cent. From an average of other experiments, it appears that when the butcher's price of salted briskets of beef is 6d. per lb., the cost of the meat, when duly boiled and fit for the table, is 8½d. per lb., and the loss incurred in boiling, arising from the extraction of fat and juices, is 18 per cent. From an average of two experiments, it appears that when the butcher's price of salted flanks of beef is 6d. per lb., the cost of the meat, when duly boiled, is 7½d. per lb., and the loss in boiling is 13½ per cent. From another experiment, it appears that, when the butcher's price of salted tail ends of beef is 7d. per lb., the cost of the meat, when duly boiled, is 8½d. per lb., and the loss in boiling is 19½ per cent. From an average of experiments 17, 18, 19, and 2 others, it appears that, when the butcher's price of legs of mutton is 8d. per lb., the cost of the meat, when duly boiled and fit for the table, is 10½d. per lb., and that the average weight lost during the boiling is 10 per cent. From an average of two experiments it appears that, when the butcher's price of legs of mutton is 8½d. per lb., the cost of the meat, when duly roasted, is 1s. per lb., and the loss incurred by roasting is 27½ per cent. From an average of two experiments, it appears that, when the butcher's price of shoul- ders of mutton is 7½d. per lb., the cost of the meat, duly roasted, is 1½d. per lb., and the loss incurred by roasting is 28 per cent. From an average of experiments it appears that, when the butcher's price of the fore-quarter of lamb is 8½d. per lb., the cost of the meat, duly roasted, is 1s. 1½d. per lb., and the loss by roasting is 22½ per cent. From experiment 30, it appears that, if the first cost of hams be 10d. per lb., the meat, duly boiled, skinned, and browned, will amount to 1s. 1½d. per lb., and the loss by boiling is 12½ per cent. From experiments 1 and 30, it appears that, when the average cost of leg of salt pork average 8d. per lb., the boiled meat amounts to 10½d. per lb., and the loss in boiling is 13½ per cent. From an experiment it appears that, if the first cost of bacon is 8½d. per lb., the meat, when duly boiled, skinned, and browned, amounts to 10½d. per lb., the loss

799
MEAT.

in boiling alone being 64 per cent. From experiment 34, it appears that, when the butcher's price of knuckle of veal is 5d. per lb., the meat, duly boiled, costs 10d. per lb., the loss in boiling being 83 per cent. From an average of experiments 35, 36, 37, it appears that, at the prices of geese quoted, which average 6d. per lb., the cost of the roasted flesh is 1s. 7d. per lb., and the loss per cent 19. From an average of three experiments, it appears that, at the prices of turkeys quoted, which average 10d. per lb., the cost of the roasted flesh is 1s. 2d. per lb., and the loss per cent is 20. From an average of experiments 41 and 42, it appears that, when turkeys are sold at the last-mentioned price, the cost of the boiled flesh is 9d. per lb.; the loss in boiling being 8 per cent. From an experiment it appears, that, when turbot in the raw state is sold at 6d. per lb., the boiled fish costs 11d. per lb.; the loss in boiling is 53 per cent. From experiment 56, it appears that, when mackerel sells in the raw state at 4d. per lb., the boiled fish costs 9d. per lb., the loss in boiling being 74 per cent. From an experiment, it appears that the roasted flesh of a woodcock sometimes costs 16s. per lb., and sometimes 2s. But the flesh of the quail is still more expensive. This bird, when fattened, is sold at the enormous price of 3s.; and, when allowance is made for the loss in cooking and the bones, the meat may be estimated at 2 oz., which brings the cost of the cooked flesh to 1/. 4s. per lb! Those to whom such morsels are necessary are not to be envied. A haunch of venison, weighing 26 lbs., will cost 31 guineas. The meat of this, when roasted and detached from the bone, will amount to about 3s. 10d. per lb.; and if the animal was more than usually fat, to 4s. The foregoing table gives the results in a still more abstract form; but the prices apply to London only. The articles are arranged in the order of their costliness in the London market. It appears from the experiments, that

800

MEAT.

The loss per cent. on roasting beef, viz. sirloins and ribs together, is 19. Do. on roasting mutton, viz. legs and shoulders together, is 19. Do. on roasting lamb, viz. the fore-quarter, is 20. Do. on roasting geese, is 19. Do. on roasting turkeys, is 19. Do. on roasting ducks, is 19. Do. on roasting chickens, is 19. Thus, the loss on roasting varies from 14 to nearly double that rate. The average loss on roasting butchers' meat is 22 per cent., and on roasting domestic poultry is 20. The loss per cent. on boiling mutton, viz. legs, is 10. Do. on boiling hams, is 10. Do. on boiling salt beef, is 15. Do. on boiling salt pork, is 15. Do. on boiling bacon, is 20. Do. on boiling knuckles of veal, is 20. Do. on boiling turkeys, is 20. Do. on boiling ducks, is 20. Thus, the loss on boiling varies from 61 to 16. The average loss on boiling butchers' meat, pork, hams, and bacon, is 12, and on boiling domestic poultry is 14. These estimates of butchers' meat do not agree with those of Professor Wallace. I shall select for contrast all those cases that can be compared. 100 lbs. of beef lost in boiling - 20. 15. Do. in roasting - 12. 19. 100 lbs. of mutton lost in boiling - 20. 10. 100 lbs. of shoulders of mutton lost in roasting - 31. 24. The average loss in boiling and roasting together is, according to Professor Wallace, 28 per cent.; according to my trials, it is but 18. I know not how to reconcile these results otherwise than by supposing a difference in the meat, or its fatness, or in the duration of the heat. I used meat of sufficient, but not unprofitable fatness, such as is preferred in families; the meat was in all cases a little rare at its centre, and the results were determined with the utmost care. In great public institutions, where economy is studied, and every thing is regulated by weight and measure, tables of this kind do not afford a guide that is to be implicitly relied on. It is obvious that another element must be taken into the calculation, to insure true results; the ratio in which each article of food satisfies the appetite, which varies with almost every individual. Butchers' meat, taking one kind with another, averages 35 per cent. of real nutritive matter; at least, such was the estimate presented by MM. Vauquelin and Percy to the French minister of the interior. Adopting this determination, we are prepared to appreciate the
quantity of real nutritive matter received into the stomach, when a meal of plain meat and vegetables has been eaten; it is not practicable to come to any conclusion when made dishes are used. It is a subject of interest, and particularly so to the inhabitants of the British Isles, who are said by foreigners to make use of the animal food than is necessary or wholesome.

In order, then, to equalize the animal and vegetable matter, and to increase the total quantity, the ratio should be 83 oz. of boiled mutton, 10 oz. of potato, and the same of turnip; the total amount of food swallowed will be 28½ oz., but the quantity of real nourishment will be but 6 oz., half being animal and half vegetable matter. This is certainly a sufficient meal for most persons who have but little laborious occupation; for, if a pint of liquid be drunk at the same time, the load on the stomach will weigh 3 lb.; and this will be increased to 4½ lb, if a pint of wine be swallowed. Now, the difference between 83 oz. of boiled meat and 10 oz. appears very trivial; but, if the greater of the two quantities be persevered in regularly every day for the term of a man's adult life of half a century, it may excite a little surprise in the person who practises it, to learn that he will have consumed a flock of sheep, consisting of about fifty-three head, in excess above what he ought to have made use of. In a life of sixty-five years, allowing 83 oz. per day for fifty years, two-thirds of that quantity for ten years, and 3 oz. a day for three years of childhood, the total animal food amounts to 350 sheep. If to this he added the excess above mentioned, the number of sheep, the cooked meat of which is devoured by one man during a life of sixty-five years, is about 400; along with 5 tons of potatoes, about the same of turnips or other vegetables, 9 tons' weight of common drink, and 6 tons' weight of wine, or a pint a day for three years; only thus, for dinner alone, above 30 tons' weight of solids and liquids must have passed through the stomach. Inordinate work will wear out any machinery before its time, especially if the work performed be of a peculiar wearing character. Whether it is advisable to add the fifty-three unnecessary sheep to one's dinner, is a question which every reader will answer to himself as he thinks proper. The food of old Parr, who died at 153 years of age, consisted of cheese, coarse bread, milk, and small beer. Would it have made no difference in the duration of his life if he had swallowed 1050 sheep! for about this number would have been his share at the usual rate, along with his twenty tons of wine. It may assist in drawing a conclusion, to recollect that when he was brought to London, and lived in splendour, “fed high, and drank plentifully of the best wines,” he soon died: and his death was generally attributed to that cause, for he had vigour of body “to have lived a good while longer,” as the reporter says (Linneth's Enquiry.)

1. Selection of Cattle and Beef.—In proportion of cattle to be sent alive to market, they should invariably possess fine symmetry and small bone, carrying the greatest weight of beef on the most valuable points, such as rumps, loins, and crops; the back well covered, the buttocks and flanks well filled up, and the whole carcass exhibiting a fullness of flesh, excepting the necks and coarser parts. They should handle hard and firm, in order to stand the voyage, and handle and look well in the market. Firm handlers, whether heifers or oxen, always out well up. A good coat of hair, too, is of great use in a sea-voyage on deck, and also in enabling cattle to stand the vicissitudes of weather in the markets, and it enables them to be turned out in safety, in case they should not be disposed of on the first market-day. Thin-coated cattle always look tender, and are, in fact, so under any circumstances. Cattle only possessing these requisite properties should be sent to Smithfield market, and any others will assuredly incur loss to the shipper. An ox or heifer of these properties, weighing 80 stones per Smithfield stone of 8 lbs., will actually realize more money than a coarse ox or heifer weighing 100 stones. Heavy cattle, however, do not take readily in Smithfield, except for a month about Christmas, unless they are remarkably handsome; nor do very light cattle, under 40 stones, for two or three months in summer, unless they are really neatly shaped, and thick on the backs and best points. The most saleable weights are from 50 stones to 55 stones. Of the Scottish breeds, the Galloway and West Highlanders fetch generally the top price; fine Angus and Aberdeenshires, of fine points and thick backs, take well; and handsome, well-bred short horns also take readily, but do not realize so much money as Galloways or West Highlanders. Fine crosses are also very saleable.

The meat intended to be sent to the carcass market in London should be taken from such cattle as we have described. It is not large quantities of lean and fat that are wanted there, but both well mixed. Ox and heifer beef of equal quality command the same prices. Rumps, loins, crops, and other fine points fitted for roasting and steaks, are more in demand than the boiling pieces, and realize comparatively higher prices, and therefore they alone should be sent. Coarse beef always fetches low prices in London, and therefore should be purchased (to use a sporting phrase) at a low figure in the country to return any profit, for the best buyers look more to quality than quantity; and as this quality of beef is rather cheaper in London than in Scotland, shippers should be cautious in sending any such thither.

2. Selection of Sheep and Mutton.—Ripe, compact sheep, of light weights, carrying a large proportion of lean on the back, loins, and shoulder, with a full round leg and handsome carcass, are admirably suited for Smithfield. Such, from 14 lb. to 20 lb. per quarter, will take readily; but they are most valuable from 16 lb. to 18 lb. The nearer the form and quality approach those of South Downs, the more likely are they to command the top prices; for the Downs have long been unrivalled favourites in Smithfield. The black-faced Linton breed approach nearly to the qualities of the South Downs, and com-
MEAT.

meat as high a price. Half-breeds from Leicester rams and Cheviot and black-faced ewes, which resemble the true breeds in form and quality, form saleable sheep in London. The old black-faced breed are too thin in the leg and back, and are in London termed "goaty." There are by far too many of this kind sent from Scotland, and they are generally, besides, only half-meated, or half-fat, and of course only fetch middling prices. They, however, generally please the consumer for flavour. Pure bred Leicesters are too fat, unless they are sent young, and do not exceed 10 lb. per quarter; when above that weight they fetch inferior prices. A fine South Down or Scotch sheep, of 18 lb. per quarter, will fetch 7d. per lb. by the carcass, whereas a heavy Leicester, Gloucester, Lincoln, or Kent, of 24 lb. a quarter and upwards, will realize no more than 6d.

The carcasses of mutton to be sent to London should, of course, be those of sheep such as are here recommended to be sent alive. Large quantities of fat are not so desirable as a proportionate mixture of fat with the lean. In using the lous and other parts of very fat mutton for chops, much of it has to be pared away, and sold for the price of raw fat, perhaps 4d. a pound; whereas well-mixed chops may be sold for 7d. or 8d. a pound. This shows the nature of the mistake committed in sending fat, heavy mutton to London. The great point is, to select ripe mutton and sheep; for the latter will stand the voyage better than half-fat, and will not lose half the quantity of flesh in three days as the latter. No overgrown animals, having masses of fat on one place and not on another, would therefore command the top price; but those having plump carcasses, well mixed with fat and lean, firmly and equally laid on, with fine symmetry and valuable points, will always command the top price, both at Smithfield and the carcass markets.

3. Selection of Lambs.—Lambs are a favourite stock to send to London, and they are always sent alive. Leicester lambs are admirably adapted for the London market. They are handsome, compact, thick on all the points, and although they might become too fat when grown to sheep, they cannot be too fat as lambs. Their flesh is white, a property much admired in London, and every joint of them looks well on the table. The lambs of the cross between the Leicester and the Cheviot and black-faced ewes are next best for fat and lean, and cut well into joints, although they have not the handsome figures of the pure Leicester. True Cheviot and black-faced lambs, unless very fat, do not take so well in Smithfield, not being so compact, taking longer time to come to maturity, not cutting up so thick, and presenting small joints on the table; but they make very delicate and high-flavoured chops. No lambs should be sent to Smithfield until they are at least three months old, and have obtained the weight of 9 lb. or 10 lb. a quarter; and if they are not fat enough, and have not attained that weight at that age, they should be kept on. Shippers may calculate on a loss of 1 lb. a quarter on the voyage; unless, therefore, lambs are from 9 lb. to 10 lb. a quarter, they would be too small after that loss, and they then become unsaleable except at low prices. Ewe lambs are preferred, being more delicate than wethers, which are next in value, for ram lambs are very unsaleable. All wether lambs, therefore, intended for Smithfield, should be castrated when a few days old, and their tails cut short, leaving not more than three inches. The docking gives them a very compact form, and it causes the flesh to grow up towards the back, long tails giving a contrary tendency.

4. Selection of Pigs and Pork.—Much caution is requisite on the part of the shipper of pigs for London. A very mistaken notion prevails among many shippers, and the notion has been contracted in ignorance of the nature of the London market, that pigs must be fat to suit the English taste. The fact is quite the reverse, for the larger the pig is fattened, the less money per pound it fetches. Pigs are worth the most money when their weight ranges from 35 lb. to 40 lb.; and from this weight up to 60 lb. or 70 lb., they are termed dairy-fed porkers. If at the former weight, they are of good symmetry, and of fair quality, delicate about the jar in the flesh, and not more than 1 inch or 1½ inch thick of fat on the back, they will fetch the top price of the day. Pigs of the average weight of 60 lb. will give about 7½ lb. per lb.; from 70 lb. to 100 lb., averaging 85 lb., and 2 inches thick of fat, 6d. per lb.; from 100 lb. to 150 lb., averaging 130 lb., and about 2½ inches of fat, 5d. to 5½d. per lb.; from 150 lb. to 200 lb., averaging about 170 lb., and about 3 inches of fat, 4d. to 4½d. per lb.; and all above the last weight and thickness of fat, only about 3½d. per lb. Besides the larger-sized, a very small fat pig is not relished in London. Indeed, we need not be surprised at this preference, when we consider that only the small lean and fat porkers are used for roasting, chops, and pickled pork, and the large fat pigs are chopped down for sausages. No pigs, therefore, should be sent to London exceeding 100 lb., exclusive of head and feet, but which are only moderately fat and of fine quality; all other qualities should be cured as litch, bacon, and hams. Pigs, if possible, should be sent on the part of London. Occasionally they arrive in pretty good order in carcass; but in carcass, in thick weather, the flesh becomes very soft, and the skin dry; and in dry weather the skin becomes quite hard and brown coloured. Of equal qualities, the live pig will draw from a halfpenny to a penny a pound more than in carcass. Feeders of pigs should be careful on what they feed their pigs, especially fish. The retail butchers are such nice judges of pork, that on buying a carcass at Newgate or Leadenhall market, and cutting a slice, they can detect the least peculiarity, fine in taste, which, if they do, they will return it again, and cause the carcass to be resold for what it will bring, rather than send any such pork to their customers.

Cutting up Meat.—The mode of cutting up meat is more diversified even than the slaughtering, almost every town having its own. But as London is the great emporium of the export meat trade of Scotland, the method of cutting up meat in the metropolis should constitute the particular study of the shippers of meat. To
acquire this necessary information, the shippers should have a few of the most expert butchers in London to slaughter and cut up the carcasses of the various sorts of animals. They should never consider themselves above acquiring such information, when their own interest will be benefited by its adoption. Whether the London method of cutting up meat is really the best of any, and we think it is, must be admitted that the London butchers must have the most extensive and varied experience; and any one has only to witness the operation performed by expert London butchers to be satisfied that they display great skill in their art, and execute their work with the utmost precision. Indeed, the precision with which they divide the different qualities of meat from the same carcass shows their thorough knowledge of the qualities of meat; and the variety of prices which different parts of the same carcass fetch, shows with what accuracy they can gratify the tastes of the various grades of their customers.

In practising this precision, they not only make the best use of the carcass, but realize the highest value for it, and at the same time gratify the taste of the greatest number of customers. In the carcass of any animal, an ox, for instance, there are different qualities of meat, and these qualities are situated in different parts of the carcass. All the best parts are in London used for roasting and steaks, and the inferior for boiling, either in pieces, or making stock for soups, or minced meat, in the various forms of pies, sausages, &c.

The carcass of an ox is cut up into the following pieces, as may be seen on referring to the numbers on the annexed cut, fig. 1.

The relative value of these different cuts of an ox may be stated at their current value, viz., when the rumps, loins, and fore-ribs of a fine ox fetch 8d. a pound, the thick flank, buttock, and middle rib will fetch 6d.; the sirloin or adze-bone, thin flank, chuck rib, brisket, and leg of mutton piece, 5d.; the clop and sticking, and neck, 3d.; and the legs and shins, 2d. a pound. Such is the difference in value of the different cuts of an ox in the meat markets in London.

As an object of comparison, we shall also give a figure of an ox cut up in the Edinburgh method, as in fig. 2, and the great difference between both methods may be seen at a glance. See cuts.

It is therefore obvious that, of the two methods of cutting up beef, the London affords much more of roasting and steak, that is, the more valuable pieces, out of the same carcass; and, of course, more money would thereby be realized from it.

Much of what we have said on the management requisite in sending beef to the London market will apply equally to sending mutton, veal, or lamb to the same market. The best pieces only should be sent to London, and the remainder kept for the home market: and were this recommendation attended to, the expense of exportation would be diminished on what was sent; for the best pieces would pack well together in a comparatively small space, whereas whole carcasses of mutton, by the roundness of the rib, occupy much unnecessary room, for which freight must be paid.

Mutton is also cut up differently in London and Scotland, as may be seen on referring to the figures at the top of next page, of which the first represents the London method.

In the fore-quarter, No. 1 is the shoulder, 2 and 3 the neck, after the shoulder has been taken off; and 3 the breast; and in the hind-quarter, 4 is the loin, which, when cut double, that is, partly from both sides of the carcass, is called a chine or saddle, and 5 is the leg. A leg of mutton in London is cut short; a haunch is cut long, taking in the hook-bone, similar to a haunch of venison. The flap of the loin is left attached to that part of the fore-quarter called the breast. The Scotch mode of cutting up mutton is represented by fig. 2, in which, in the hind quarter, No. 1 is the gigot, and 2 the
MEAT.

Fig. 1.  

Fig. 2.

of veal. It is like a round of beef with a part of the thin flank left to be skewered around it. 

The round bone is taken out, and stuffing put into its place. When theith-bone and hookbone are cut from the loin, the piece is called a chump of veal. The hind-quarter of veal thus consists of fillet, chump, loin, and leg. 

The fore-quarter is cut in the same manner as mutton, having shoulder, breast, and neck. 

In Scotland, veal is cut very much like mutton.

The London mode of cutting up pork is the same as the Scotch mode of cutting up mutton, so fig. 2 will illustrate the mode; in which, in the hind-quarter, No. 1 is the leg, and 2 is the loin; in the fore, 3, back-rib, chine, or hand; and 4, breast and shoulders, spring or belly. 

The spring is used for pickling, and the hand for roasting, and for chops, or sausages. 

In Scotland, the hind-quarter consists of leg and loin, and the fore of back-ribs and breast. 

For pickling or roasting, pork is cut in the hind-quarter like that of English mutton, and in the fore like that of Scotch. In both countries, the ham is cut out alike. (Donovan's Dom. Econ.; Quart. Jour. of Agr. vol. iii. p. 241-281.) See CATTLE and SALTING.

MEDICK (Medicago). An extensive genus of herbaceous, mostly procumbent, plants. The perennial herbaceous species are sometimes cultivated for ornament; they will grow in any common garden soil, and are increased by dividing the roots of the plants in spring. 

The shrubby kinds grow in a similar soil, and are readily increased by cuttings. The seeds of the annual species require to be sown in the open border in spring. There are six indigenous species.

1. Purple medick, or lucern (M. sativa). See LUCERN.

2. Yellow sickle medick, or button-jags (M. falcata). This perennial species grows on dry, gravelly banks and old walls. The root is long and woody. In habit it very closely resembles lucern, but the numerous stems are procumbent, spreading every way, hairy. The flowers, which blow in June and July, are generally pale-yellow, but occasionally violet, and more frequently green, evidently from a combination of these two colours. The legumes are black, downy, sickle-shaped, not twisted in a screw, as in lucern. This species is, perhaps, as good fodder as lucern, though less succulent, and, from its position, less accessible to the scythe. It withstands severe winters better than lucern, and is eaten eagerly by cattle and horses, though its stalks are hard and woody.

3. Black trefoil medick, or nonsuch (M. lupulina). This annual species is, in England, very common in meadow pastures and cultivated fields, where it flowers from May till August. The black medick has the habit of some of the procumbent yellow trefoils, and has such general resemblance to the proper trefoils or clovers, that it is often mistaken for some of the smaller species. The form and colour of the seed-pods afford a ready distinction. 

The root is tapering, and somewhat fibrous. Flowers small, yellow, from 30 to 40 and upwards in each spike, which is at first roundish, afterwards ovate. Legumes kidney-

loin; and in the fore, 3 the back ribs, and 4 the breast and shoulders. The gigot is cut about half-way between the leg and haunch of the London method; and the fore-quarter is cut right through the shoulders in two places, called back-ribs and breast. Shoulders of mutton are never cut off in Scotland before being cooked, except by keepers of eating-houses; but the London plan of cutting mutton is decidedly the best, the shoulder forming an excellent roast, and the best end of the neck-piece being admirably suited for chops.

The different joints of mutton vary almost as much in price in London as pieces of beef. The leg is sometimes sold as high as 10/- a pound, whilst the breast of the same sheep will only fetch 4d. or 5d.; and if, in the wholesale market, the whole carcass is sold at 6d. a pound, the hind-quarter will be worth 7d. and the fore only 5d. From these facts it is obvious, that it is the interest of the shipper only to send hind-quarters of mutton to London, for which 7d. a pound may be easily obtained, and a ready market for them in the west-end butchers, who seldom deal in fore-quarters. The fore-quarters could be sold at home; hence realizing as much for them as they could fetch in London, besides saving on them the freight, commission, and wharfage. They form excellent joints for tradesmen's families, and are, in fact, generally preferred by them to the hind-quarters, which are considered dry eating, and certainly do not make so good broth as the fore-quarter. 

Besides the saving of room in packing the hind-quarters, they would run no risk of being stained when sent by themselves, as the staining generally arises from blood oozing out of the veins in the fore-quarter.

Lamb is cut up in London in much the same manner as mutton, excepting that the neck and breast, when the shoulder is taken off, is roasted whole, and the piece is called ribs of lamb. 

In Scotland lamb is cut up exactly as mutton. Veal is cut up in London in a different way from any other meat. The knife is drawn between the buttock and itch-bone, and through the pope's eye, taking a sloping direction through the coarse end of the buttock, leaving a flap. The piece thus cut out is called a fillet.
MELILOT.
shaped, rugged and veiny, single-seeded, turning black when ripe. Sir J. E. Smith speaks of this as "one of the most valuable of artificial grasses, affording excellent fodder for sheep;" but this good opinion is hardly borne out by experience, for, though Arthur Young makes frequent mention of it, Sinclair, in his more recent experiments on the grasses, observes that it is only fit for light soils, and these must be deep, as the root penetrates to a considerable depth. It does not appear to be fit for separate cultivation, nor even to be employed in any large proportion in a mixture of other seeds; and the root being annual, its use is, therefore, confined to the alternate husbandry.

4. Spotted medick (M. marulata). This is another annual species, growing on a gravely soil in the southern parts of England. The root is fibrous, beset with little fleshy knobs. Stems prostrate, various in length. Leaves inversely heart-shaped, spotted. Stipules dilated, sharply toothed. Flowers yellow, larger small, two or three together. Legumes spiral, depressed, fringed with long spreading bristles; when ripe, brown, not black. This has been mentioned, but not much recommended as a fodder for cattle.

5. Flat-toothed medick (M. maricola). This is a doubtful native, growing on the sea-coast. It is an annual, and flowers in June and July.

6. Little bur medick (M. minutum). This is a little prostrate annual species, growing in sandy fields, but rare, clothed in every part with fine, soft, rather silky hairs.

MELIOLAR (Melilotus). A genus of large-growing fruit trees, which are very ornamental, and therefore worth a place in every shrubbery. Any common soil suits them, and they are readily increased by budding or grafting on the common hawthorn, or they may be increased by seeds, which do not vegetate till the second year.

MELILOT COMMON, Melilot Trefoil, King's clover, Hart's clover. Pl. 19, b. (Trifolium officinale.) This plant is very nearly allied to the long-rooted clover: the tapering root, however, appears to be strictly annual. The lower leaves are oblong, wedge-shaped; the upper ones elliptical: they are more serrate, and smaller in every respect than those of the long-rooted clover. The flowers are smaller and more drooping. The legume contains often more than two seeds, which is seldom or never the case in the long-rooted clover.

In England the common melilot grows wild in thickets, hedges, and the borders of fields, sometimes in the prairies of America. Stem 2 or 3 feet high, erect. Clusters uniflateral, 2 inches or more in length, on long axillary footstalks. Flowers numerous, all drooping towards one side, of a full yellow, veiny. Stipules awl-shaped. Legumes prominent, acute, transversely wrinkled, hairy.

All the species of live-stock are said to eat this clover. The whole plant in drying acquires a scent like new hay, but far stronger. The seeds, when mixed with bread-corn, give it a nauseous flavour. This plant, or a variety of it, is used in making the Swiss cheese called "Scotch-cheddar." It is grown in a mill, and mixed with the curd into a kind of paste, which is put into conical moulds, and there dried. See Schinziger.

From the experience of Sinclair and others, this plant appears to be very much inferior to the long-rooted clover, and cannot be put to any use for which that species is not equally good or superior: it grows chiefly in clayey soils. In very exposed situations it attains only to a small size; while in such as are sheltered it sometimes reaches to the height of six feet. It ripens an abundance of seed, and flowers in the third or last week of June. Melilot is out of use in medicine, though it served too long to give a green colour and an
odious scent to a sort of blister plaster, called by its name and no less whatever.

MELILOTUS leucautha major is the celebrated Bokhara Clover, a plant which Mr. Robert Arthur, of Edinburgh, says, "claims a place in every flower-garden, for its beauty. It is an herbaceous plant of very striking appearance, 10 or 12 feet in height, covered with spikes of white pea-blossoms, which also shed a sweet perfume. Hence it is sometimes called Sweet Flowering Clover.

"I esteem its value in agriculture of greater importance. The objections to its cultivation are, that cattle give a preference to other green food, and that the stem contains too much woody fibre. The plant, however, is new to Britain, and we know that man and animals frequently require successive trials of new food before taste is acquired for it. As a proof of this, I understand that some cattle are getting very fond of this clover; and we know that the tissue of plants in general is changed more and more into woody fibre as they progress towards maturity. Nature increases the woody fibre of this clover for support as it elongates its gigantic stem. If, however, it is cut for cattle, when about 10 feet in height, it will be found nearly as succulent as the common red clover.

"I exhibited plants of it at the Highland Society's show, last September, 10 feet in height, being the second crop of it that season, from poor sandy land. I know no plant whatever that will produce so much weight of vegetable matter in equal time and space; and were it only for the production of vegetable manure, it is a boon to the agricultural world. In my experiments with it last summer, as a manure, for new varieties of Alsike (?) Clover, I found it to be the cheapest manure.

"In the economical formation of manure, it might be liberally supplied, with other food, throughout the summer, to young cattle and pigs, in an open straw-yard profusely bedded over with layers of turf, peat-earth, whins, broom, brushwood, ferns, straw, weeds, &c., and thus save much outlay on the purchase of foreign manures.

"The Bokhara Clover may be sown at any time throughout the growing season; but the most profitable time to sow it is immediately after a crop of early potatoes, or even after grass, barley, wheat, &c. The land being well manured, ploughed over, and harrowed smooth, it may be sown in shallow drills 18 inches apart; being cut once in autumn, it will produce a much earlier spring crop than tares, Italian rye-grass, &c. It should always be cut very close to the ground, as the shoots produced from beneath the surface are the most luxuriant, and it will thus stand a severe win-

MELON CULTURE.

ter much better than when its vitality is exposed on long stubble. Treated in this way with me, it yields two successive winters, and acquires all the characteristics of a perennial root. I have no doubt of its continuing perennial and more vigorous with the age of the plants, if only cut close in autumn, and toppedress with rich compost."

Mr. James Gowen, who resides at Mount Airy, near Philadelphia, has been much in the practice of keeping up a considerable stock of uncommonly fine cattle, and soiling them in summer upon lucern, rye, and red clover. He has raised patches of the melon, and from his observation says, "there is no grass or plant I have yet seen that affords to me such promise as the Sweet-scented or Bokhara Clover." (Cultivator, Nov. 1842.)

MELON, THE COMMON, or MUSK (Cucumis melo). An herbaceous, succulent, climbing, or trailing annual, cultivated for its fruit in hot eastern countries from time immemorial. The varieties of the melon are numerous; yet few of them comparatively are worthy of cultivation in England. The larger varieties especially are deficient in flavour and richness. Mr. Knight says, that whoever is acquainted with the green-fleshed, and Salonica, or white-fleshed, will cultivate no other.

The cantaloupes are varieties characterized by their rings being universally covered with reticulations. With the exception of the green, or oblong-ribbed, these bear round fruit, more or less approaching a flattened spheroid. Their common name is derived from that of one of the country-seats of the pope, where they are much cultivated.

MELON CULTURE. The warm summers of the Southern and most of the Middle States, are highly favourable to the culture of melons of every description, which in some places constitute a very profitable crop. The following communication relative to the culture of the musk melon or cantaloup, addressed to the Editor of the Cultivator, by T. G. Bergen, a person well versed in the business, will show how this is managed on Long Island, for the New York market:

The kind which we at present cultivate, says Mr. Bergen, are with which the New York market is principally supplied, is known among us by the name of Skillman melons, They average about 6 inches in diameter, are nearly round, have a rough skin, and their flesh is of a green colour. This is the sixth variety which has been in vogue during my recollection, and the finest of them all. The seed from which all these varieties originated, I believe to have been imported from the coasts of the Mediterranean. They soon degenerate unless care is taken in the selection of the seed. We prefer for melons a rich sandy soil, and on this they flourish better than on any other, and are not so liable to speck in rainy weather. When planted on a red clover sod I have seldom failed having a good crop; but when this is not to be had, we prefer preparing the ground by sowing with rye in August or September of the preceding year, as described in my former communication on the cultivation of cucumbers: the ground is also pre-
pared in a similar manner in the spring, except that the hills are furrowed 5 feet apart, and the same kind and quantity of manure made use of.

We generally commence planting about a week later than we do cucumbers, but occasionally at the same time, dropping from 20 to 30 seeds into a hill, and covering them about an inch deep with fine soil. Eight or 10 days after putting in the first seed we commence planting over, which we seldom perform the second time, unless by examination we find the first seed about to fail. The seed of melons is not so liable to rot as that of cucumbers, but long storms are very apt to destroy the young plants, and they will even produce great injury when the plants have vined off the hills. In 1837, a succession of wet weather caused the ends of the principal part of the melon-vines in our vicinity to die as late as the 8th of July; but mine fortunately did not suffer as much as those of my neighbours. We cultivate the plants in the same manner as cucumbers, except that in hoeing it is generally necessary to remove a small portion of the soil from between them, in consequence of their being too short to admit of the young weeds being covered without injury to the plants. We gradually thin them down to 4 in a hill, standing from 5 to 6 inches apart. The plants are liable to the depredations of the same species of insects which prey upon cucumbers, and they are destroyed in the same manner.

Melon vines are in bearing from 5 to 6 weeks; whenever a drought occurs, this period is much less, for that of 1838 finished mine in 4 weeks. They often bear a second crop, which answers for pickling, but I have known this crop to come to perfection.

When the fruit is ripe, it requires to be gathered every day, otherwise there would be large quantities lost in consequence of becoming too ripe and soft. When ripe, they have a yellowish colour; but such as are cracked around the stem and come off easily from the vines, we always gather, for they will be fit for eating by the next day, when sold in the markets.

To insure good crops, melons should not be planted two years in succession on the same ground; they require a rotation. Marshall, an English writer, recommends the carrying of cucumber and melon seeds a week or two in the breeches pockets previous to planting, to dry away some of the more watery particles; we were believers of this doctrine, it would be a difficult matter, and required large pockets or a regiment of small ones to carry it into practice, since some of us, to secure our crops, plant from 3 to 4 bushels of seed in a season. The following is the number of hills planted, produce (large quantities of unsaleable ones fed to the hogs excepted), and amount of sales for the preceding 4 years: viz.

**METEOROLOGY.**

**MELON, WATER (Cucumis cirrulatus).** A plant well known in the United States for its delicious and refreshing fruit. To acquire the greatest perfection it demands a warm and sandy soil, and this if finds in New Jersey, and the South. The winter-melon is extensively cultivated. There are several varieties, such as the long and striped Carolina, the more round and dark-skinned Spanish, &c. In some parts of southern Russia, a kind of beer is brewed from their very abundant and cheap water-melons, with the addition of hops: they also prepare a conserve or marmalade from this fruit, which is a good substitute for syrup or molasses.

**MENDING.** A country term used to signify the improving the quality or texture of land by the application of manure.

**MERCURY (Mercurialis).** These are regarded as mere weeds, possessing narcotic, fetid, and dangerous qualities.

**MERINO SHEEP.** See SHEEP.

**MESLIN.** A term applied in New England to the crop of peas and oats when sown together.

**MESLIN-CORN.** A term applied to wheat and rye produced in a state of moisture.

**METEOROLOGY.** The science of meteors, or the science which explains the various phenomena which have their origin in the atmosphere. Under the term meteorology, it is now usual to include not merely the observation of the accidental phenomena to which the name of meteor is applied, but every terrestrial as well as atmospheric phenomenon, whether accidental or permanent, depending on the action of heat, light, electricity, and magnetism. In this extended signification, meteorology comprehends climatology, and the greater part of physical geography; and its object is to determine the diversified and incessantly changing influences of the four great agents of nature now named, on land, in the sea, and in the atmosphere. It is the object of meteorology to investigate and discover the modes of operation, and the causes instrumental, as well as final, of the multitude of interesting phenomena which exercise an influence on the animal and vegetable kingdoms. To this science belongs the examination of the force of radiation from the sun, or the temperature directly produced by his beams; the inquiry into the constitution, mechanical as well as chemical, of that intimate mixture of gaseous bodies which is the subject of what are called atmospheric changes; the scrutiny of the laws governing the variations of climate; that also of those which regulate the diminution of heat in the atmosphere, in proportion to the altitude; the development of the principles determining the quantity and state of the aqueous portion of the atmosphere; and the acquirement of knowledge, in short, on every subject of science presented by the atmosphere itself, or by its modes of relation to the aqueous and mineral kingdoms, and the general laws of its influence on organized matter. This branch of natural history also comprehends the examination of two great series of phenomena, not strictly comprised by the foregoing enumeration; by which, on the one side, its boundaries are...

807
MIGNONETTE.

MICA. A well-known mineral, with a pearly, metallic lustre, consisting of extremely thin, elastic plates or layers somewhat resembling glass. The largest sheets are brought from Siberia, and used instead of glass, especially to enclose fire where it is desirable to see the flame, as in stoves, &c. Mica enters into the composition of granite. Its specific gravity is 2.65. When analyzed it is shown to contain potash, magnesia, silica, oxide of iron, with other ingredients of well-known fertilizing properties. (See GEOLOGY.) Hence, where any of these are deficient in soils, the application of mica must be advantageous.

MICE (Mus). A very destructive sort of vermin to many of the cultivator’s growing and housed crops, and which should, therefore, be destroyed as soon as possible. Cats, dogs, owls, snakes, and hedge-hogs are the natural enemies of rats and mice, and should, therefore, be encouraged about the farm.

To destroy Rats and Mice in Corn Stacks.—The following method was adopted by the late Mr. John Gibson, of Millbeck Hall, Keswick, and is still continued by his son, Mr. Joseph Gibson, of the same place, with never-failing success. It is accomplished by simply driving in a few hedge-stakes, at about 4 feet distance, round the stack, and then most of the holes in the woolen or linen web, of about 6-ths or 7-ths wide, upon the stakes, so as to be perfectly close at the bottom, of which particular care must be taken, in order that none of the vermin may creep under the folds. It is certain that none will attempt to climb over the top, and it matters not whether there are fifty or a hundred within the enclosed area, they will be quite safe. An active lad and a dog may easily destroy any number, and he must be a clumsy fellow if he lose one in a hundred. A few neighbours, by subscribing about 2s. 6d. each, might get an article at 10s. a yard that would serve them all for about 20 years. If the above simple method were generally adopted for a short time, those destructive enemies to the stack-yard would soon be considerably reduced. A correspondent of the Mark Lane Express suggests the following plan for the destruction of these obnoxious vermin. Feed with flour and a few sweet almonds bruised and mixed together with a small quantity of treacle, to form a paste (add a few drops of oil of aniseed), for 5 or 6 nights, until they take it freely, never laying more of the mixture than they will eat up clean; then add a teaspoonful of carbonate of barium to about a pound of the paste. I prefer the barytes to arsenic, it being free from the sour taste of the arsenic, which the rats will never take a second time. By using the above composition, I have kept my premises clear, without employing a rat-catcher, at the expense of a few shillings a year.

MID-RIB. In botany, the middle vein of a leaf which passes from the petiole to the apex.

MIGNONETTE (Reseda, to calm or appease; the Latins considered its application useful in external bruises). The sweet mignonette (R. odorata) is an old and universal favourite, on account of the very pleasant odour emitted by the flowers. Though usually annual, by care in a green-house and constantly...
pruning, the cultivated mignonette may be rendered perennial, and even shrubby.

MILDEW, or RUST. Of all the many diseases which attack our cultivated plants, not one is so destructive as the mildew. It is the "plague" of our wheat crops; and as that fatal distemper is always lurking in some district of climates warmer than our own, so the mildew is always in our fields, waiting for circumstances favourable to its outspread, and ready to destroy the expected harvest of the husbandman. So constantly present is this destructive disorder, that in the fairest fields of wheat grown in the richest corn districts of England, a farmer, when he saw a single acre entirely uninfected. Every year the farmer is more or less injured by this disease, for the produce of each acre of wheat is unquestionably reduced annually several bushels. Yet those who suffer most by the loss, the farmers themselves, are almost universally ignorant of the fact; and their attention is rarely arrested by it till a year occurs in which their crop of wheat is nearly annihilated.

Its prevailing injurious nature was well known in an age as ancient as that of the Hebrews; and it had not spared the Greeks and Romans. Even the poets, as Horace in his Odes, speak of it as the "sterile Rubigo" (Carmin. lib. 3, ode 23); and warning voices have not been since wanting to speak loudly of its ravages. Mr. Marshall says, "a certain preventive of the mildew would be a discovery worth millions to this country;" and many others have coincided in this estimate of its injuries.

This disease is known to be the effect produced by a minute fungus belonging to a genus closely allied to that which causes the smut. The roots of this fungus penetrate the vessels of the plant, and are nourished by the sap intended for perfecting its seed; consequently, if the fungi are so numerous in each stem as to make it a marked "mildew year," the grain is either partially or totally shrivelled, owing to the roots of these parasites intercepting the sap in its upward passage.

The ignorance relative to this disease is not a consequence of its novelty, since it has been known and dreaded in the earliest ages to which a culture extended. Thus when God held out as a warning to the Israelites the afflictions he would bring on them if disobedient, he enumerated the pestilence and the sword to destroy their persons, "with blasting and with mildew," to lay waste their fields (Deut. xxviii. 22; 1 Kings viii. 37; 2 Chron. vi. 28); and when the same Almighty Being had published that rebellious people, he reminded them by his prophet; "I have smitten you with blasting and mildew; when your gardens and your vineyards, and your fig trees, and your olive trees increased, the palpem-worm destroyed them." (Amos iv. 9, 11.) "I smote you with blasting, and with mildew, and with hail, in all the labours of your hands." (Haggai ii. 17.) The Hebrews called it yarocoon, implying a yellow pallidness arising from moisture. To the Greeks it was known as crustis, χρόσης; and Theophrastus, who wrote his History of Plants about 320 years before the Christian era, observes (lib. viii. c. 10) that it occurs more frequently to corn than to pulse; that in the climate of Greece barley was more subject to it than wheat; particularly a variety then known as achillum barley, they had taught them, that the crops on high lying lands were seldom attacked by this disease; but that the hollows surrounded by hills, where winds could not get at the crops they bore, were most frequently infected. It is chiefly generated, concludes Theophrastus, during the full moon.

By the Romans, the mildew was denominated "rubigo." Pliny informs us, in his History of Plants (lib. vii. c. 28 and 29), that it was the prevailing opinion that this disease arises from the heat of the sun, and certain writers have given and obtaining a caustic or burning quality from the intense heat of the sun. This naturalist himself thought, on the contrary, that the disease arises from cold, considering that infection first occurs during the sun, and always about the new or full moon. Pliny, and the still later writers of the Geoponica (for this work is composed of fragments of Roman writers living after the removal of the seat of empire to Constantinople, though written in the Greek language), considered that the best remedies were stinking pungent smuts; because they recommend fish, horns, goat's dung, &c., to be burned on such side of the field as would enable the wind to diffuse the smoke over and throughout the crop. They evidently had the same prejudice as is now entertained by our own farmers, that the mists which frequently prevail during midday in the hottest periods of summer are the cause of the mildew; for they direct those fumigations to be performed at such time as it is seen in the atmosphere. They also thought that if branches of the laurel were fixed among their corn, the mildew would pass from the crops to those branches. (Geopon. lib. v. c. 33; Plant Hist. Plant. lib. xvii. c. 17, &c.) One of their practices recommended is much more rational, namely, to bruise the leaves or roots of the colocynth, to macerate these in water, and, before the sun has risen, to sprinkle the infected crop with the liquor thus obtained. It is possible that the juice of the colocynth, which is a violent purgative to the human system, may be destructive to the fungus constituting the disease. It approaches to that which, in modern times, has been found the only effectual curative treatment; and the direction that the application should be performed in the morning evinces that it was a direction suggested and confirmed by experience. Columella (lib. ii. c. 12) says, that hoeing corn during wet weather is apt to induce mildew.

Some modern writers have considered that the rubigo of the Romans is the disease known to us as the smut; but, independent of the name, which evidently referred to the red or rusty hue of the disease, and which is not a characteristic of the last-named disorder, we have the direct testimony of Virgil (Geo. I. 150), that the rubigo was a disease of the straw; his words are, "Mox et frumentis labor additus; ut mala culmos esset rubigo, &c." Horace (Carmiunnam, lib. iii. ode xxiii.) and Ovid (Fast. iv. 907) speak of the same vegetable epidemic. The Greeks and Romans were as conscious as the Hebrews of the destruction
MILDEW.

it would inflict on their crops. They considered it as the instrument of vengeance directed by a particular deity, to whom they applied the same appellation as to the disease itself. (Schneider's Scriptorum Rei Rusticae, vol. i. pt. ii. p. 246.) To propitiate this presiding deity, a festival entitled Rubigalia, was instituted by Numa in the eleventh year of his reign, that is, 704 years before the birth of Christ. It was celebrated annually on the 25th of April, in the neighbourhood of a grove, at the fifth milestone, on the Clodian Way, and comprised sacrifices, races, and obscenities. Reddish-coloured bitsches (russe canes) were sacrificed, because the lesser dog-star was then in the heavens, and was considered unpropitious to corn. (Plinii Hist. Plant. lib. xviii. c. 29; Varsi Flacci Facti, p. 63.)

Ovid, who enters fully into the religious performances of the festival, says, that the limbs of a sheep and the entrails of a dog were offered as a sacrifice on the occasion; and that the priest informed him that he knew of no reason for the latter animal being sacrificed, but that its name coincided with that of the constellation which at that season was apparent in the sky. The prayer addressed by the priest to the presiding deity marks so strongly their knowledge of the extent and inclemencies of the disease, that I shall give a nearly literal translation of a part:

"O, blighting Rubigo, spare the corn-plants.
And let the ear wave gently o'er the surface of the earth.
Suffer the crops which have been nourished by the propitious
Stars of autumn, to grow until they become fit for the sickle.
Thine at no small power; the crops thou hast marked
The dispirited cultivator reckons as lost.
Neither winds, nor showers, so much injure the corn;
Neither when bitten by the frost does it acquire a hue so palid.
As if the sun fervently heats the moist stalks;
Then, O! dread goddess, is the opportunity for thy wrath;
Be merciful, I pray, and withhold your rusting hands from the crops;
Nor hast the cultivated land: it is sufficient to be able to do harm."

The misty weather, mistaken by the Roman cultivators as actually a cloud of mildew, is only one of many numerous instances which might be quoted where causes of the disease have been considered to be the disease itself. To enumerate these would form a long catalogue of mistakes; yet these I should not hesitate to detail, because the refutation would incidentally introduce much useful information, but that they will for the most part be noticed among the circumstances which promote the occurrence and aid the progress of this epidemic.

The first person, I believe, who correctly pointed out the nature of mildew, was Felice Fontana, who, in the year 1767, published at Lucca a very particular description of the fungus occasioning it, in a work entitled "Osservazione sopra la Ruggine del Grano." Since then it has engaged the attention of many botanists, and the results of their researches have been to establish it as a distinct species of fungus, though they differ as to the genus to which they attach it. It is the Puccinia graminis of Persoon (Disp. i. 3, f. 3); and it is the Uredo frumenti of Sowerby.

In Plate 2 there is a representation of this fungus, in which l, is a portion of wheat-straw affected with rust, magnified, to show the parasitic plant or fungus, giving rise to the disease called rust, blight, and mildew.

m, Another portion of a diseased stem in a green state, and before the fungus is quite ripe.

n, The small portion marked l (l), still more strongly magnified.

o, p, qr, s, t, u, Very highly magnified representations of the fungus parasite in different stages of growth and maturity.

o, Shows it in the young state; p, full-grown; q, two plants bursting and shedding their seeds when under water in the microscope; r, two plants bursting in a dry place; s, apparently abortive; t, seeds in a dry state; u, a small part of the bottom of a pore, with some of the parasitic fungi growing upon it.

Rust grows on the leaves and stems of wheat, &c., appears in dense diffuse tufts, often confluent, forming long, parallel lines on the culms; at first brownish-yellow, but changing to black. Sporidia elongated, elevate, very slightly constricted at the septum; upper cell the shortest; stipes filiform. It must not be confounded with another parasitical fungus, which is common upon the wheat-leaves and culms, but which is not so injurious, namely, the Uredo rubigo, of Descandolle (Flora Franca, vol. vi. p. 83). Characterized by spots yellow; halos oval, scattered, generally epigous; epidermis at length bursting longitudinally; sporidia sub-globose, red-brown, easily dispersed. If the straw of wheat be examined with the assistance of a magnifying glass, its striped surface will be seen to arise from longitudinal partitions of the outer bark or epidermis. The depressed partitions are furnished throughout their length with 1 or 2 rows of pores or orifices, which seem capable of emitting or imbibing moisture as the wants of the plant may require. Similar pores, though varying in form and arrangement, pervade the leaves and chaff, or glumes; and it is in these pores that the seeds of the parasitical Puccinia obtain admission, and, vegetating in the cavities to which they lead, doubtless thrust their minute roots into the cellular texture beneath the bark, and intercept for their own nourishment that sap which should proceed to the grain for its development and completion. The corn necessarily becomes shrivelled, proportionally as the fungi are more or less numerous on the plant: and as it is the nutriment that would have perfected the interior of the grain, which is chiefly extracted by the fungi, for the exterior form is nearly completed before the mildew occurs, the proportion of flour to bran is always much reduced. Sir J. Banks observed, in 1804, which was a "mildew year," that some of the wheat would not yield from a sack so much as a stone of flour.

Sir Humphry, then Mr. Davy, placed the loss caused by this fungus beyond a doubt, by chemical analysis. He found that 1000 parts of
MILDEW.

The Abbé Rozier, in his "Dictionary," observes that it is "caused by the drops of fog or dew, dissipated by a hot sun;" an opinion which is the echo of Ovid's verses forming part of the Flamen's prayer for the preservation of the Roman crops from this disease—

"Quantum, si culmus Titan incalcat is; ubi Tunc locus est irae Diva tremendae tuae."

And such a season, as I have before observed, has a damp atmosphere, which, above all other states of the air, is favourable to the vegetation of this Puccinia. There is no doubt, also, that in such seasons vegetables are more than ordinarily weak and prone to disease, in which condition they are more liable to the attacks of parasitic plants. "The application of cold water to the plant," says Mr. Knight, "on which the sun is shining strongly, is very injurious to its health, and therefore likely to give increased activity to any disease to which the plant is subject." This observation follows the detail of an experiment, in which he found that sprinkling wheat plants growing on ground very dry, with cold water, in the afternoon of a warm, bright day, caused them to be extensively mildewed. A considerable absorption, therefore, probably took place; and to this absorption," says he, "and the effects of a sudden change of temperature, as secondary causes, I am disposed to attribute the appearance of the disease; but whether the seeds of the mildew were carried into the pores of the plants by the water, or existed there before, is a question which I shall not attempt to solve." (Banks, On the Blight in Corn, p. 30.) There is no difficulty in accounting whence the seeds of the fungus came; for Mr. Knight records, in the previous page, that other wheat plants close by were extensively mildewed.

The observations of Mr. Marshall, which were the results of long experience in many counties in England, coincide with the preceding opinions. "In a dry, warm summer," he remarks, "which is well known to be favourable to the health, vigour, and productiveness of the wheat crop, the seeds of the fungus are harmless, so long as the fine weather continues. On the contrary, in a cold, wet season, which gives languor and weakness to the wheat plants, few crops escape entirely. A succession of cold rains, while the grain is forming, is very conducive." Mr. Marshall previously concludes that "The fungi are an effect, not the cause of the disease;" an error which is at once refuted by the fact, that if all the fungi are removed from a plant, it is speedily cured.

Of other circumstances favourable or unfavourable to the occurrence or exasperation of mildew, little need be said, because they have comparatively little influence upon its occurrence. All soils and situations are liable to its incursions; for it is, in the fullest sense of the term, epidemic. The soil on which it appears the most rarely is a tenacious clay; and that on which, when it does occur, its ravages are the most extensive and destructive, is the light, calcareous, and rich. "As far as my observations extant," says Mr. Egremont, "the soils wherein clay predominates have yielded crops the least affected by the mildew. The soils most liable to have their crops injured,
MILDEW.

particularly that of wheat, are the following, and in the order stated:—Peat or moor, calcar-eous, calcaraceous loams, sand, sandy loams, and another kind not found in any great breadth, but in patches, chiefly but not exclu-sively in clayey soils. The practical farmer calls it gray earth." (Egremont's Obs. on the Milde-w, p. 90.)

The slightly superior power of clayey soils to protect the crop growing upon them from being the most severely affected by the milde-w, probably arises from the temperature of such soils being less liable than lighter ones to sudden vicissitudes of temperature. Dr. Hales found, in the month of August, when the temperature of the air and of the surface of the soil were 88°, that the temperature of the soil 16 inches below the surface was 70°. In October, when the air and surface were at 85°, the temperature at 16 inches beneath was 48°, and at 24 inches 50°. This statement led me to make a few experiments upon the compara-tive rapidity of cooling, or, in other words, the power of conducting heat of various soils; and I invariably found, that the mercury in a ther-mometer, whose bulb was buried equally deep in a silicious, as those of others were in a calcaraceous and in an aluminoit soil, rose most rapidly, and that in the last-named most slowly. Their rapidity of cooling followed the same order. Some experiments substantiating the same fact will be found in Sir H. Davy's Agri-cultural Chemistry, p. 179. Every gardener knows the injury his plants sustain from sud-den vicissitudes of temperature. "Whatever has a tendency to check a quick and great loss of heat in the substances which surround such vegetables, particularly their roots, will be best calculated to save them from that injury, and from vegetable death; consequently, those earths which are the worst conductors of heat, or, in other words, are the longest in heating or cooling, will be most favourable in resisting any sudden alteration, and the vegetables growing on them will be the least injured when so assaulted." (Egremont's Observations on the Milde-w, p. 30.)

Situation appears to have rather more tute-lary power than the soil, since I have invari-ably found the wheat growing in fields lying in closely enclosed valleys more frequently and more seriously injured by mildew than those upon elevated exposures. "A Lincolnshire Farmer," Mr. Lambeth and other writers in the forty-fourth vol. of the Annals of Agriculture, agree in this observation, and it is no more than might be anticipated from our knowledge of the habits of the fungus tribe; such situations being always more damp, and subject to a moist, foggy atmosphere.

All varieties of wheat are liable to the disease, but the white is always the earliest affected, and the bearded or rivet the last. This may arise from the latter variety having a firmer epider-mis, arising from its containing a little more silex, and thence having its pores less easily acted upon by atmospheric changes, and con-sequently less liable to the entrance of the seeds of this fungus. Moreover, the hardness of the epidermis checks their rapid outspre-
The age of the seeds, the thickness of sowing it, and previous or subsequent cultivation, appear to have no preservative influence; therefore, it now only remains to consider whether the seeds of the fungi come to the crop, which will lead to a consideration of the modes of prevention; and, lastly, whether there is any practicable cure. This seems to me little doubt that the fungus is communicated from the soil to the crop. It is certainly not conveyed thither with the seed-corn, for no washing, no cleansing, nor pickling of this has ever been observed to have any effect. In "mildew years," all fields of any infected districts are affected; and when it is only partial, one end, or a breadth across the middle of a field, of which the seed has all been treated alike, will be grievously injured, whilst the other parts suffer little more than ordinarily; for I have previously noticed, every year, and in all fields, the mildew is partially present. There is little difficulty in accounting for this. Every Puccinia sheds some hundreds of seeds, more minute and lighter even than those of the puff-ball; and as every wheat crop annually produces some, these are wafted over neighbouring closes by every wind during their seeding-time, which is chiefly in the months between May and October. In the soil upon which those seeds alight, they attach themselves to the stubble or other matters, and vegetate, reproducing seeds, or remaining without germination until the following spring. This fungus has also the characteristic of spreading by stooing, or throwing out offsets. This may be seen if its progress is watched upon any culm which it affects. I once placed in a paper box some pieces of straw that were more completely mildewed than any I had before observed; this was left during the whole winter in a closet, which at this season is unusually damp. Upon opening the box in the spring following, I found the Puccinia had grown and spread in various rectilinear forms, upon one of its sides, and upon the bottom, a fact which I remember to have seen confirmed in one of the volumes of the Quarterly Journal of Science. The fungus, then, though its natural habitat is the culm of the wheat, will vegetate upon other vegetable bodies; and this satisfactorily explains the mode in which it may, after being preserved through the winter, be conveyed to the succeeding year's crop,—to say nothing of those seeds which may be attached to the straw of the preceding year, and be conveyed to the next year's crop by various modes.

These facts demonstrate that prevention is impossible; for however careful a farmer may be to avoid every source whence the seeds of the Puccinia may arrive, yet every summer wind may waft them to his crops from other, even far-distant lands. To prevent the communication to the wheat from the soil by the stooing, or spreading power of the fungus, it will be well to sprinkle the surface with salt, immediately after sowing; at the rate of 5 or 6 bushels to the acre; and in the spring, early in May, to apply, in a similar manner, about the same quantity of caustic fresh-slacked lime, applications of which are not only destructive of the Puccinia, but also of slugs, and promote the general health of the crop.

For testimonies to the power of common salt to prevent, in some instances, the occurrence of mildew, I would refer the reader to my brother's Essay on the Uses of Salt, p. 50—51, where I have found the concurrent testimony of Sir John Sinclair, Mr. Sickler, Rev. R. Hoblyn, Mr. S. Robinson, Mr. Wood, and Dr. Paris. Mr. Prevost, quoted by Sir John Sinclair, states that the sulphate of copper, if dissolved in water at the rate of 3½ oz. to the gallon, forms a solution which will prevent the attack of mildew upon the wheat plants arising from seed which has been steeped in it. I am afraid it has no such power.

Salt, if not a complete preventive, is an effective cure of the mildew. Mr. Chatterton, a Lincolnshire farmer, says, in the 44th vol. of the Annals of Agric., that "on the sea-side the wheat is little damaged by the mildew, yet within 3 miles inland the crops are as much affected as those still further from the sea." This fact can be supported by the experience of most farmers whose fields skirt our native shores; and unquestionably it is owing, not only to the soil containing a greater proportion of common salt than is found in more inland soils, but because the sea-haze, which rises almost nightly in the summer season, bathes, as it were, the crops in the immediate vicinity of the coast; and this haze holds in solution a portion of salt.

The following well-attested communication from the late Rev. Edmund Cartwright, of Hollenden House, near Tunbridge, is conclusive on this subject, and gives full directions to the farmer how to apply, and at what expense, a practical remedy.

"It gives me great pleasure to have it in my power to furnish you with some information respecting the application of salt, which, perhaps, you are not aware of. I, and a neighbour of mine, have applied it as a remedy for the mildew in wheat, with the most unequivocal success. I first made the discovery 2 years ago; my experiments at that time were upon a very limited scale; they have this year extended only over an acre and a half, but under circumstances that leave not a shadow of doubt of salt being an absolute specific for mildew, in the most aggravated stages of the disorder; of this I will state to you a convincing proof. In the year 1818 I found a few ears of wheat, which I conceived to be a new and improved variety; from these ears I raised as much wheat as last year planted a land 4 feet wide and 100 yards in length: the produce I had promised to Mr. Coke; and, to augment that produce, I had the ground, previously to planting, highly manured; and as soon as the wheat came up I gave it a good dressing with soot, and this dressing was repeated once or twice; in consequence of this superabundant dressing, the wheat, as might indeed have been expected, was as rank as the wheat you may observe growing accidentally upon a dunghill, which never fails to rot upon the ground, without bringing a single grain to maturity. The mil
dew made its appearance on this particular part of my field, while the straw was quite green, and the grain in a milky state; notwithstanding the danger that might be apprehended to the wheat itself, from its being thus succulent, I ventured to give it a dressing with salt and water; as a heavy shower of rain fell a few hours afterwards, the dressing was repeated the next morning. The proportion of salt to the water, I 1 pound in a gallon, laid on with a plasterer's brush, the operator bearing a pail of the mixture in one hand, and the brush in the other, making his casts as when sowing corn, or else with a common watering-pot, which, being swung with great force, throws the water very rapidly; 2 men will get over about 4 acres a day—the one to spread, the other to supply the mixture. The result was, that the mildew was completely subdued, and the wheat went forward to maturity; and although the sample was not so bold as it might have been, it was sound and marketable. In other parts of the field where the mildew showed itself, not under the aggravated circumstances described above, but as it usually appears, the wheat was not in the least injured by it after the salt and water was applied; it was, indeed, as fine a sample as could be grown. Both mine and my neighbour's wheat was examined by many practical farmers, who are so decidedly convinced of the efficacy of my remedy, that they intend never to be without a reserve of salt ready to meet the enemy the moment he appears. The effect of the salt upon the mildew, to those who do not consider the manner of its operation, is truly astonishing: I believe it to be instant death to the fungus; this, however, is certain, in less than 48 hours the straw nearly recovers its original colour and brightness. The certainty and celerity of its operation I account for thus: the mildew, it is now well ascertained, is a parasitical plant of the fungus tribe, the principal constituent of which tribe is water; when salt, therefore, is applied to them, the aqueous particles are immediately absorbed, and their vitality destroyed. The action of salt upon mushrooms, as in making mushroom catsup, confirms this theory." (Johnson's Essay on Salt, 3d ed. p. 52—54.)

I can afford decided testimony to the efficacy of the cure recommended by Mr. Cartwright; but I would add these precautions. The safest quantity of salt per gallon is 8 oz., and then the application may be rendered more effectual by frequent repetition, without any danger of injury to the plants. If the application is not made during a clouded day, it is best to defer it until the evening. Some have recommended a rope, held at its extremities by two men, to be drawn up and down each ridge of the infected crop to remove the fungus; and there is no doubt that this treatment is partially effectual, for the parasite is removed whenever it comes in contact with the rope, but the points of contact necessarily are limited.

Professor Henslow endeavours to prove (by strengthening with additional evidence his previously expressed opinions) the specific identity of the fungi producing rust and mildew. See Rust, Ergot, Dat Ror, &c.

---

**MILK.**

Mr. John Baker of Leeds, in commenting upon my brother's essay, is of opinion that the berberry has a considerable influence in the communication of the mildew to wheat, and gives several instances which seem to support his view of the case. But the distinction between the parasite of the berberry has already been mentioned, and it is scarcely necessary to repeat that the one cannot produce the other.

**MILE (Lat. Mille passuum, a thousand paces).** The following table, given on the authority of Kelly's Cambist, shows the length of the modern mile, and also the league, of various countries, and their relation to the English statute mile.

According to the same authority, the Arabian mile is 2145 yards, the Persian parasang 6068 yards, the Russian werst 1167 yards, and the Turkish meile 1826 yards. The English geographical mile is 1-60th of a degree of latitude, or about 2025 yards; the geographical league of England and France is 3 such miles, or 6075 yards; and the German geographical mile is equal to 4 English geographical miles, or 8100 yards.

**MILFOIL, THE WOOLLY YELLOW.** See Yarrow.

**MILIARY.** In botany, a term signifying granulated; resembling many seeds.

**MILK (Germ. Milch).** A well-known fluid, secreted by animals for the nourishment of their young. See LACTOMETER, BUTTER, CHEESE, DAIRY, CATTLE, &c.

Cow's milk is that principally used by Europeans; that of the goat, and even of the sheep, is used in some parts of Britain; that of the mare is a favourite beverage in Tartary when it is fermented. If milk be left at rest, the fatty globules separate, rise to the surface, and form cream; if it be long agitated, they attract oxygen, coalesce, and form butter.

Milk owes its whiteness and opacity to an emulsion composed of the caseous matter and butter, with sugar of milk, extractive matters, salts, and free lactic acid; the latter of which causes fresh milk to redden litmus paper. Milk, in general, contains from 10 to 12 per cent. of solid matter, on being evaporated to dryness by a steam heat. The mean specific gravity of cows' milk is 1-030, but it is less if the milk be rich in cream. The specific gravity of the skimmed milk is 1-035; and of the cream is 1-044. 100 parts of cream milk contain —
When milk contained in wire-corked bottles is heated to the boiling point in a water-bath, the oxygen of the included small portion of air under the cork seems to be carbonated, and the milk will afterwards keep fresh, it is said, for a year or two; as green gooseberries and peas do by the same treatment.

The number of cows kept in London and its environs for the supply of milk is estimated by Mr. Macculloch to amount to 9000, and their annual produce of milk to be equal to 78,500,000 quarts. For this purpose the Yorkshire cow is preferred to all others. The daily average of milk yielded by one of this breed is estimated, according to Mr. Youatt, at 22 or 24 quarts.

The quantity and quality of the milk produced by a cow is materially influenced by the food and distance from calving. Some interesting experiments to determine this were made by MM. Bonssingault and Le Bel. They observe, “In the observations, of which the following table presents the abstract, it will be seen that the quantity of milk given by the cows progressively diminished. This diminution cannot be attributed to the regimen to which the cows were subjected, since, in again putting them on the food on which they had previously fed, the same quantity of milk was not obtained as at first; the diminution was continued. The distance from the period at which the cow has calved seems to be the principal cause of the decrease of the milk. This cause is so strongly marked, that it may even prevent the influence that the nature of the food exercises over it from being seen.

Indeed, this result permits us to state, that the nature of the food consumed does not exert so very sensible an influence on the quantity and chemical composition of milk (we do not say on its quality), if the cows receive equal nutrition from the different kinds of food. It is very evident, that if the weight of the feeds were not calculated according to that of the equivalents, great variations would be observed in the products of milk; but then those variations would be principally caused by the augmentation or diminution of the nutritive matter.

We know, for example, that cows which, during winter, are reduced to simple feeding on chopped straw, cease almost entirely to produce milk, and with difficulty recover their ordinary rate of production; in cognisance of such a fact, we are led to ascribe the return and abundance of milk exclusively to the properties of the green food in spring, whilst that effect is in a great part produced by a real increase in the feeds.

“In establishments where a regular rotation is followed, healthy and abundant nourishment to cattle in winter is in a manner assured, the difference, if any exist, betwixt the feeding in winter and summer, being in all cases much less considerable. These are the results of experiments made during a year on eight cows constantly fed together on a great variety of food.”

There is a paper on the adulteration of milk, by M. Barruel (Quar. Jour. of Agr. vol. ii. p. 304), in which he states that the substances used to adulterate milk in London and Paris are usually flour, sugar-candy, potash, and sometimes iodine, to give it its bluish colour.

In Stephens’s “Book of the Farm,” we find the following interesting details relative to the subject of milk, milk-cows, and their treatment in Scotland, and more especially in the city of Edinburgh.

Cows are kept on every species of farm.
MILK.

though for very different purposes. On carse and pastoral farms they are merely useful in supplying milk to the farmer and his servants. On dairy farms, they afford butter and cheese for sale. On some farms near large towns, they chiefly supply milk for sale. And on farms of mixed husbandry, hay is kept for the purpose of breeding young stock.

On carse and pastoral farms, cows receive only a few turnips in winter, when they are dry, and are kept on from year to year; but where the farmer supplies milk to his workpeople, as a part of wages, they are disposed of in the yeld state, and others in milk, or at the calving, bought in to supply their place, and these receive a large allowance of turnips, with perhaps a little hay. On these farms, little regard is paid to the breed of the cow, the fact of being a good milker being the only criterion of excellence.

On true dairy farms, the winter season is not a favourable one for making butter and cheese for sale; for, do what you like to neutralize the effect of the usual rooted green crops on these products, and especially butter, they remain unpalatable to the taste. The cows are therefore in calf during this season, and receive the treatment described above until the period of calving in spring.

In and near large towns, the dairy-man must always have a large supply of his customers, and it is his interest to render the milk as palatable as possible. For the purpose of maintaining the supply, he buys cows at all seasons, just caived or about to calve. He disposes of the calves, without attempting to fatten them; and to render the milk he sells palatable, he cooks all the food partaken of by the cows. When the cows run dry, they are fattened for the butcher, and not allowed to breed again.

The cows in the public dairies in Edinburgh are supported in winter on a variety of substances, turnips, barley, oats, hay-seeds, chaff, cut hay. One or more of these substances, with turnips, are cooked together, and the usual process in doing this, and administering the cooked food, is as follows:—Turnips, deprived of tops and tails, and washed clean, are put into the bottom of a boiler, and covered near to its top with a quantity of malt comins, cut hay, hay-seeds, chaff, or barley, or more than one of these, as the articles can be procured. Water is then poured into the boiler sufficient to boil them, and a lid placed upon it. After being thoroughly boiled and simmered, the mess is put into tubs, when a little pounded rock-salt is stewed over it, and chopped into a mash with a spade. As much dreg is then poured upon the hot mash as to make it lukewarm, and of such a consistence as a cow may drink up. From 1 to 13 stable-paifuls of this mixture,—from 40 to 60 pints imperial,—according to the known appetite of the cow, is then poured into the trough belonging to each. The trough is afterwards removed and cleaned, and the manger is ready for the reception of fodder—hay or straw. This mess is given 3 times a day, after the cows have been milked, for dairy-men understand that animals should not be disturbed while eating their food. The times of milking are 6 A.M., 12 noon, and 7 P.M. The sweet milk and cream obtained by these means, and received direct from the dairy, are pretty good. The former sells in Edinburgh at 1s., and the latter at 1s. the imperial pint. Dr. Cleland states the price of the poorest milk in Glasgow at 14d. the imperial pint.

It will be observed that none of the articles usually given to cows are so expensive as oil-cake, cabbages, kohli-rabi, or cole-seed. These products were employed by the late Mr. Curwen in his experiments to ascertain the cost of raising milk for supplying the poor, and the results show they left him very little profit. (Curwen’s Agricultural Hints, p. 47—52.)

Cattle are fed on other substances than turnips, either with themselves or in conjunction with turnips. Oil-cake and potatoes are the most common substances used for this purpose. Linseed oil and linseed have been recommend—ed, and many are fed at distilleries on draf and dreg, as the refuse of distillation are termed; and these are also sold to the farmers for the purpose of feeding. Oats, barley-meal, and bean-meal, have also been pressed into the service of feeding cattle.

The potatoes used in feeding cattle are either the common kinds known in human food, or others raised on purpose, such as the yam and ox-noble; and they are given either alternately with turnips, or together. In feeding cattle with potatoes of any kind, and in any way, there is considerable risk of flatulence and choking. To prevent the latter, the potatoes should be smashed with a hammer, or with an instrument like a pavier’s rammer, and though juice should come out in the operation, no loss is incurred, as it is considered of no service in feeding. To prevent flatulence from potatoes is no easy matter; but a friend of mine used a plan which completely answered the purpose, which was, mixing cut straw with the broken potatoes. The straw obliging the cattle to chew every mouthful before being swallowed, may prevent such a large quantity of gas being generated in the paunch as bruised potatoes alone would do, and it is this gas which occasions that distressing complaint called hooven. A farm-steward, who had considerable experience in feeding cattle on potatoes on a led-farm, always placed as many potatoes, whole, before cattle as they could consume, and they never swelled on eating them, because, as he conjectured, and perhaps rightly, they do not eat them so greedily when in their power to take them at will, as when doled out in small quantities. This fact confirms the propriety of mixing cut straw amongst potatoes that are given in small quantities, in order to satisfying the appetite, and filling the paunch with unfermentable matter. The only precaution required in giving a full supply of potatoes, is to give only a few and frequently at first, and gradually to increase the quantity.

Oil-cake has been long employed in England for the feeding of cattle, and it is making its way in that respect into Scotland. It consists of the compressed husks of linseed, after the oil has been expressed from it, and is formed into thin oblong cakes. The cakes are
broke into pieces by a machine. Cattle are never entirely fed on oil-cake, but in conjunction with other substances, as turnips, potatoes, cut hay, or cut straw. When given with cut hay or straw, an ox will eat from 7 to 9 lb. of cake a day, and the hay or straw induces rumination, which the cake itself is not likely to do. When given with other substances, as turnips or potatoes, 3 lb. or 4 lb. a day will suffice. A mixture of oil-cake and cut meadow-hay forms a very palatable and nutritious food for oxen, and is a favourite one in England. Oil-cake costs from 7J. to 10J. a ton.

Statement of the comparative quality of Milk from 8 Alderney and 8 Kerry (Irish) Cows, tested from a Lactometer holding 1 Pint of Milk, and divided into 100 parts by Index.

Buck churned from 3 pints of cream from each:

Alderneys - 1 lb. 8 oz. 1 lb. 6 oz. to the pound.
Kerrys - 1 lb. 4 oz. 3

This was taken in August, when the Alderney's produce of cream was at the lowest.

MILK-FEVER. Cows in high condition are most subject to puerperal fever. This inflammatory disease sometimes appears as early as two hours after parturition; if 4 or 5 days have elapsed, the animal may generally be considered safe. On the appearance of this fever, from 6 to 10 quarts of blood should be taken, according to the age and size of the animal. The bowels must be opened, or the disease will run its course; and purging once established in an early stage, the fever will, in the majority of instances, rapidly subside, leaving the strength of the constitution untouched. (Younatt on Cattle, p. 547, 548.)

MILK-HOUSES AND CELLARS. The milk-houses in Holland and elsewhere, and the spring-houses of Pennsylvania, have been referred to and described under the head of Dairy. Of late, cellars under houses, properly arranged, are coming to be preferred for the purpose of keeping milk to either milk-houses, milk-vaults, or even spring-houses. Among the advantages claimed for cellars are, being at hand every where at a small cost; and keeping drier, thus less disposing to must. Mr. Miller, of Delaware, a correspondent of the Farmers' Cabinet (July, 1843), speaking of the cellars used in the vicinity of Wilmington, says:—It is found sufficient, if the cellar be sunk a few feet below the surface of the earth, with a wide and shallow window on each side, the bottom of it level with the ground outside; well protected with a wire guard to keep out vermin, large flies, &c., and provided with a close glazed sash, which can be opened and closed at pleasure, by lifting it up to the ceiling, which ought to be no higher than the top of the windows; so that the air of the cellar can be ventilated by opening the windows of the two opposite sides, according to the way the wind sets at the time, shutting them quickly when necessary; for in cold, windy, or damp weather, the sooner the windows are again closed, the better. Indeed, to the management of the cellar in this particular, much of the success of dairying is to be attributed; cold and damp air being unfriendly to the formation of cream, and its proper and entire separation from the milk. Hence, therefore, it is a bad practice to set the pans on the brick floor of the cellar; they ought always to be placed around on shelves, about three feet in height, and these, after being well washed with hot water, should be wiped quite dry, that no mouldy evaporation might take place to spoil the butter. The air near the floor of a dairy is always impure, being loaded with acid vapours and putrid exhalations, the density of which confines it to the lowest part of the room; hence it is, that the doors of some dairies are made with lattice work, that the air near the floor, as well as at that near the ceiling, might be ventilated at the same time; these lattices being furnished with sliding panels, may be kept close in bad weather. The milk-cellar ought always to have a northern aspect, and be well shaded by trees, not growing too near the windows, so as to impede a dry current of air, or to create a moist atmosphere; this consideration being of more importance than would readily be imagined.

Cellars thus constructed and carefully attended, will, no doubt, supersede the use of spring-houses generally, before many years have passed away; by which the business of the dairy will be rendered more agreeable, less laborious, and far less inimical to the health of those, particularly of females, whose occupation it is to attend to its never-ceasing duties. In the Wilmington market, “cellar-butter” usually commands an extra price.

MILKING. In the operation of milking, the great rules to observe are, regularity, gentleness, and cleanliness. The following observations are taken from an American periodical: “When you go to milk, take a vessel of cold water and sponge. Wash the udder and teats clean, dashing on the cold water. This will prevent the teats from becoming sore, and the udder hot and feverish, besides rendering the process of milking much neater. Milk with clean hands. The whole business of milking is frequently conducted in such a slovenly manner that the milk is entirely unfit for food. The cow should be milked while eating her fodder at morning and evening. She should always be milked and fed at the same time in the day, and uniformly by the same person. Milk without interruption. Be sure to milk the cow as dry as possible. To be milked by different hands, at different times in the day, in
MILK-PARSLEY.

MILK SICKNESS.

a slow, interrupted, gossiping manner, and leaving part of the milk in the udder, will ruin the best cow in the world. If the cow has suffered from this, turn her out in the warm weather, and after milking, dress them with the following salve: Melt together 1 oz. of yellow wax, and 3 oz. of lard, and as these begin to get cool, rub in a little of sugar of lead, and a drachm of finely powdered aloes. (Tealett on Cattle, p. 552.)

MILK-PARSLEY (Selinum, from selinor, the Greek name for parsley; applied to this genus on account of the resemblance in the leaves). This is a hardy genus of plants of no interest. The only species indigenous to England is the marsh milk-parsley (S. palustre), which is perennial, or, as some have it, biennial, growing in wet and boggy meadows, with flowers white, numerous, uniform. The root serves the Russians for ginger; and the whole herb abounds with a white, bitter, fetid juice, of the consistence of cream, which soon dries to a brownish acrid resin.

MILK SICKNESS. This name, together with "Trembles," has been applied to a peculiar and most malignant disease occurring in some localities of the Western United States, and affecting certain kinds of farm-stock, and persons who make use of the meat or dairy products of infected cattle. Bishop Hennipin, a French missionary, who ascended the western waters early in the last century, mentions the existence of this singular disease affecting animals. Although the cause and precise nature of so frightful a malady are still enveloped in great obscurity, and the treatment is far from being so generally successful as could be desired, it may be interesting to be acquainted with some facts connected with its existence. Dr. George B. Graff, a highly intelligent physician of Edgar county, Illinois, has a communication upon the subject in the American Journal of the Medical Sciences (April, 1841), from which we draw the following details:

The milk sickness is a disease peculiar to the United States, occurring seldom, if ever, to the eastward of the Alleghany mountains. It is in a greater or less degree met with in all the Western States, as far south as Mississippi, and extends north to the boundary. The states of Indiana and Illinois are most subject to its occurrence, whilst its existence in the bordering states is more or less connective. Among the early settlers it committed dreadful ravages, and in the formation of our Western settlements, its prevalence often served as a cause to disband a community, and compel the inhabitants to seek a location which enjoyed immunity from its occurrence. Many of the otherwise most desirable portions of that country remained long exempted from settlement, and even now the inhabitants of these localities have, as a condition of their residence, entirely to abstain from the use of milk, its preparations, or the flesh of their cattle.

Its occurrence or prevalence is confined to no season or description of weather, existing in a like degree in the heat of summer or cold of winter, and with like virulence and frequency during a dry or wet season. An opinion is entertained by some, that it is more frequently met with in the spring and fall months, whilst others have expressed a belief of its more common occurrence during the heat of summer. However this may be, we know of no season during which it does not occur.

The animals in which it has been observed are the beef-cattle, horses, sheep, and goats, which seem to acquire it with their food or drink.

We will first speak of the symptoms manifested in cattle affected with it, as it is only through them that we have yet found the disease communicated to man. They may be affected to such a degree as that their flesh and milk will produce the disease, and yet they themselves manifest no unhealthy symptoms whatever. This latent condition of the disease may be discovered by subjecting the suspected animal to a violent degree of exercise, when, according to the intensity of the existing cause, it will be seized with tremors, spasms, convulsions, or even death. This is a precaution practised by butchers in these countries always before slaughtering an animal in anywise suspected of the poisonous contamination. An ordinary degree of exertion will not develop these phenomena unless it produces the symptoms usually preceding a fatal termination. When, for instance, a cow is sufficiently deeply affected, nothing peculiar is observed until immediately preceding the outbreak of the fatal symptoms. She is then observed to walk about, without any apparent object in view; all food is refused, and there is evidence of impaired vision. The eye is first of a fiery appearance, increasing to a deepened red colour, until the animal is observed to stagger and fall, when, if she rises, the trembling of the whole muscular system will prevent the maintenance of the standing position. The animal usually dies after repeated convulsions, never lingering beyond a few hours. Often it falls suddenly, as if it received a blow from a heavy body on the head, and death is produced in a few minutes.

From the tremulous motion imparted to the muscles, the affection has received the common name of the "Trembles" in cattle. A case which was characterized by the great violence of its symptoms, I had an opportunity to examine very shortly after death. The brain I found suffused with a large quantity of fluid blood, which, from the amount contained within the cranium, must have made great pressure on every part.

In man the symptoms differ from these, and are varied. The length of time found to elapse from the reception of the cause to the appearance of the disease, is dependent on a multiplicity of circumstances, as the age, sex, or condition of the patient, and violence of the poison. It may be developed early as the third, or deferred until the tenth day. As a premonitory symptom, a peculiar and indescribable fetor from the lungs is the most prominent; and so universally have I found it present and to precede the disease, that in almost every instance where I have been brought in proximity to a person predisposed or attacked, have I been able to foretell its approach, and pro-
MILK SICKNESS.

MILK SICKNESS.

nounce on the character of the disease. This
tetor can no more be mistaken by a person
acustomed to it, than that which is so univer-
sally attendant on variola; and it may in fact
be safely stated to be pathognomonic of the
forming and early stage of milk sickness.
This halitus from the lungs, which I have
never found entirely wanting even some days
previous to an attack, increases in intensity
until the disease is fully developed, when it
gradually disappears with the spinal symp-
toms, and the termination of 4 or 5 days
cannot be detected. A person labouring under
the peculiar effluvia from the air passages, in
many cases complains of no illness, and ap-
pears entirely unconscious of his situation,
unless advised of it by his friends or attend-
ants. His appetite may be, and usually is,
destroyed; and after the lapse of a few days
he is taken down with pain and excessive irri-
tability of the stomach, obstinate constipation
of the bowels, a cessation of all biliary secre-
tion, general febrile action, sometimes an in-
tense burning sensation in the epigastric region,
with early and obstinate coldness of the ex-
tremities. Often the symptoms are observed to
differ widely from these. Besides the pecu-
lar smell emitted, there is a premonition of the
attack; for some days previous to its develop-
ment, the patient experiences a restlessness and
uneasiness which he cannot describe, with a
dread of some impending calamity, confu-
sion of ideas, and other indications of irrita-
tion of the brain and nervous system. Vomiting
announces the onset of an attack. This
continues at short intervals for many days, the
matters thrown off the stomach consisting of the
fluids swallowed, mixed with a glairy mucus,
and not unfrequently tinged with blood. Some
days frequently elapse before pain in the
stomach is complained of, but during the time
the suffering is intolerable, consisting of a sen-
sation of deep distress, which, though referred
to the prederma, or abdomen, the sufferer can-
not locate in any particular spot. Pain in the
limbs is complained of, and to a decidedly refer-
each to the extremities, but is more constant-
ly located in the spine, particularly at the nape
of the neck. The pulse, during the forming
stage, possesses greater force and volume, with
slightly increased action. The bowels will
remain obstinately constipated, the powers of
nature being incompetent to relieve the con-
tinuance, so that unless it be done by appropriate
remedies, at the end of 6 or 8 days an offensive
discharge takes place, quickly followed by dis-
solution, the symptoms being those which
would indicate disinorganization of the struc-
ture of the intestines. The tongue, during the
initiatory stage, is slightly furred, but other-
wise not much changed in appearance. This
coat disappears soon after the occurrence of
vomiting, and becomes clean, of a pale-red or
pink colour, greatly resembling a piece of raw
veal. Next to the fetor mentioned, the change
of volume occurring in the tongue may be
viewed as the great characteristic of this dis-
case. It rapidly attains an inordinate size,
colour, and texture of the mucous, and so flabby
and soft in its texture as to retain perfectly the
impressions left by the teeth, when extruded.
Often a number of efforts are necessary before
it can be forced out, and then it has a tremen-
dous motion. This condition of the tongue
changes with the stage of the disease. When
the vomiting has been suspended, and free
evacuations from the bowels obtained, it is re-
duced in volume, the surface is for a time
smooth and glazed, soon after becomes dark,
cracks open in transverse fissures, is hardened,
with an obstinately dry and rough surface. Of
all the primary symptoms vomiting is the last
to disappear; it ceases very gradually to annoy
the patient, and its continued absence is the
most certain indication of a state of convales-
cence. In no disease is there a greater differ-
ence or diversity of symptoms than are usually
found in different cases to constitute what may
be properly termed the secondary stage of milk
sickness.

In some cases the patient is affected with
fearfulness, low muttering delirium, nervous
tremors, and the whole train of symptoms asso-
ciated in low typhus fever. When recovery
takes place after severe attacks, the convales-
cence is very slow, and years may elapse before
a perfect restoration to health. Indeed, it has
been a question with many, whether those once
severely attacked ever regain a perfect integrity
of constitution. In cases which terminate fa-
tally (of which description is a large majority),
a length of time of from 1 to 4 weeks is re-
quired, proportionate to the intensity of the
primary effects, the propriety of the treatment,
and the natural powers of the resistance of the
constitution, as they often seem to die from a
wearing out, or gradual destruction of cerebral
and nervous energy. Those cases which occur
during the summer months, are most decidedly
inflammatory, whilst in the winter there is
always observed a disposition to assume a low
form. The autumnal cases, in their secondary
fever, are liable to assume a remittent aspect,
and I have seen them eventuate in a well-
marked intermittent. When recovery has taken
place, the patient retains not the slightest recol-
clection of any thing which occurred during the
progress of the disease, and this forgetfulness
often extends as far back as some days previous
to the active development of the disease.

Cause.—The cause of this disease in animals
is as yet shrouded in mystery and uncertainty.
No satisfactory account of its nature has ever
yet been given, and it has in turn been sup-
posed to be of vegetable, mineral, and even
aerial origin. The limits of its prevalence is
not often over a large continuous tract of
country, but rather circumscribed, and sur-
rounded by localities never known to produce it.
No example is known in which the property
of producing the disease has been acquired by
any locality which did not previously possess it.
The boundaries which were at the first dis-
covered of the country found to separate the
infected from healthy districts, remain un-
changed. The locality which serves to pro-
duce the disease, most commonly extends as a
vein of variable breadth, traversing the country
for a considerable distance. It can be traced
in one instance for nearly a hundred miles,
running parallel to the course of the Wabash
river, in the state of Indiana.

819
MILK SICKNESS.

Again—it will be found to occupy an isolated spot, comprised in an area of 100 acres, whilst, for a considerable distance around, it is not produced. Thus, having the locality perfectly circumscribed, much labour has been expended in order to discover some production peculiar to the locality. The search has been uniformly unsuccessful, and after considerable deliberation the general appearance of these infected districts is somewhat peculiar. I have always observed that the situation of the ground is elevated above that of the surrounding country, occupying what is denominated a ridge, and that the quality of the soil is in general of an inferior description. The growth of timber is not observed to be so luxuriant as in situations otherwise similar, but is scrubby, and stunted in its perfect development, in many instances simulating what in the west is denominated "Barrens." Throughout the entire district in which these localities are interspersed, there is observed an absence of the occurrence of stones scattered over the surface, whilst in the infected tracts they are almost universally present. They are of a small size and darkened aspect externally, breaking with a regular and shining fracture, and, upon analysis, imperfectly made, were found to contain a considerable portion of iron, with slight traces of copper. Another more decided and peculiar appearance, which serves to distinguish them from other spots, is the breaking forth of numerous feeble springs, furnishing but a trifling supply of water, but not varying in quantity with the change of seasons. In its appearance, it presents the general evidences of a sulphurous and ferruginous contamination. Experiments made upon the water collected from these springs, or more properly called oozes from the soil, with the greatest care by the employment of the most delicate chemical re-agents, failed to indicate the presence of any mineral except iron, sulphur, traces of magnesium, and a quantity of copper barely capable of being demonstrated. A belief being entertained by many that the disease is occasioned by arsenic, or some of its salts, I with much care and patience subjected not only the water, but likewise the earth, from these districts to a most rigid examination, and by no test was I furnished with the slightest evidence of its presence.

An intelligent medical friend expressed to me his belief that it was produced by the inhalation of some noxious gases generated during the decomposition, of the mineral part of the mineral and organic substance of the milk of the infected cattle, which were regularly housed each evening, escaped its attacks, and that when suffered to remain at large, they were frequently seized with the disease. It is difficult to form this belief of the nature of the cause, as we can hardly conceive the particular action of any combination of circumstances, capable of giving rise to such an emanation only at night, ceasing to act during the day. The most popular belief is in favour of a vegetable origin. The advocates of this method of production having failed to designate the plant which they supposed occasions it, have endeavoured to sustain their views by supposing that the poison exists in some shrub or tree, which is eaten by the cattle, but confess their inability to designate any such peculiar growth confined to these localities. If certain fields which are known to affect cattle fed upon them, be suffered to grow in grass, and the hay produced be given to them for their continual food, no disease results, which is a strong circumstance, ES, to demonstrate that the active poisonous principle is destroyed by the desiccation. Again, it has frequently appeared with its greatest virulence when the ground has been for weeks previously covered with snow.

Butter and cheese, manufactured from the milk drawn from an infected cow, are supposed to be the most concentrated forms of this poison. They possess no distinguishing appearance, odour, or taste, from the healthy article. A very minute quantity of either will suffice to develop the disease in man. The cream, ordinarily sufficient to be added to the coffee drunk at a single meal, is said to have induced an attack. The butter or cheese eaten at one repast, has frequently been known to prove effective. The property is not contained in any of the elements of the milk exclusively, but distributed throughout the whole of them, being possessed by the buttermilk as well as by the whey. Beef, in the quantity of a very few ounces, will produce the disease, and, it is generally believed, in a more violent and fatal form than when it is produced by milk, or any of its preparations.

In the course of my observations I had an opportunity to experiment with a cow suffering in but a slight degree from the cause. She was affected with tremors when unusually exercised, exhibited a red and suffused eye, with frequent twitches of portions of the muscular system. She was kept confined without an opportunity to exercise, and was fed upon ordinary food. At the end of 8 days, the milk drawn from her possessed as violent poisonous properties as at the time of her incarceration. Her confinement was continued for a week longer, at the end of which period, the milk taken from her was found in an entirely healthy condition, and the eyes were restored to their natural appearance. In this instance it will be seen that the property of imparting the poison to the milk was lost in the space of between 8 and 15 days. We, of course, cannot fix on the precise period, but we would infer that the property is suddenly destroyed rather than gradually dissipated.

My trials with the poisoned flesh were, for the most part, made upon dogs, which I confined, and often watched the effect of the poison when administered at regular intervals. In the space of 48 hours from the commencement of the administration of either the butter, cheese, or flesh, from poisoned animals, I have observed unequivocal appearances of their peculiar action. In a few hours a thirst greater than natural is created; the appetite remains unimpaired until the expiration of the fourth or fifth day; or just before the appearance of fatal symptoms, when the animal will refuse drinks, and the most inviting descriptions of food.

Vomiting does not, as in man, always precede death, but the bowels are constipated throughout, except that, in a single instance.
observed copious alvine discharges largely mixed with blood. One ounce of butter or cheese, or 4 ounces of beef, either raw or boiled, administered three times a day, with certain provoking fatal within 6 days, and often earlier. In these cases all exertions and exercise must be prevented, or death will occur much sooner, even as early as the third day. When an animal has been subjected to its influence for only a short time, and is induced to fatigue itself, or is driven a distance at full speed, he suddenly stops and falls, and the severity and duration of the convulsion or spasm is in proportion to the intensity of the action of the poison. Often he will appear to entirely recover from the first attack, but to be repeatedly upon the renewal of the exercise to a sufficient degree.

There is, however, one animal which, from some peculiarity of organization, is rendered proof against the pernicious effects of this otherwise powerful agent. I allude to the hog. Most industriously did I feed a troublesome sow running at large, administering, daily, 5 or 6 pounds of infected beef. This was persevered in for more than a fortnight, and under these circumstances the fattened, which was compelled to desist from the great quantity necessary to supply her voracious appetite, without enjoying the satisfaction to perceive one muscular twitch as an evidence that it produced the slightest effect. When I last saw her she enjoyed excellent apparent health, and was the mother of a numerous offspring.

From all the experiments I have made, and the reasoning used, I can arrive at no conclusion, so far as relates to the nature of the ultimate cause in man, to which it can only be communicated through the medium of an animal, and that capability of production can be acquired only by the animals of circumscribed localities. An intelligent medical friend, alike distinguished as a statesman, Dr. John W. Davis, of Indiana, in a late letter to me, expresses a belief that milk is never a cause of the disease. He merely states his belief of the fact, without the evidences or observations which have led him to the denial of a proposition heretofore viewed as settled beyond dispute. My own experience enables me to say that I have seen a peculiar affection which I felt assured could have been no other than the milk sickness, in a city remote from any of its local causes, attacking every individual who partook of a certain cheese which had been purchased from a wagon arriving from an infected district. In this instance the well-marked symptoms, confined to those only who partook of this cheese, appearing nearly at the same time, with no occurrence of new causes after the removal of this cause, all together afford strong evidence of the nature of the origin.

There is a murderous practice now carried on in certain districts, in which the inhabitants will not themselves consume the butter and cheese manufactured; but, with little solicitude for the lives or health of others, they send it in large quantities, to be sold in the cities of the West, particularly Louisville, Kentucky, and St. Louis, Missouri. Of the truth of this I am well apprized by actual observation, and I am as certain that it has often caused death in those cities, when the medical attendants viewed it as some anomalous form of disease, not suspecting the means by which poison had been conveyed among them. Physicians of the latter city having been questioned particularly on this subject, have mentioned to me a singular and often fatal disease which appeared in certain families, the cases occurring simultaneously, and all traces of it disappearing suddenly, and which I cannot doubt were the result of poisoned butter or cheese. This recklessness of human life it should be our endeavour to prevent, and the heartless wretches who practise it should be brought to suffer a punishment commensurate with the enormity of their crime. From the wide extent of the country in which it is carried on, we will readily perceive the difficulties to be encountered in the effort to put a stop to the practice. This being the case, our next proper aim should be to investigate the nature of the cause, and established a more proper plan of treatment by which it may be robbed of its terrors, and the present large proportionate mortality diminished.

Nature and Treatment of the Disease.—Much diversity of opinion exists among medical men in regard to the essential nature and most proper mode of treating this fatal disease, from which hundreds of persons throughout the West and Southwest annually perish.

Owing to the want of success which has so uniformly attended the practice of their physicians, many of the inhabitants depend entirely on their domestic remedies. It is in that country emphatically one of the _opporta međicorum_.

"The primary operation of the poison," says Dr. Graff, "seems to be on the brain and nervous system, and this is indicated by the cerebral irritation which so often proceeds, and always accompanies an attack, as well as by autopsic appearances. Without an exception, in the animals poisoned, I always found the brain and meninges phlogosed with a greater or less degree of inflammatory action."

Dr. Graff relates the following circumstances connected with the occurrence of the disease, which will tend to show how its mode of development and characteristics. The entire family of Mr. Frazier, moving westward, purchased a quantity of fresh beef in Indiana, of which every member of the company partook heartily, daily, until the evening of the fourth day, when they arrived in the Doctor’s neighbourhood. On this evening they all retired apparently in their usual health, but during the night he was summoned to attend a female with an attack of milk sickness. Upon a careful examination he discovered the peculiar smell present with every member of the family, and, on inquiry, ascertained about the beef, and the locality in which it was purchased, "which," he says, "at once satisfied him that they were doomed. Before the next morning every member of that company of 6 was attacked in a violent manner, and only one of the number recovered."

The Legislatures of several Western States have offered rewards for the discovery of the origin of the milk sickness, in order to lead to its prevention and cure. The reward offered 922.
MILLET.

in Kentucky is $1000. A creeping vine has been of late years generally believed to be the occasion of the disease, but this has not been so well established as to enable the person who made the supposed discovery to claim the rewards.

MILK-VETCH (Astragalus). This is an extensive genus of herbaceous and shrubby plants; many of the species are very handsome, and well suited for the flower-garden. There are 4 species indigenous to Brazil.

MILK-WORT (Polygala, from poly, much, and gala, milk; reputed effects of the plant on cattle that feed upon it.) All the species of this genus are very showy. The annual kinds require sowing in the open ground, preferring a peat soil. Some of the species possess useful medicinal qualities. Decandolle enumerates above 160 species in this genus, but only one is British.

A considerable number of the species are natives of the United States, among which the best known is the P. senega, or Seneca snake-root.

MILLET (Panicum, from panicula, a panicle, or panis, bread). A useful genus of grasses, one species of which, called Bengal grass, was some years ago introduced into Pennsylvania as an object of culture, and excited much interest for a time among farmers. It was found, however, not to be so valuable as the usual summer crop of which it occupied the place, and it is now pretty much abandoned. The seed is sown in the early part of May. (Flora Cestrica.)

Of the millet there are three distinct genera: the Polish millet (Digitaria), cultivated in Poland; the common millet (Panicum), or panic grass, cultivated in Germany, and sometimes in England; and the great or Indian millet (Holcus), cultivated in India, Italy, and America.

Of the common millet there are 3 species: Setaria Germánica, a native of the south of Europe; the P. milvorum (Pl. 3, 1), a native of the East Indies; and the Setaria Italica (m), also of Indian origin.

The German Millet (Fr. Mota de Hongrie; S. Germánica, Pl. 3, k) rises with a jointed reed-like stalk, about 3 feet high, and about the size of the common reed, with a leaf at each joint, 1½ foot long, and about an inch broad at the base, where broadest, ending in an acute point, rough to the touch, embracing the stalks at the base, and turning downwards about half the length. The stalks are terminated by compact spikes, about the thickness of a man's finger at the bottom, growing taper towards the top, 8 or 9 inches long, and closely set with small roundish grain. It is annual, and perishes soon after the seeds are ripe. There are three varieties of it, the yellow, white, and purple grained. It was formerly cultivated for bread in some of the northern countries.

The Common or Cultivated Millet (Fr. Millet commun; Panicum milvorum), rises with a reed-like channelled stalk, from 3 to 4 feet high; at every joint there is one reed-like leaf, joined on the top of the sheath, which embraces and covers that joint of the stalk below the leaf, and is clothed with soft hairs; the leaf has none, but has several small longitudinal furrows running parallel to the midrib. The stalk is terminated by a large loose panicle hanging on one side. Of this species there are two varieties, the brown and the yellow; the latter of which was formerly in cultivation, and is now sometimes sown for feeding poultry, and as a substitute for rice.

The Italian Millet (Panicum d'Italie; Fr. Millet a grappes; Setaria Italica, Pl. 3, m), rises with a reed-like stalk, nearly 4 feet high, and much thicker than that of the preceding; the leaves are also broader. The spikes are a foot long, and twice the thickness of those of the common millet, but not so compact, being composed of several roundish clustered spikes; the grain is also larger. There are two or three varieties of this, differing only in the colour of the grain. It is frequently cultivated in Italy (whence its trivial name), and other warm countries. It is a native of India, and of the Middle East.

The Polish Millet, or manna grass of the Germans (Digitaria sanguinalis, formerly Panicum sanguinalis, Pl. 3, n), is a low, decumbent, annual plant, seldom rising above 9 inches or a foot high, with hairy leaves and slender panicles. It tillers much, and forms a close tuft, spreading and rooting at the joints. It is a native of England, but not common. It grows in abundance in Poland, and is sometimes cultivated, the seeds being used like those of the other millets as a substitute for rice, or go.

The Great or Indian Millet (Lat. Holcus sorghum, Sorghum vulgare, Pl. 3, o; Fr. Sorgho, gros millet d'Italie; Ger. Sorgsamen; It. Sagina; Span. Mela) has a stem which rises 5 or 6 feet high, is strong, reedy, and like those of the maize, but smaller. The leaves are long and broad, having a deep furrow through the centre, where the midrib is depressed in the upper surface, and is very prominent below. The leaves are 2½ feet long, and 2½ feet broad. It is cultivated in the Middle East and China.

The flowers come out in large panicles at the top of the stalks, resembling, at first appearance, the male spikes of the Turkey wheat (maize); these are succeeded by large, roundish seeds, which are wrapped round with the chaff. This grain is a native of India, where it is much used to feed poultry, and is frequently sent to Europe for the same purpose. It is much cultivated in Arabia, and most parts of Asia Minor; and has been introduced into Italy, Spain, Switzerland, and some parts of Germany, also into China, Cochin China, and the West Indies, where it grows commonly 5 or 6 feet high, or more, and, being esteemed a hearty food for labourers, is called negro Guinea corn. Its long awns or bristles defend it from the birds. In England, the autumns are seldom dry and warm enough to ripen the seed well in the field. In Arabia it is called dora or dura; the flour is very white, and they make good bread of it, or rather cakes, about 2 inches in thickness. The bread which they make of it in some parts of Italy is dark and coarse. In Tuscany it is used chiefly for feeding poultry and pigeons; sometimes for swine, kine, and horses. Celsalpinus says, that cattle fed on the green herb are apt to swell and die, but thrive on it when dried. They make brushes.
and brooms of its stalks in Italy, which Ray observed in the shops of Venice, and which are sent to England. Of this species there are two distinct varieties; one distinguished by black, and the other by red, husked seeds, besides subvarieties.

The only sorts of millet which are cultivated with success in England are the German, cultivated, and the Polish sorts. According to Professor Thaer, the cultivated is to be preferred, as having the largest grain.

The soil for the millet should be warm, sandy, rich, and well pulverized to a good depth. In England the seed is sown in May, very thin, and not deeply covered. In the course of its growth the plant, Professor Thaer observes, is more improved by stirring the soil, after which it grows astonishingly fast, and smothers all weeds.

In harvesting the millet, great care is requisite not to shed the seed; and as it ripens rather unequally, it would be an advantage to cut off the spikes as they ripen. No grain is easier to thrash, or to free from its husk by the mill. It is used instead of rice, and in Germany bears about the same price. It produces a large bulk of straw, which is much esteemed as fodder. (Loudon's Ency. of Agriculture.)

The great Indian millet will grow in England to the height of 5 or 6 feet; but will not ripen its seeds, or even flower, if the season is not dry and warm. It would doubtless succeed in the United States.

MILLET-GRASS, Milica (Fr. millet; Lat. milium, from mille, a thousand, in allusion to the immense number of seeds produced by it). These are hardy, annual, and perennial grasses; but in England the climate is seldom warm enough to ripen the seed, or to allow of their being cultivated to advantage. The hardened corolla, forming a coat to the seed, affords a mark of distinction between this genus and Agrostis, no less obvious than important, as those most deeply versed in grasses will most readily allow.

There are two English species:

1. Spreading millet-grass (M. effusum). Growing very common in moist, shady places. The root is perennial and fibrous, with several creeping shoots. Stems erect, slender, generally 3 or 4 feet high, with about 4 joints, leafy, smooth. Leaves bright-green, flat, very smooth, thin and weak. Flowers solitary, slightly drooping, ovate, in a loose spreading panicle, without awns; panicles from 4 inches to a foot in length. Mr. Curtis observes, that this is distinguished from the panic grasses, to which it has the greatest affinity, by having a calyx of two valves only. The produce of this grass is very light in proportion to its bulk, and it is but little nutritious. Birds are remarkably fond of the seeds; so much is it likely, that for the sake of the seed only, it could be cultivated to advantage on the farm. But in covers where game are preserved there cannot be a better grass encouraged; it will save the corn fields. About the beginning of August is the best season for sowing the seed. The surface of the ground near the roots of the bushes should be lightly stirred, and the seeds scattered over it and raked in; a few of the decaying leaves that cover the ground should afterwards be thrown over. It flowers in the second week or latter end of June, and the seed ripens in the middle of July and beginning of August.

2. Panic millet-grass (M. lanigerum). This annual species is less common, and grows principally in fields where water has stagnated, especially towards the sea. The stem is branched from the bottom and smooth. Flowers in a dense, spiked, erect panicle, pale-green, bristly; corolla awned.

MILLS (Lat. molia). The term mill seems to have signified originally an engine for grinding corn, but it is now used in a general sense to denote a great variety of machines, whose action depends chiefly on circular motion. The particular purpose is usually indicated by a prefix: thus, bark-mill, cotton-mill, flour-mill, oil-mill, saw-mill, spinning-mill, &c.

The machinery by which it is necessary to accomplish the ultimate objects of the mill must obviously vary almost indefinitely. Many voluminous works on this subject have been published, as well as separate accounts of particular structures.

The Saw-mill is well worthy of notice. It is composed of a small iron cylinder, usually about 8 or 9 inches wide, and 6 inches in diameter, tapering slightly to one end, and fluted on the inside. Within this a barrel of the same form, but a size less, and fluted on the outside, revolves by the turning of a spindle on which it is fixed. The meal is rendered finer or coarser in proportion as the working barrel is set nearer to or farther from the small end. This mill is made entirely of iron and steel, and is usually attached to a post. It is provided with a hopper, and is worked by a crank fixed at one end of the spindle, while a fly-wheel revolves at the other. It is used for beans, peas, and other pulse, for malt and various kinds of grain, and is a very useful and ingenious contrivance, but requires care in its adjustment and general management.

Bean-mill. A mill for grinding beans, constructed by Seaman and Bryant of Melton, in Suffolk, is as simple and effective an implement of the kind as any we have seen. It is placed on a wooden stand, with crank, fly-wheel, and hopper; and consists of a coarsely fluted barrel, working against a flat cutting plate; the latter being set at the proper distance from the barrel by means of a screw. It is used chiefly for beans and peas, but may be employed for grinding malt, by exchanging the barrel and cutting-plate for a pair of rollers.

The Norfolk Crusher is similar in appearance to the foregoing, and is worked by two rollers of equal dimensions, each being flanged at one end, and reversed so as to prevent the grain from falling off at the side. The rollers are perfectly smooth, and consequently, as its name implies, it crushes the grain instead of cutting it.

The Suffolk Crusher is simply a variety of the above, and differs from it in having its hind roller finely grooved, and of half the dimensions of the front one; this has no flange, but works within the flanges of the front roller.

823
MILLSTONE GRIT.

which are attached at both ends. To render these mills effective for crushing oats, the rollers should be left rough as they come from the lathe, to draw in the kernels, as the latter are apt to start back at the moment of entering between the rollers, if they are polished. A grooved or fluted roller has not been found adequate to the perfect bruising or cutting of oats, and a mill that shall effect this object may be considered a desideratum in agricultural mechanics.

MILLSTONE GRIT. A geological term applied to a group of strata which occur between the mountain limestone and the superficial coal formations; it is a coarse-grained quartzose sandstone.

MINT (Mentha). The poets celebrate Minthe, a daughter of Cocy tus, as being transformed into mint by Proserpine in a fit of jealousy. (Ovid. Metam. 10, v. 729). This is an extensive and well-known genus of useful herbs, with the culture and propagation of which every one is familiar. In England there are more than a dozen native species, besides numerous cultivated varieties. The roots are perennial, creeping widely. All the herbage is more or less hairy, but variable in that respect; rarely woolly or finely downy; full of pellucid dots, lodging a copious essential oil, which is pungently aromatic, cordial, and stimulating, and is thence used in medicine as an excitant and stimulant. The folowing are the indigenous species. Horse-mint (M. sylvensis), round-leaved mint (M. rotundifolia), spear or green mint (M. viridis), black or peppermint (M. piperita), bergamot mint (M. cirrata), hairy mint (M. hisruna), fragrant sharp-leaved mint (M. acutifolia), tall red mint (M. rubra), bushy red mint (M. gentilia), narrow-leaved mint (M. gracilis), corn-mint (M. arvensis), rugged field-mint (M. agrostis), and pennyroyal (M. pulegiurn). See Cat-mint, Horse-mint, Peppermint, Penny-Royal, Spear-mint, &c.

MISSELTOE (Viscum; from venus, birdlime, on account of the sticky nature of the berries). The mistletoe is a well-known parasite, readily propagated by sticking the berries on thorn or apple trees, after a little of the outer bark has been cut off, and tying a shade or net over them, to protect them from the birds. Sheep eagerly devour this plant, which is frequently cut off the trees for them during the severe winters; nay, it is even said to preserve them from the rot. Its branches are much sought after at Christmas to hang up in houses, along with other evergreens. It was one of those plants held sacred to the Druids.

MIST. See Fog.

MITE. See Cheese-Mite.

MIXEN. A compost heap.

MIXTURE OF SOILS, in agriculture, is the addition of one soil to another, to improve its fertility.

There is perhaps no agricultural improvement more important in both its immediate and permanent effects than the careful, judicious mixture of soils, and there is no question more likely to repay the cultivator for the care he bestows upon it.

This mode of improving the land was one which very early engaged the attention of the farmer. Nature herself, in fact, pointed out to him the means of producing the richest of soils by earthy mixtures in very intelligible language. The solid matters brought down from the distant hills by the flood-waters, and deposited in the valleys where the waters rested, evidently formed, by the mixture of different strata, and by their union only, the rich alluvial soils of the old and the new worlds; for that the mechanical and chemical process of denuding earth into a fine state of division is not the sole cause of the increased fertility, is apparent to every farmer.

It is useless, he well knows, to expect the debris of the hills to produce fertilizing effects on soil of a similar composition. It is the dissimilarity of the earths which insures a maximum fertile mixture: thus, in the soil of the rich marshes of the banks of the Thames are found the clay of the London basin, the sands of Middlesex, and the chalks of Oxfordshire and Kent; and in a similar manner are formed all rich alluvial lands. This good effect of earthy deposits naturally pointed out to the Italian farmers the use of earthy additions to the soil. Columella expressly notices the use of sand, gravel, marl, and chalk (book ii. c. 16, p. 93); and the people of Megara, according to Theophrastus, had made similar observations upon the importance of mixing together different strata of earth (lib. iii. c. 25); for every fifth or sixth year they trenched the gravel to a depth equal to that they imagined the rain had penetrated. The early inhabitants of Britain employed marl, as the people of Gaul did lime, for spreading over their lands. And that this was done to a very considerable extent, is shown by several facts. Thus, marl-pits are mentioned as early as 1255, in the charter of the forest, and again in the statute of Wales in the 12 Edward I. And so early as the days of Richard, Duke of Cornwall, the Cornishmen and farmers had a grant by which they were empowered to take the calcareous sand of Padstow harbour, and spread it over their clayey lands. The successful mixture of the farmers' soils, therefore, is not a modern improvement; it has evidently been practised with success in all climates, in different ages, and on every description of cultivatable land.

I have witnessed, however, even in soils to all appearance similar in composition, some very extraordinary results from their mere mixture. Thus, in the gravelly soils of Spring Park, near Croydon, the ground is often excavated to a depth of many feet through strata of barren gravel and red sand, for the purpose of obtaining the white or silver sand which exists beneath them. When this fine sand is removed, the gravel and red sand is thrown back into the pit, the ground merely levelled, and then either let to cottagers for gardens or planted with forest trees; in either case the effect is remarkable: all kinds of either fir or deciduous trees will now vegetate with remarkable luxuriance; and in the cottage-garden thus formed, several species of vegetables, such as beans and potatoes, will produce very excellent crops in the very soils in which they would have perished previous to their mixture.
MIXTURE OF SOILS.

These instances are remarkable, and well worthy of the careful consideration of the farmer; for the poverty of both the sand and the gravel, which is thus so successfully mingled together, is very great. The appearance of the soil here gave no indications of any good being derived from the union of the two. The black gravel and the red sand were equally sterile; yet their mere mixture yielded a productive soil.

The permanent advantages of mixing soils, too, is not confined to merely those entirely of an earthy composition; earths which contain inert organic matter, such as peat or moss earth, are highly valuable additions to some soils. Thus, peat earth was successful added to the sandy soils of Merionethshay by Sir Robert Vaughan. The Cheshire farmers add a mixture of moss and calcareous earth to their "tight-bound earth," the effect of which they describe as having "a loosening operation," that is, it renders the soil of their strong clays less tenacious, and consequently promotes the ready access of the moisture and gases of the atmosphere to the roots of the farmers' crops; their vigour is promoted, their food better supplied. There are certain natural indications with regard to the admixture of soils which are self-evident to every cultivator; and there are others which are well understood in particular districts. The Norfolk farmers consider that marl is not far from the surface when the weed coltsfoot (Tussilago farfara) abounds: and that all lands will be much benefited by manuring which produces the weeds corn-marigold, or brindle (Chrysanthemum segetem), and smartweed, or pale-flowered persicaria (Polygonum Persicaria).

In the transfer of the earths the farmer will find it a profitable practice, especially when the distance is great, to have them previously dug in pits, and dried in the sun. In this way the weight of either chalk, marl, or clay is much more considerably reduced than the cultivator would suppose. I have found that when moist chalk is dried in this way it loses from 20 to 24 per cent. of water. Strong adhesive clay, under similar circumstances, loses from 32 to 41 per cent, and marl from 18 to 25 per cent. of its weight; so that supposing he carried 100 cubic yards of each of these fertilizers, by merely having them previously dried, he saves in weight of carriage.

As there are only these earths present to any extent in all cultivated soils, and as the proportion which they bear to each other makes the chief difference between fertile and barren lands, I shall confine my attention in this paper to the application of 1. Chalk, 2. Clay, 3. Sand, to land which is naturally deficient in them; and in entering upon the investigation, I shall suppose that the farmer is aware that it is merely the excess of one of these earths which renders a soil unproductive, and that the application of the deficient earths operates so advantageously by tending to render the composition more similar to those of richer soils, in which the earths are mixed in a more fertile proportion. It is of the first importance, however, that the farmer should be aware of this fact; let him, to this end, contrast the analysis of a barren soil like that of Bagshot Heath, which is composed of

| Coarse silicious sand | 32 | Part.
| Fine sand | 32 |
| Iron, clay, and chalk | 0 | 11 |
| 400 |

with that of the soil of a Lincolnshire pasture, which contains, in the same weight,

| Fine calcareous sand and silicious sand | 100 |
| Soluble matters | 6 |
| Organic matters | 40 |
| Chalk | 8 |
| Oxide of iron | 25 |
| Alumina (pure clay) | 65 |
| Lax (earth of flint) | 61 |
| Water, and loss | 1 |
| 400 |

The soil of Bagshot, he will observe, contains nearly twice as much silicious matters, and only one-fifth the proportion of chalk and alumina, that is present in the pasture from Croft in Lincolnshire.

Chalk and marl are both used for the sake of the carbonate of lime they contain, and they may, therefore, be treated of under one head. The proportion in which I have witnessed these applied per acre naturally varied with the expense of the carriage of the material. On the light gravelly soil of the coast of Essex, I have used, in common with my neighbours, about 20 to 25 tons of the chalk of Kent per acre, at a cost of about 6s. per ton; but of marl the quantity applied in the same district is from 50 to 100 tons per acre, which may be commonly procured for the expense of carriage and spreading; and this addition to the soil is a very permanent improvement. Chalking, the Essex farmers say, lasts for 20 years, and marling for a man's life.

Upon analyzing a productive soil, worth 30s. per acre, which had been thus chalked about five years previously, it was found to contain

| Stones and gravel, principally silicious | 27 |
| Vegetable fibres | 15 |
| Soluble matters, principally vegetable extract | 9-5 |
| Carbonates of lime and magnesia | 18 |
| Oxide of iron | 4 |
| Animal and vegetable matters | 1 |
| Silica | 4-5 |
| Alumina | 40 |
| Loss | 1 |
| 100 |

A portion of the same field (which was an enclosure from a poor common), not chalked, being examined, was found to yield nearly the same proportion of ingredients, but the chalk was almost entirely absent. Now, before the addition of the chalk, the land was too poor to yield any thing except the fern and the furze.

In Dorsetshire, near Weymouth, and on the Coomb Hills, which separate Berks from Hampshire, where chalk is in many places readily obtained by sinking a well, and drawing it up
MIXTURE OF SOILS.

by a windlass to the surface, the quantity applied per acre is much more considerable. I have seen from 50 to 100, or even 150 tons per acre, spread on the gravel and clay lands with decided success.

The cultivator sometimes deludes himself with the conclusion that applying sand, or marl, or clay, to a poor soil, merely serves to freshen it for a time, and that the effects of such applications are only apparent for a limited period. Some comparative experiments, however, which were made 16 years since on some poor, hungry, inert heath-land in Norfolk, have up to this time served to demonstrate the error of such a conclusion. In these experiments the ground was marled with 20 cubic yards only per acre, and the same of compost; it was then planted with a proper mixture of forest trees, and by the side of it a portion of the heath, in a state of nature, was also planted with the same mixture of deciduous and fir trees. Sixteen years have annually served to demonstrate, by the luxuriance of the marled wood, the permanent effect produced by this mixture of soils. The growth of the trees has been there rapid and permanent; but on the adjoining soil, the trees have been stunted in their growth, miserable in appearance, and profitless to their owner.

Time has made no alteration; while the marled soil has yielded an annual and luxuriant crop, the land left in its original state has demonstrated by its produce that something was wanting, some earthy ingredient only needed to render it no longer barren, and the adjoining marled land has further shown of what that addition was composed.

The expense per acre of this marling, and otherwise preparing the soil, was

In this instance the marl had to be carried about a quarter of a mile.

It is difficult to account for the want of that general attention to the use of earthy admixtures which so many successful experiments with them would lead us to anticipate. Mr. Rodwell, of Livermere, in Suffolk, successfully clayed and marled 820 acres of sandy heath not many years since, using about 140,000 tumbril loads, which, at 81d. per cubic yard, cost him 4958/. He found, from experience, that clay was to be preferred to marl on all his sandy soils. The result was highly satisfactory: 350l. per annum was added to the value of the estate.

This excellent farmer practised also the system of hand-borrowing the clay. “The men make good earnings at 10d. a cubic yard, wheeling it 30 rods; and down to 7d. a yard at shorter distances;” and on the whole, deemed this “the cheapest method of all others, especially on heavier soils.” But he did by far the greatest part by tumbrils, the expense of which, by contract carting, and labour, was 8d. per cubic yard. He found also, contrary to the commonly received opinion, that deep ploughing was the best for his marled and clayed lands.

“I have found,” he said, “that the clay and marl works the better, the more soil it has to incorporate with.”

One cause of the failures which have sometimes taken place in the attempted improvement of soils by their admixture, arises from the want of a thorough union of the heavy clays, added to the light sandy soils. The earths were in these cases never incorporated by the aid of the harrow, on such frosty mornings as are best adapted to the mixture, and, in consequence, the more ponderous lumps of clay or marl were allowed to gradually sink, as the farmers say, into the sand; and in some such soils as these, the stratum of clay and marl which was applied 10 years since may now be found in one unbroken seam, at a depth of 12 or 14 inches in the soil. Such erroneous modes of applying the earths are much to be lamented: they decide no controverted question,—they prejudice the unreflecting cultivator,—they add nothing to the common stock of agricultural knowledge.

This error was noted by the late General Vavasour: he told the farmers very correctly, that under a poor sand, a stratum of clay, marl, or other substance peculiarly adapted to give fertility to the soil will generally be found that nature seems to have designed that no land should be unproductive, and if any be unfruitful, the cause is in the ignorance or indolence of man. If clay marl, he thought, could be had at a convenient distance, 75 cubic yards per acre was a good covering; if of a shelly or soapy marl, 20 or 25 yards will be sufficient.

The marl, after being spread, should be repeatedly rolled and harrowed, to divide and pulverize it the better.

The application of sand to the farmers' heavy clay soils is a practice which, in several districts of England, is attended with very decided success. Thus, in that part of Suffolk which is bounded on two sides by the rivers Orwell and Stour, there is found a fine red sand abounding with shells, both in their perfect and broken state, which, when applied to the clay soils at the rate of 20 to 30 tons per acre, is productive of very excellent permanent good effects.

In the valley of the Kennett, in Berkshire, in similar proportions I have witnessed the use of the gravelly débris of the Bath Road used upon the peaty soils of that district with excellent effect, and with equal success on some stiff clay meadow-land; the result of dressing it with about 30 tons per acre with the same road-sand is equally decided. The land is not only prevented from cracking in the summer months, but the produce of grass is very materially increased.

The employment of sea-sand is a very ancient custom in the west of England; it is one, in fact, to which no one can assign the period of its commencement: many thousand tons per annum are carried away by the farmers who cultivate the lands in the neighbourhood of Padstow Harbour, even on horses' backs, and they think it well worth their while to carry this sand some miles into the interior of the country. In a similar manner the farmers of
MIXTURE OF SOILS.

Devon dredge for the sand at the mouth of the Tamar, and when they have filled their barges, carry it up the river. They deem the fine-grained sand the most immediate in its effects, but both are very durable, and decided improvements to the soil. The coarse sand, they say, lasts for many years.

The composition of the sands of Padstow Harbour, and of the estuary of the Tamar, are very similar; they contain from 60 to 70 per cent. of carbonate of lime, and are both preferred by the farmers, when they can be obtained, mixed with the sea-water.

Another, but the least commonly practised mode of improving the staple of a soil by earthy additions, is claying; a system of fertilizing, the good effects of which are much less immediately apparent than chalking, and hence one of the chief causes of its disuse. It requires some little time to elapse, and some stirring of the soil, before the clay is so well mixed with a sandy soil as to produce that general increased attraction and retentive power for the atmospheric moisture which ever constitutes the chief good result of claying poor soils. Clay must be, moreover, applied in rather larger proportions to the soil than chalk; for not only is its application rarely required as a direct food for plants, for the mere alumina which it contains, since this earth enters into the composition of plants in very small proportions, but there is also another reason for a more liberal addition of clay being required, which is the impure state in which the alumina exists in what are commonly called clay soils. For instance, chalk usually contains, when perfectly dry, about 98 per cent. of carbonate of lime. Mr. Kirwan found in a specimen of chalk 2 per cent of alumina, or cided effects than the addition of a much larger proportion of the most tenacious clay. Chalk, too, when merely spread on the surface of the soil, and exposed to the action of frost, speedily crumbles to powder, and is intimately combined with the other earths of the soils. The clay, however, is too adhesive to be thus readily, and without some little labour, so intimately mixed with the soil: its effects, however excellent, are much more slowly apparent; but patience and judicious management of clay will do wonders, even on the most unlikely soils; and I could not, perhaps, state any more complete cases of the recovery of an absolutely barren soil by means of clay and chalk, and, indeed, too, at a reasonably profitable rate, than those successful experiments which have recently been made on the shingle of the sea-coast near Eastbourne, in Sussex, consisting entirely of silicious pebbles, varying in size from that of hazel-nuts to hen's eggs, and that extending to a depth of many feet.

In this case the clay was drawn in hand-carts by three men, rather better than a quarter of a mile. The cart contained about 880 lb. of clay, or about 13 cubic feet. Eight of these cart-loads, or about 35 tons, were spread over each square yard of 16½ feet, which, when first spread loosely and in lumps, made the soil 5 or 6 inches deep, and when it had become settled and solid, about 4 inches; each cart took back a load of shingle to fill up the hole made by the excavation of the clay. The work was laborious, but the men readily earned about 18.6d. per day, and were contented. They did their work by contract, receiving 3s. per square rod for the shingle they thus covered, or 24l. per acre; and for this sum they carried 250 tons of clay. The clay is of the ordinary red description, so common in Sussex, and though not particularly adhesive, is yet sufficiently so to form a plate, on which in wet weather the water stands, although this superstructure of clay is resting on a mass of coarse shingle stones, 15 feet in depth. This experiment was made on a small field of about 3 acres in 1839, and promises as well as a similar effort made with the same clay in 1832.

But the heaviest clay soils seldom contain more than 20 per cent. of alumina; in the stiff clays of Sussex and the Weald of Kent are found only about 28 per cent. of this earth; even the adhesive clays employed by the potter yield only about 33 per cent. of alumina, porcelain earth only 47 per cent.

The following is the analysis of a heavy Sussex clay soil:

The farmer, therefore, who applies 50 tons per acre of such a clay to a sandy field, only adds about 14 tons of alumina to the soil; but if he applies 50 tons of chalk, he adds 49 tons of carbonate of lime.

Hence, is the reason why, in all efforts to alter the earthy constituents of a soil, a much smaller quantity of chalk produces more de-
up by the sea can be called soil) not affording a single substance of any kind which could, to any extent, be profitably mixed with the clay. The attempt, therefore, was one of much more difficulty than any case which usually presents itself to the notice of the cultivator. It was not a mere claying a poor sand or chalk, or peat, either of which would assist in forming a mould, but the entire soil had to be formed; and this, it will be seen, was accomplished successfully and profitably, and by manual labour only.

Some valuable observations and experiments upon claying a light sand are contained in a letter... 

``Mr. Linton, the description of land improved "was a light barren sand; the substratum a white sand, from 1 to 4 feet deep; the surface of the same texture, but darker in its colour, through the decomposition of vegetable matter upon it. Beneath the bed of sand lay a yellowish kind of clay, about 1 foot thick; under it a rich marl, about 18 feet deep. The land generally being very wet, my first object was to underdrain it thoroughly with tiles; unless this is first done, where necessary, marling is a waste of capital. I cut my drains about 24 inches deep, and 9 yards apart." As to the choice of clay, Mr. Linton tested it with vinegar and water: the description he used "effervesced nearly as tartaric acid and carbonate of soda do when mixed together in water; this was my test, that it contained a quantity of carbonate of lime, which rendered it fit for my purpose, and worthy of the name of marl. I consider, that on the proper testing and selection of the clay or marl, choice, as I may say, is the secret of the success of marling operations. All clay will do good, there is no doubt, but on the quality used must rest the amount of benefit obtained." In these experiments "the soil was made completely level by the plough-harrows, and in some places the spade, after which it was ready for the marl being laid on, which was done at all times of the year," he prefers, however, doing this when the land is in seeds. The quantity laid on "varied from 100 to 200 cubic yards per acre, the average 150 yards. Where the land was very light and barren (which mostly is the case on elevated parts), a larger quantity was laid on; but where it was a better soil, a much less quantity answered the same purpose, my object being to lay on just as much as would grow wheat after seeds; to do more than this would have been an injury to the land, for eating turnips upon it with sheep, and for the barley crop; when sufficiently clayed to grow wheat after seeds, a point requiring close attention, I always found it effectively done for any other crop."

``The way in which it was done. It was necessary, in the first place, to fix upon the most favourable situation for the pit, keeping three objects in view. 1. The most convenient place for carting to the plot of ground intended to be marled. 2. The best situation for a pond to answer for a permanent watering-place, cutting, if possible, across a fence, so as to water 2 fields, one from each mouth of the pit. 3. Where the clay could least get with the least difficulty. After the place was fixed upon, the work was carried on by 5 diggers, a driver, 4 horses or beasts, and 2 carts (which are of the Scotch kind, with short bodies and broad wheels); the pit was dug with a gradual descent, so that 3 horses could draw out about a ton, which was shot out where wanted, the last returning by the time the other was loaded: thus, 3 horses were always ready for the loaded cart: the clay was spread by the diggers, at broken times after being exposed to the action of the air; rain, after either frosty or drouthy weather, would cause it to fall to pieces, sufficiently for harrowing and ploughing in. The expense I paid for digging filling the carts, and spreading marling, from 4d. to 5d. per cubic yard (full 1 ton), varying according to the quantity of stones imbedded in the clay; the total expense per acre was as follows:--

<table>

Mr. Linton marled 80 acres in this way; but by employing a windlass to draw the cart out of the pit, he reduced the expense per acre 7s. As regards the improvement of the land by marling, the value of the produce in 4 years before marling was

"The land," Mr. Linton adds, "is never so productive the first 2 years (or until the clay has got well pulverized and mixed with the sand) as it is afterwards, and it will grow a good crop or a fine sample of barley for 5 or 6 years after the clay is laid on. I have therefore sown oats instead. If people (he concludes) would improve the land they have, particularly light land, by draining, marling, &c., they would realize a far greater return for the outlay than by purchasing more." (Journal, Roy. Agric. Soc. vol. ii. p. 67.)

From these facts the cultivator, I think, will arrive at the conclusion, that the judicious admixture of soils, and other applications of manual labour, for the purpose of increasing their productiveness, can hardly fail, sooner or later, to amply repay him for the labour he thus employs. It is an improvement, let him remember, that, when once accomplished, lasts forever, since the very character of the soil is changed; his organic manures, such as farmyard compost, oil-cake, and even bones, are gradually dissolved or decomposed, and disappear from the land, are absorbed by his crops, or evolved in the gases of putrefaction; but no such results arise from either deepening the soil or the addition of the earths, they, when once united to the soil, remain there to increase the crops, to lessen the toils, and to add to the profits of succeeding cultivators, even in distant periods. And to effect these important,
these national results, let him, too, remember, that no neighbouring lands are impoverished, no organic matters are drawn from one field to enrich another; the dead, the deep-buried earth is merely brought to the surface, and that while man's profitless in the mass diffuses riches and gladness when spread over the farmer's fields.

**MOLASSES** (Port. Melasso). The saccharine principle in the dregs or refuse drainings from the casks, &c., of sugar, and the uncrystallizable part of the juice of the cane separated from the sugar during the process of granulation. It consists of sugar prevented from crystallizing by acids, saline, and other matters. All cattle are fond of sweets, and thrive well upon substances which yield a large proportion of saccharine juice, of which no better proof can be afforded than the condition of the cattle and swine of the West India Islands, which are fed mainly on the tops and refuse of the cane after the juice has been expressed for sugar. Mr. E. Waters (Comm. to Board of Agr. vol. vi. p. 30) gives the result of a very satisfactory experiment as to the advantage of feeding live-stock with molasses. There can be no doubt that when this substance can be had cheap, its use must prove very beneficial in improving the condition of cattle.

**MOLE.** A species of the genus Talpa, common in England and other parts of Europe. This quadrupod exhibits in perfection that modification of structure by which the mamifferous animal is adapted to a subterranean life. Its head is long, conical, and tapering to the snout, which is strengthened by a bone, and by strong gribbles worked by powerful muscles. The body is almost cylindrical, thickest behind the head, and gradually diminishes to the tail. There is no outward indication of a neck, that part being enlarged to the size of the chest by the massive muscles which act upon the head and fore-legs. These, which are the principal instruments by which the mole excavates its long and intricate burrows, are the shortest, broadest, and strongest, in proportion to the size of the animal, which are to be met with in the mamifferous class. The food of the mole consists of worms, insects, and the roots of plants; its voracity is great, and it soon perishes if food be scarce or wanting. The sense of sight is very feeble; the eyes being minute and rudimental; but the other faculties of smell and hearing, as being more serviceable in its dark retreat, are extremely acute. The female prepares a nest of moss, dry herbage, roots, and leaves, in a chamber commonly formed by excavating and enlarging the point of intersection of 3 or 4 passages. The young are brought forth to the number of 4 or 5 in April, and sometimes later.

The farmer views the operations of the mole as destructive to his crops, by exposing and destroying their roots, or by overthrowing the plants in the construction of the mole-hills; his burrows, moreover, become the haunts and hiding-places of the field-mouse and other destructive animals. The mole is also accused of piercing the sides of dams and canals, and letting out the water, and of carrying off quantities of young corn to form its nest. Hence every means are devised to capture and destroy it, and in Europe men gain a livelihood exclusively by mole-capture. The American naturalist, however, pleads that the injury which it perpetrates is slight, and that it is more than counterbalanced by the benefit which it produces by turning up and lightening the soil, top-dressing pasture-land, and especially by its immense destruction of earth-worms, slugs, grubs, wire-worms, and many other noxious animals and insects which inhabit the superficial layer of the ground, and occasion great injury to the roots of grass, corn, and many other plants. The soundest practical conclusion lies probably in the mean of these opinions; and the enlightened agriculturist, while he takes prompt measures to prevent the undue increase of the mole, would do well to reflect on the disadvantages which might follow its total extermination. The Etrick Shepherd (James Hogg), from a course of 30 years' hard-earned experience and observation, speaks of the pernicious effects of destroying the moles on sheep pastures. He alleges, that besides the inferior pasturage which the soil affords when moles have been exterminated, the piping and the foot-rot, two baneful diseases, come in their place to annihilate the stock.

There can be no question that moles do much injury to gardens, by destroying the neatness of the beds, rooting up onions, tulips, and other tubers; but in the wide-spread surface of the field it is a question whether he does not do more good by his teeth than injury by his snout.

The animal so well known in the United States under the name of mole, belongs to an entirely different genus of quadrupeds from the common mole of Europe. The late Dr. Godman has designated the American, the shrew-mole, and given, in his Rambles of a Naturalist, a most interesting account of its habits, &c. It is the sculops aequationis of naturalists. Whether the true mole has ever been found in the United States, appears doubtful. Moles live in pairs, and frequent soils of loose textures most abounding in earth-worms and insects. They exhibit great dexterity in skinning the worms, which they always do before they eat them, stripping the skin from end to end, and squeezing out all the contents of the body.

In the United States where professional mole-catchers are not yet to be met with, other means of destroying the pest are resorted to. Dogs are sometimes found very expert in digging out moles. Mole-traps are also used, and for a good design of one see Ellsworth's Report. It is found that if fine shreds of fresh lean beef are placed in their burrows, the moles will eat them, if found soon after deposit; and if poison, arsenic or strychnine, is placed on these shreds, they are frequently killed. The trap most recommended is one constructed on the principle of that of a figure of which is given in the Cultivator. Wherever the mole shows itself in numbers, it is a pest of no small magnitude. For accurate descriptions, with drawings, of the various animals known in the United
Mole-cricket. Moon influence of.

States under the names of moles, or mice, the reader is referred to the 1st volume of the Natural History of the State of New York.

Mole-cricket (Gryllotalpa vulgaris, Acheta gryllotalpa). This destructive insect is known in different localities in England, under the several names of churh-worm, jarz-worm, eve-churr, and earth-crab. The mole-cricket measures 2 inches in length, and 4 lines in breadth. Its colour is dark-brown. The most remarkable feature in the insect is the size and strength of its fore-arms. The power which is requisite to move them is great. The cavity of the main trunk is divided lengthways by a double ginglymus partition, surmounted by a bony frame, with an inferior condyle, with which the inner part of the base of the clavicle of the arm is hinged; and by this mechanism the arms are moved. The mole-cricket burrows under ground, and devours the roots of plants. The female hollows out a place for herself in the earth, about half a foot from the surface, in the month of June, lays her eggs in a heap, which often contains from 200 to 300. They are shining yellowish-brown, and of the size and shape of a grain of millet. The young, which are hatched in July or August, greatly resemble black ants, and feed, like the old ones, on the tender roots of grass, corn, and various culinary vegetables. They betray their presence under the earth by the withering yellow patches in the meadows, and by the withering decay of culinary vegetables in the gardens. In October or November they bury themselves deeper in the earth, as a protection from cold, and come again to the surface in the warm days in March. Their presence is discovered by their throwing up the earth like moles. The best method of destroying them is to dig up the young brood; but boiling water or oil of any kind poured over their holes will be found effectual. (Kollar on Insects, p. 144.)

For a description of the American mole-cricket see Cricket.

Mole-plough. See draining and ploughs.

Mole-tree (Euphorbia lathyris). Commonly called Caper Spurge, and by the French Epurage: a plant with a biennial root; stem 2 to 3 feet high; found in the United States in gardens and lots. It is a naturalized foreigner, and was originally introduced under a notion that it afforded a protection against the incursions of moles. The same common impression once existed in regard to the Palma Christi; but little faith seems now to be attached to either plant as protectives against moles.

Monadelphous. In botany, having the filaments cohering into a tube, or one bundle.

Monandrous. A botanical term applied to plants having only one stamen, or male organ.

Moniflorum. In botany, formed like a necklace; that is to say, articulated with alternate swellings and contractions resembling a string of beads.

Monk's hood. See Wolf's-bane.

Monocotyledonous. In botany, having only one seed-leaf or cotyledon.

Moon, influence of. The following observations upon this subject are taken from a lecture delivered before the Franklin Institute of Pennsylvania, by G. Emerson, M. D., of Philadelphia.

There is, perhaps, no opinion relative to the phenomena of the natural world, more universally maintained, than that the moon exerts a decided influence over the states of the weather. This long-cherished notion has doubtless derived increased strength, since it was shown that the ocean tides depend upon a physical connection subsisting between our planet and her satellite.

I, however, think it capable of conclusive demonstration, that the moon exerts no influence in the production of wet or dry weather.

I assume it as incontrovertibly proven, by the experiments of Mr. Dalton, that the watery vapour from which rain and all the precipitations are formed, owes its elevation and suspension, in an invisible form, entirely to heat, deprived of a due proportion of which, by any refrigerating cause, it is condensed, and falls from the atmosphere in one or other of the forms of aqueous precipitation. The conditions of wet or dry weather are, consequently, to be regarded as regulated solely by temperature.

Now, the nicest experiments have failed to show that the presence and light of the moon are attended by the slightest change of temperature. The lunar rays have been concentrated by powerful lenses and the largest reflectors, and thrown upon that most delicate test of heat, the differential thermometer, without any indication of their effect in raising the temperature. Unless, therefore, it can be proved that the moon exerts some perceptible influence upon the temperature of our atmosphere, we shall be warranted in believing that she has no power in determining the conditions of the weather, whether this shall be wet or dry.

I am fully aware of the multitudes of observations which have from time to time been made upon this question, and that most of those reported do to favour a belief contrary to the position here taken.

It cannot be denied that the power of the moon, so conspicuously manifested in the production of the ocean tides, may also be felt by the atmosphere. The aerial ocean must, weight for weight, be as subservient to the law of attraction subsisting between the earth and her satellite, as any other terrestrial matter; and I have no doubt of the correctness of the results of observations made in Italy and France, by Polina, Plaugerques, and others, which go to prove that the mean height of the barometer is affected by the different positions of the moon in relation to the earth, the greatest mean elevations corresponding with the quarters. But, in thus admitting the existence of lunar influence upon the terrestrial atmosphere, we should not deceive ourselves in regard to the nature of this influence. We must not admit that every cause which operates in producing the rise or depression of the mercurial column, is capable of influencing the hygrometric conditions of the air, or, in other words, exercising an influence in the production of wet or dry weather. The attraction subsisting between
the earth and moon, causes an accumulation of the liquid and movable materials spread over the terrestrial surface, on that part addressed, towards the moon; hence, the rise observed in the sea, and in the mercurial column. But all this is owing to the agency of gravity, or attraction, which, we contend, has nothing to do with the production of wet or dry weather; the elevation and deposition of aqueous vapour being, as we have said before, subject to the agency of temperature alone.

As to the calculations, the results of which seem so irrefutably in favour of lunar influence upon the weather, we think it easy to show that they must be founded upon deceptive data, and will not bear a close examination. The estimates of Toaldo, a celebrated Italian philosopher, embrace a series of laborious observations, collected during many years, and compute the number of changes of weather to the different phases of the moon, as follows:

New moon - - - 6 to 1;  
Full moon - - - 5 to 1;  
First quarter - - - 2 to 1;  
Second quarter - - - 2 to 1;  
Perigee - - - 5 to 1;  
Apogee - - - 4 to 1.

That is to say, of 7 new moons, 6 were attended with a change of weather, and at one of them there was no change; of 6 full moons, 5 were attended with a change; and, at the quarters, the changes were twice as frequent as the continuance of the previous weather.

Now, such a computation, coming from so high an authority, might almost be deemed conclusive upon the subject. When, however, we come to inquire more closely into the circumstances involved in the calculation, we find ample grounds for suspecting its accuracy. In the first place, the term "change of weather" is used by Toaldo in an ambiguous and arbitrary sense, so that we are left ignorant of the specific change he refers to. But, worse than this, he does not restrict himself to the day when the change takes place, but includes any changes within 2 or 3 days preceding or following a phase. It is easy to conceive how a person, especially one possessed in favour of a prevailing opinion, might have been led, with such a privilege as to limit, to take or reject a change, to throw it into one quarter or another, as he might choose to dispose of it, for the purpose of endowing the moon with a power to which he thought her entitled.

The results of a series of observations made by Pilgrim, make it appear that the new moon has less to do with the changes of the weather than the other phases; a conclusion diametrically opposed to that of Toaldo, just referred to. As the estimate of Pilgrim is founded on observations extending through a series of no less than 52 years, it might be regarded, in point of authority, as at least equal to that of the Italian philosopher. How are these clashing results of observations, professing to be made with the utmost attention, to be reconciled with truth? Do they not leave us to infer that the data employed have been either deceptive, unskilfully grouped, or that some incidental or accidental circumstances have interfered with the estimates, and led to erroneous conclusions?

The belief in the moon's influence over the natural operations going forward upon our earth, has by no means been confined to the weather; and it would be a tedious task to enumerate all the agencies she has been allowed to possess over organic and vegetable life both animate and inanimate. Many of the opinions vulgarly entertained upon this head, are founded on well-established facts, the error lying, not in the observations, but in the theory which makes the moon the "cause of phenomena, of which she is only the silent and unconcerned spectator." The distinguished philosopher from whom we have just quoted, has cited a number of highly interesting cases, which show in the clearest manner how the effects that have been ascribed to the moon's influence, can be readily traced to natural agencies operating around us, and with which modern philosophy has rendered us familiar. Such, for example, as the pernicious influence upon vegetation, attributed by gardeners and agriculturists to the April moon; the effect of the moon's rays in hastening the putrefaction of animal substances, &c.; all of which effects are doubtless connected with the presence of moonlight, merely, however, as an incidental circumstance, for they would take place equally well in a clear atmosphere, even should there be no such body as the moon in existence.

Let us take, for example, the case of the April moon, denominated by the French gardeners "la lune rousse." The change in this case takes place in April, and the full either about the end of this month, or some time in May; at which particular season, in our climate, the mean temperature of the air is but little above the freezing point. Under these circumstances the radiation from the earth, during a clear night, will often reduce its temperature to, or even below, the freezing point; whilst a thermometer suspended in the air, a few feet from the ground, will remain several degrees above 32°. Thus, the tender plants in the soil may become actually frost-bitten, whilst the moon has been apparently too warm to admit of such an occurrence. If, on the contrary, the night be cloudy, the plants will suffer no injury; no, as the gardeners allege, because there is no moonlight to hurt them, but because the radiation and cooling of the earth will not take place. Thus, moonlight or starlight, the injury to vegetation will be precisely the same, and the effect might as well be ascribed to the stars as to the moon.

And, again, it has been noticed by Pliny and Plutarch, and is generally believed in most countries at the present day, that the moon's light sheds a copious humidity on substances exposed to its rays, and hastens the putrefaction of animal substances. That a copious humidity is often shed during a moonlight night, is not to be disputed; neither can it be doubted that meats will spoil sooner, if exposed to her rays, than if protected from them. The nature and source of this humidity can be no mysteries now that the rationale of the
formation of dew is so happily explained; and it is sufficient to say, that the moisture deposited upon the meat causes it to spoil much sooner than if kept covered, when it would remain dry. Meats are constantly preserved by simple drying; and even the mummies in the dry caverns of Egypt have lasted thousands of years, mainly from their depositories being perfectly free from moisture. The preserving agency of embalming is, perhaps, a secondary consideration, when compared with the subsequent state of dryness in which the bodies are kept.

As to the notion of lunar influence on disease, which still counts numerous partisans, I regard it as upon precisely the same footing as the exploded doctrine of the agency of the stars, so long and stoutly maintained. Upon the whole, therefore, I look upon it as clearly demonstrable, upon established philosophical principles.

1st. That wet and dry weather are matters regulated solely by changes of temperature, over which the moon has no control:

2d. That the mutual influence exerted between the earth and moon, as shown in the ocean and atmospheric tides, depends upon the play of another and entirely distinct principle, namely, evaporation or attraction:

3d. That most, if not all, the effects upon animal and vegetable substances, popularly ascribed to the action of the moon, are to be traced to natural agencies, entirely independent of this satellite.

MOON-TREFOIL. A name for one of the species of medic (Medicago arborescens).

MOONWORT (Botrychium, from botrys, a bunch; in reference to the form of the fructification, which is much like a bunch of grapes). The species of this genus of ferns are curious and interesting plants; one only is indigenous, the common moonwort (B. lanaria), which is a perennial growing in mountainous pastures or meadows. The root consists of several simple, cylindrical, clustered or whorled fibres. The herb is very smooth, a little succulent, of a pale opaque green, erect, not a span high. Leaf solitary, pinnate; leaflets fan-shaped, notched.

MOOR. An uncultivated surface of country, without trees, and with few grasses or other herbage fit for pasture; and usually containing scattered plants of heath, with a dark peaty soil. Moor lands are generally the least fitted for culture of any description of surface, not rocky or mountainous. Moors are covered with a very thin layer of soft, black, sterile soil; and the subsoil is generally gravel or retentive ferruginous clay. By the destruction of the heath or other bad herbage, and by sowing down with grass-seeds, they may be improved. In many cases, also, trees will grow on drained moors; in which case the soil ultimately becomes ameliorated by the shade they afford, and the fall and decay of their leaves.

MOORLAND PAN. This is a name given in Scotland to an indurated combination of clay, small stones, and iron in a particular state, situated either immediately, or at some distance below the path of the plough, and which is nearly impervious to water. All indurated incrustations, however, formed under the sole of the plough, says a writer in a valuable agricultural Journal, are not moorband pans. In good alluvial loam of greater depth than the plough-furrow, and rendered adhesive by pressure, an incrustation or firming of the subsoil—that is, the bottom upon which the plough moves, is frequently formed by the sole of the plough rubbing constantly on the soil at the same depth. This incrusted earth can retain water, but its effects on soils and plants are innocuous compared to those of moorband pan. Nevertheless, its disruption by deep ploughing is injurious to the soil, and we have experienced it in very fine deep mould. From an analysis by Mr. John Gray, of Dilston, of two portions of moorband pan obtained from Mylnfield Plain, 120 parts of one were found to contain 34 of oxide of iron, 74 of silice, and 6 of alumina or clay and loss; the other contained 43 parts of oxide of iron, 64 of silice, and 8 of alumina and loss.

MOOSE. See Deer.

MOOSE-ELM. See Elm, Red.

MOOSE-WOOD. The name of a species of maple (Acer striatum), so called in the northern section of the United States, but in the Middle States known by the common name of striped maple.

MOOR-GRASS (Sesleria, named in honour of M. Sesler, a physician and botanist of the 18th century). These are uninteresting grasses in an agricultural point of view.

MORASS. Moor lands saturated with water to such an extent as not to bear the tread of cattle. A morass is to a moor what a marsh is to a meadow. It is evident that the drainage of morasses and moors, by lessening the evaporation of water from their surfaces, must tend to improve the local climate. See Peat and Plantations.

MORDANT. Any substance used to fix dyes or colouring matters upon different stuffs.

MOREL (Germ. moschel). The Moschella esculenta is one of the few edible fungi which may be used as food with safety. It occasionally occurs in woods and orchards, whence it finds its way to the markets; but it is of comparatively rare occurrence. It has a hollow stalk an inch or two high, and a yellowish or grayish indented head 2 or 3 inches deep. See Fungi, and Mushrooms.

MORTAR. A well-known cement employed for building purposes, which is thus described by Dr. Thomson: "It is composed of quicklime and sand, reduced to a paste with water. When dry it becomes as hard as stone, and as durable; and adhering very strongly to the surface of the stones which it is employed to cement, the whole wall in fact becomes nothing else than one single stone. But this effect is produced very imperfectly unless the mortar be very well prepared. The lime ought to be pure, completely free from carbonic acid, and in the state of a very fine powder; the sand should be free from clay, and partly in the state of fine sand, and partly in that of gravel; the water should be pure, and if previously..."
saturated with lime, so much the better." The best proportions, according to the experiments of Dr. Higgins, are 3 parts of fine sand, 4 parts of coarse sand, 1 part of quicklime, recently slacked, and as little water as possible. The stony consistence which mortar acquires is owing partly to the absorption of carbonic acid, but principally to the combination of part of the water with the lime. This last circumstance is the reason that, if to common mortar one-fourth part of lime, reduced to powder without being slacked, be added, the mortar, when dry, acquires much greater solidity than it otherwise would do. This was first proposed by Loriot; and afterwards, Moreau found the following proportions to answer best:-

<table>
<thead>
<tr>
<th>Material</th>
<th>Parts</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fine sand</td>
<td>3</td>
</tr>
<tr>
<td>Cement of well-baked bricks</td>
<td>3</td>
</tr>
<tr>
<td>Slacked lime</td>
<td>2</td>
</tr>
<tr>
<td>Unslacked lime</td>
<td>10</td>
</tr>
</tbody>
</table>

The same advantages may be obtained by using as little water as possible in slaking the lime. Higgins found that the addition of burnt bones, in the proportion of not more than one-fifth of the lime employed, improved mortar by giving it tenacity, and rendering it less apt to crack.

When a little clay is added to mortar, it acquires the important property of hardening under water; so that it may be employed by the farmer in those edifices which are constantly exposed to the action of water. Lime-stone is found not unfrequently mixed with clay; and in that case it becomes brown by calcination, instead of white. These native limestones are employed for making water mortar; but good water mortar may be made by the following process: Mix together 4 parts of blue clay, 6 parts of black oxide of manganese, and 90 parts of limestone, all in powder. Calcine this mixture to expel the carbonic acid; mix it with 60 parts of sand, and form it into a mortar with a sufficient quantity of water. The best mortar for resisting water is made by mixing lime with puzzolana, a volcanic sand brought from Italy. Moreau informs us that basaltes, which is very common in this country, may be substituted for puzzolana. It must be heated in a furnace, thrown while red-hot into water, and then passed through a sieve.

MOSSES, in common language, are any minute, small-leaved, cryptogamic plants. Thus, club-moss is a lycopodium; Iceland and reindeer mosses are lichens; and the numerous species of Jungermannia are all comprehended under the same term. But in systematical botany no plants are considered mosses, except such as belong to the natural order, Bryaceae or Musci. Such plants are simple-leaved; without spiral vessels or stomata; with a distinct axis of growth; and with the spores, or reproductive matter enclosed in cases called sporangia or thece, covered by a cap or calyptra. It is not a little singular that such plants should have cases called staminodia, containing powdery matter; among which are found animalculae, not distinguishable from such as are called spermatic, and which swim about freely in water. None of the mosses are of any known use, except for the purpose of packing plants, and surrounding their roots when they are sent to a distance. They are bad conductors of heat, and might be employed, instead of straw, to guard delicate-growing plants from the influence of frost.

MOSS LAND. Land abounding in peat moss, but not so much saturated with water as to become peat bog or morass. Many remedies have been prescribed for the destruction of moss. A good scarifying or harrowing, with short, sharp tines, succeeded by a top-dressing of morass or swale, is probably the most efficacious: lime in any form is less powerful, though (especially when combined with sand) it remarkably promotes the growth of trefoil tribes and other grasses, highly palatable to cattle, but does not avail to the exclusion of moss.

Mr. Bishop of Perthshire, who has obtained from the Highland Society of Scotland a prize for an essay "On the Management of Pasture in regard to the Destruction of Musci," suggests as the most certain remedy, that a great portion of the summer's grass should remain unconsumed on the ground until the following winter, when the barer it is eaten before the new growth of spring, the finer will be the following summer's grass. Breaking up the land, and sowing appropriate grasses after a course of culture, is a certain remedy, but often a very inconvenient one. Mr. W. Bell gives an account of certain experiments which he carried on very successfully for converting moss into manure by the application of whale oil.

Mr. A. Blackadder, speaking of the manures for decomposing moss, says: Adjacent rock strata ought to be carefully explored, as in general they have each their corresponding earthy covering, more or less adapted to the purposes of vegetation. Where the rocks are of the primitive class, or of the coal formation, their disintegrated portions, and oftentimes their superficial covers, are of inferior value as a soil; but even the rock-earth of the latter, as also of clay-slate, lime, or even the old red sandstone, though not previously mingled nor superimposed in the moss, are yet valuable as ingredients of composites for top-dressing, as are also those of the finer sandstone, greenstone, and sea-sand containing calcareous matters in a state of decomposition, or even where these are absent. While sand laid over moss produces rapid decomposition, and consequent vegetation, no such effect is produced by the purer clays. Putrescent matters, whether animal or vegetable, possess the most powerful influence. Lime, unless in compost, seems to have no such effect on simple mosses; and its effects on mixed mosses, or those in a state of partial decomposition, must depend on the quantity of foreign matter mixed with the circumstances. The value of moss greatly depends on local circumstances, and particularly with regard to the supply of operatives at the commencement of improvements; access to putrescent manures; markets for the sale of the produce; soils affording materials for top-dressing; and turf suitable for wedge-drains.
or for drain-tiles, or stone for drains, or clean gravel, if found preferable, the expense at which these can be laid down at the mosh must enter into the calculation. Or, again, if the mosh is to be entirely removed, whether an adequate supply of water can be obtained, with access to a river or to the sea, into which it may be floated off. Nothing adds more to the intrinsic value of moss than mixtures of other soils during the progress of its formation, either by means of the wind in carrying drift sand, or by water transporting earthly particles. When, again, a considerable quantity is thus superimposed, the soil ceases to be a moss, properly so called, and is an alluvial soil upon a moss subsoil. In either case, little more is required than thorough draining, in order to the production, by the ordinary means, of the best crops; and such is the description of the greater part of the moses hitherto successfully improved in Scotland. The same writer furnishes some causes of the failure in moss improvements.

MOTH. Clothes-moth, Fur-moth, Grease-moth, &c. The various kinds of destructive moths, found in houses, stores, barns, granaries, and mills, are mostly very small insects; the largest of them, when arrived at maturity, expanding their wings only about eight-tenths of an inch. The ravages of some of these little creatures are too well known to need a particular description. Among them may be mentioned the clothes-moth (Tinea ventana), the tapestry-moth or carpet-moth (T. topazellae), the fur-moth (T. pulliottae), the hair-moth (T. crinella), and the grain-moth (T. granella), with some others belonging to a group, which may be called Tineans (Tineodea); also the pack-moth (Anacampis saricella), which is very destructive to wool and fabrics made of this material, and the Angoumois grain-moth (A. cerealella), both of which are to be included among the Yponomeutians. In the cabinet of the Boston Society of Natural History, the cases, containing the large and beautiful collection of shells, were formerly lined with fine white flannel. In this some moths soon established themselves, and multiplied in the course of a few years, did so much damage that it became necessary entirely to remove the moth-eaten linings. In their winged state these moths were of a light buff colour, with the lustre of satin, and had a thick orange-coloured tuft on the forehead; the wings were deeply fringed, and the first pair were lance-shaped, and expanded rather more than half an inch. This species agrees very well with the description given, by the old naturalist, of the Tinea flavipunctella or the orange-fronted tinea, and with Wood's figure of Tinea destructor, the destroyer. Should it prove to be different from these, it may be named the satin-buff moth. Objects of natural history are very apt to be injured by another moth, closely resembling the foregoing, and differing from it chiefly in being somewhat smaller, and in having the hind-wings tinged with gray. Chocolate, as Réaumur has remarked, is devoured by another tinea, whose little silken cases are often seen between the cakes, and I have also found them in chocolate put up in tin cases. Other articles of food are also devoured by some of these tinea, and even our books are not spared by them.

Habits of Moths, and Means of preserving Clothes, &c., from their Attacks. — The tineans, in the winged state, have 4 short and slender feelers, a thick tuft on the forehead, and very narrow wings, which are deeply fringed. They lay their eggs in the spring, in May and June, and die immediately afterwards. The eggs (according to Latreille and Dupontel, from whose works the following remarks are chiefly extracted) are hatched in 15 days, and the little whitish caterpillars or moth-worms proceeding therefrom immediately begin to gnaw the substances within their reach, and cover themselves with the fragments, shaping them into little hollow rolls and lining them with silk. They pass the summer within these rolls, some carrying them about on their backs as they move along, and others fastening them to the substance they are eating; and they enlarge them from time to time by adding portions to the two open extremities, and by gores set into the sides, which they slit open for this purpose. Concealed within their movable cases, or in their lint-covered burrows, they carry on the work of destruction through the summer; but in the autumn they leave off eating, make fast their habitations, and remain at rest and seemingly torpid through the winter. Early in the spring they change to chrysalids within their cases, and in about 20 days afterwards are transformed to winged moths, and come forth, and fly about in the evening, till they have paired and are ready to lay their eggs. They then contrive to slip through cracks into dark closets, chests, and drawers, under the edges of carpets, in the folds of curtains and of garments hanging up, and into various other places, where they immediately lay the foundation for a new colony of destructive moth-worms.

Early in June the prudent housekeeper will take care to beat up their quarters and put them to flight, or to disturb them so as to defeat their designs and destroy their eggs and young. With this end in view, the closets, chests, and drawers, will be opened, and emptied of their contents, and all woollen garments, and bedding, furs, feathers, carpets, curtains, and the like, will be removed and exposed to the air, and to the heat of the sun, for several hours together, and will not be put back in their places without a thorough brushing, beating, or shaking. By these means, the moths and their eggs will be dislodged and destroyed. In old houses, that are much infested by moths, the cracks in the floors, in the wainscot, around the walls and shelves of closets, and even in the furniture used for holding clothes, should be brushed over with spirits of turpentine. Sheets of paper sprinkled with spirits of turpentine, camphor in coarse powder, or leaves of tobacco, should be placed among the clothes, when they are laid aside for the summer. Furs, plumes, and other small articles, not in constant use, are best preserved by being put, with a few tobacco leaves, or bits of camphor, into bags made of thick brown paper, and closely sewed or pasted up at the end. Chests of camphor wood, red cedar, or of Spanish cedar,
are found to be the best for keeping all articles from moths and other vermin. The cloth linings of carriages can be secured forever from the attacks of moths by being washed or sponged on both sides with a solution of the corrosive sublimate of mercury in alcohol, made just strong enough not to leave a white stain on a black feather. Moths can be killed by fumigating the article containing them with tobacco smoke or with sulphur, or by shutting it in a tight vessel and then plunging the latter into boiling water, or exposing it to steam, for the space of 15 minutes, or by putting it into an oven heated to about 150 degrees Fahrenheit, the thermometer.

Stored grain is exposed to much injury from the depredations of two little moths, in Europe, and is attacked in the same way, and apparently by the same insects, in the United States. See Corn-Moth, Grain-Weevil, and Insects. MOTH MULLEIN. See Mullein.

MOTTLED. In botany, signifies marked with blotches of colour of unequal intensity, passing insensibly into each other. It is synonymous with maculated; as, for instance, in the species of common hemlock (Conium maculatum).

MOULD. A general name for the finely divided earthy substance that forms the upper stratum or surface soil of land, and in which all kinds of vegetables strike root and thrive. See Analysis of Soils, Earths, and Humus. MOULD-BOARD. See Plough.

MOULD ON HOPS. A vegetable disease, which is liable to affect the hop plant, in the more advanced periods of its growth, and produce much mischief to the crop. See Mildew and Hops.

MOULDEBAERT. This implement of Flemish husbandry resembles a large square maulshovel: it is strongly prepared with three bars of iron on the lower side, secured by 12 bolts, and is drawn by a pair of horses with swingletrees. It is used for transporting compost, mould, &c., from one spot to another. Its usual dimensions are as follows: breadth across, 3 feet 6 inches; length, 3 feet; height of back, 1 foot 6 inches; length of handle, 4 feet. The person who drives, with long reins, by pressing moderately on the handle as the horses go forward, collects and transports about 5 cwt. of earth to the place where it is to be laid down, which is done in the most expeditious manner, by his letting go the handle; this causes the front edge of the implement to dip and catch against the ground, whereby it is at once turned over and emptied of its load. The extremity of the handle, to which a rope is affixed, by this upsetting strikes against, and rests upon, the swingletree bar, and in this manner the mouldebaert is drawn along towards the heap of earth or compost; the driver then, by taking up the rope, draws back the handle, collects his load as before, proceeds to the spot which is to receive it, and the horses are never for a moment delayed.

MOURNING. The fall of the plumage of birds. It may be either partial or total: the complete moult generally takes place annually; the partial moult occurs at the change of plumage to which some species of birds are subject at the breeding season. The moult is always accompanied by the development of a new plumage, which may be of a different colour from that which is lost. MOUNTAIN ASH. See Rowan Tree.

MOUNTAIN ERYNGIUM (Bauhinia; in memory of John and Caspar Bauhin, botanists of the sixteenth century). A genus of showy and interesting evergreen shrubs, which will succeed well in a mixture of sand, loam, and peat.

MOUNTAIN LAUREL. See Kalmia Latifolia.

MOUNTAIN MAHOGANY (Betula lenta). Black Birch. See Birch.

MOUSE-EAR CHICKWEED. See Chickweed.

MOUSE-EAR SCORPIONWEED. See Scorpion-Grass.

MOW. A pile or heap of corn, straw, or hay placed together for the purpose of being kept dry. See Stack and Rick.

MOW-BURNT. A term applied to such substances as are over-heated in the mow by the process of fermentation.

MOWING. The act of cutting down corn, grass, &c., by the scythe.

MOWING MACHINES. See Reaping Machines.

MUCILAGE. A turbid, slimy fluid, produced by treating some vegetable substances with cold water, others with hot. It resembles gum, but is distinguished from it by not forming a thick curd with the solution of Goulard's extract. See Starch, Linseed, Marsh Mallow, &c.

MUCK. A farming term for any sort of material, such as dung, straw, &c., that is moist, or in a fermenting or decomposing state.

MUD. The mechanically suspended matters of water deposited at the bottom of rivers, ponds, ditches, &c. As much of this kind of material should be collected as possible, and be thrown up into heaps in order to become mellow. It contains much carbonaceous matter, and is an excellent manure, either in the simple or compound state, mixed with compost, or with a bushel of lime or salt to each cubic yard.

MUDWORT (Limosella; from limos, mud, in allusion to the habitation of the species; whence, also, the English name). The common mudwort (L. aquatica) is an English annual subaquatic plant, growing in muddy spots, where water has stagnated during winter. The herb is diminutive and quite smooth.

MUGWORT (Artemisia vulgaris). This species of Artemisia grows very common about English hedges, in waste ground, and the rough borders of fields. This species is weakly aromatic, and bitterish; and has, from remote antiquity, been esteemed an active warm medicine in decoction.

MULBERRY TREE (Morus; from the Celtic word mor, signifying black, in allusion to the colour of the fruit). The species of Morus, or mulberry, grow from 10 to 30 feet high. A moist situation and loamy soil, with a free exposure to the sun, suit them best.

1. The common mulberry (M. nigra) is in general cultivation for the sale of its fruit, which is well known.

835
2. The white mulberry (M. alba) is extensively cultivated in many countries for its leaves, which form the chief food of silkworms.

The mulberry tree may be propagated by layers, cuttings, or grafting. The principal use of the fruit of the black mulberry is for the dessert; but from its cooling and laxative properties, its juice, diluted with water, is sometimes used as a beverage in fevers. It is also employed in the form of syrup for medicinal purposes, chiefly to colour other fluid medicines. The juice is also used to give a dark tinge to liquors and confections. When properly fermented and prepared, the fruit yields a pleasant vinous liquor, known under the name of mulberry wine. In the cider counties they are sometimes mixed with apples, to form a beverage known as mulberry cider. The bark of the root has an acrid bitter taste, and is a powerful cathartic; hence it has been successfully used as a vermifuge, in doses of a scruple, in powder. The wood of the tree is yellow, tolerably hard, and may be applied to a variety of uses in turning and carving. It is, however, necessary to steep it in water before it is worked, in order to remove the tough and fibrous bark, which is capable of being converted into strong cordage, ropes, and brown paper.

Linnaeus has enumerated seven species of the mulberry known in his day, all which are employed to feed silkworms, except the Tintoria and India, of which the first named furnishes the well-known dyeing substance called fustic.

The species of mulberry found growing wild in the United States, is the Morus rubra of botanists, the berries being of a round and oblong form, and red, or dark purple, the pulp enveloping numerous small seeds. When perfectly ripe they are pleasant and wholesome.

The varieties of mulberry employed in Europe for feeding the silkworm form a long list. They have usually been multiplied by engrafting the finer kinds on the stalks of the common white Italian mulberry. Hence the fine, large, and firm-leaved kind called the Rose of Provence, Rose of Lombardy, &c. The exertions made to improve the tree and increase the size of the leaf by repeatedly sowing the seed of the best kinds, has resulted in the greatest success, and now the Moretta, Etala, and other varieties, are obtained from seed, with leaves sufficiently large to render grafting unnecessary.

Besides these long-known varieties of mulberry used for feeding silkworms, comparatively few of which have been employed in the United States, there are two others, namely, the Multicaulis and the Chinese, which have been very greatly multiplied, especially the former. The Chinese is usually produced from seeds imported from Canton. Its growth is exceedingly vigorous, and its leaves heart-shaped, flat, and very large. The Multicaulis is always propagated from cuttings or layers, and is more hardy than the Chinese, with larger leaves, which are always hollow and uneven. Even where the severe winter frosts of the Northern States cause the Multicaulis to be cut down, the suckers spring up from the old roots so as to afford in good season an abundance of foliage. Of late years, a hybrid variety of mulberry has been produced in France by shaking the pollen of the Moretta flowers over the flowers of the Multicaulis. The seed of the Multicaulis produced by this mixture, produces a hybrid variety with more valuable qualities than the parent, and nearly as great a capacity for propagation by layers and cuttings. The leaf of the Multicaulis has large flat leaves, like those of the Chinese or Canton seedlings. They are firm, and much relished by the worms. They endure frost equally well with the white mulberry, and are exceedingly well adapted to the silk-culture, both from their great precocity of growth, hardiness, and valuable qualities for feeding the worm and making good silk.

MULE. This is the well-known offspring of the ass and the mare, and of the she-ass and the horse. In the latter case, the produce is called a jennet, and is much less hardy, and therefore rarely bred. The term mule is generally applied in the animal creation in the same sense with hybrid in the vegetable world, signifying the intermixture of two distinct species. Mules are very hardy animals, and therefore much used in warm climates, where they are preferred to horses, either for the purposes of draught or carriage. Considerable numbers are likewise employed in Ireland, and in some of the northern counties of Britain, on account of their great strength and durability. No animal is more sure-footed or more hardy; but the pace of the mule is disagreeable to those unaccustomed to its action. The diseases to which the mule is liable are few. He attains double the age of the horse, and is much more easily maintained. The mules of the south of Europe are frequently very fine animals, 16 or 17 hands in height, active, handsome, and peculiarly patient of labour; but very inferior in beauty to the horse, particularly about the head and tail. The importation of Spanish asses into England has tended greatly to improve the mules, many of which, when bred with care, are sufficiently thick-set and heavy for all those purposes in which our largest draught-horses are employed.

To have large and handsome mules, the mare should be of a large breed, well proportioned, with rather small limbs, a moderate-sized head, and a good forehead; and the ass should be of the large Spanish breed.

MULLEIN (Verbascum; said to be from barbascum, bearded, in allusion to the bearded filaments). The English species of Verbascum are strong, robust-growing plants, producing an abundance of showy yellow flowers, and on that account they are well adapted for planting in the garden at the back of flower borders, or in shrubberies. They grow freely in any soil, and are readily increased by seeds; some of the perennial kinds by divisions of the root. (Paxton's Bot. Dict.) There are as many as 6 wild species common to Britain, viz., great mullein, or high taper (V. thapsus); white mullein (V. lychnites); yellow hoary, or Norfolk mullein (V. pulvurientum); dark or black
MUSTARD, CULTIVATED.

MUSTARD, white, Lat. arvensis, is a perennial, the moth mullein annual, and the rest are biennial in habit. They mostly grow to the height of 3 to 5 feet, in fields and waste places, on chalky and gravelly soils. The species of mullein common in the United States, in the fields of slovenly farmers, is the Verbascum thapsus of botanists.

MUNJEET. A kind of madder grown in the East Indies.

MURGARICA, called also Hydrochloric acid; or Marine acid, and Spirit of seasalt. In botany, implies covered with short, sharp points.

MURRAIN. A contagious, malignant epidemic, which frequently prevails in hot, dry seasons among cattle, carrying off vast numbers. It once used to sweep off the horned stock of whole districts, and there are few years in which it is not now seen in some part of the kingdom. It principally appears in marshy and woody districts, or where under-draining has been neglected, or the cattle have been exposed and half-starved. The disease is known by the animals hanging down their heads, which are swollen, by short and hot breathing, cough, palpitation of the heart, staggering, an abundant secretion of viscid matter in the eyes, rattling in the throat, and a slimy tongue. The early stage of murrain is one of fever, and the treatment should correspond with this: bleeding and small doses of purgative medicine will be serviceable. The peculiar febrile diarrhoea must be met with both in parent and bird, mingled also with vegetable tonics. In combating the putraneous and gangrenous stage, the chlorid of lime will be the best external application; while a little of it, administered with the other medicines inwardly, may possibly lessen the tendency to general decomposition. Above all, the infected animal should be immediately removed from the sound ones. (Vonatt on Cattle, p. 379.)

MUSCLE (Fr. mouscle; Sax. mureia). Fleshy fibres, susceptible of contractions and relaxations. They constitute what is commonly called flesh, the most nutritious species of animal food. See Flesh and Gelatin.

MUSHROOMS (Fr. muscherson; Lat. Agaricus, from Agaria, a city, or Agarus, a river of Sarmatia, now Malamonda). A more extensive genus than this is not known in the whole vegetable kingdom. Some species, as the common mushroom, A. campestris, A. vaginatus, &c., are well known for the wholesomeness of the food which is prepared from them. Others, as A. muscarius, A. necator, the whole genus Amanita, and many others, are very dangerous poisons; indeed, the latter quality exists more or less in so many species, and these resemble those that are wholesome so nearly as to render it advisable to be exceedingly cautious in the use of fungi, for the most dreadful effects are well known to have resulted from want of caution in this respect.

The edible mushroom (A. campestris), is nearly inodorous, but has a grateful flavour. The crown or hat is at first hemispherical, then convex, and at last flat; fleshy; about 2 to 6 inches broad; white, or very light-brown, slightly scaly, the scales soft and fibrous; gills pink, changing to fuscos black; the flesh, when divided, usually changes to a reddish tinge. The use of the mushroom, as an article of diet, was known to the ancients. See Fungi.

To produce mushrooms artificially, beds variously constructed are employed; and, from the numerous modes which have been invented and adopted for their production, some accompanied with extraordinary experiments, it is obvious that this "voluptuous poison" is with us, as it was with the Romans, in high estimation.

MUSSELS, or MUSCLES (Mytilus edulis). A species of shell-fish which abound on the rocky shores on the borders of the sea in many parts of the British islands, adhering to the rocks. Muscles are also found in immense beds, both in deep water and above the low water-mark, in the British seas. Where they can be collected in large quantities they may be made use of as an excellent manure, either alone or in the state of compost, with earthy substances.

MUST. A term applied to new wine and wort before it is fermented. It is also given to the saccharine juice of several fruits susceptible of the vinous fermentation, and particularly to the expressed juice of the grape before its conversion into wine.

MUSTARD (Fr. moutarde; Lat. Sinapis; mucacinit; on account of its making the eyes water, moutard). A genus of upright, branching, annual or biennial herbs, often hairy or bristly. There are five wild species common to the British islands:

1. Wild mustard (S. arvensis). A very troublesome annual weed in corn-fields; also abundant in waste ground newly disturbed. The seeds serve as an inferior kind of mustard, or rather, to adulterate that made from the common mustard. See Charlton.

2. White mustard (S. alba). 3. Common mustard (S. nigra), are annuals, in general cultivation, but are also found wild on waste ground and by road-sides, &c. See Cultivated Mustard.

4. Narrow-leaved wall-mustard (S. temulifolia). This perennial species is found growing on old walls and heaps of rubbish about most ancient cities. The root is tapering, rather woody. Herb for the most part entirely smooth, and more or less glaucous all over; feath when bruised. Stem bushy, erect, 1½ or 2 feet high, with numerous round, leafy branches, occasionally besprinkled with a few hairs.

5. Sand mustard (S. muralis). This annual species flourishes on sandy, barren ground near the sea. The root is small and tapering.

MUSTARD, CULTIVATED. The species of Sinapis generally grown in the kitchen garden for domestic purposes are the white mustard (S. alba), and the common or black mustard (S. nigra). The first is the one grown for salads; but the seed of both is employed in the manufacture of mustard.

The soil they succeed in best is a fine, rich, mouldy loam, in which the supply of moisture

837
MUTTON.  

is regular; it may much rather incline to lightness than tenacity. If grown for salading, it need not be dug deep; but if for seed, to full the depth of the blade of the spade. In early spring, and late in autumn, the situation should be such as to give it a high and cool place; it is apt to be de- stroyed, shaded from the meridian sun. For salading, the white may be sown throughout the year. From the beginning of November to the same period in March, in a gentle hotbed appropriated to the purpose, in one already employed for some other plant, or in the corner of a stove. From the close of February to the close of April, it may be sown in the open ground, on a warm, sheltered border; and from thence to the middle of September, in a shady one. Both the white and black, for seed, may be sown at the close of March, in an open compartment.

For salading, it is sown in flat-bottomed drills, about half an inch deep and six inches apart. The seed cannot well be sown too thick. The mould which covers the drills should be entirely divested of stones. Water must be given occasionally in dry weather, as a due supply of moisture is the chief inducement to a quick vegetation. The sowings are to be performed once or twice in a fortnight, according to the demand. Cress (Lepidium sativum), is the almost constant accompaniment of this salad herb; and as the mode of cultivation of each is identical, it is only necessary to remark that, as cress is rather tardier in vegetating than mustard, it is necessary for the obtaining them both in perfection at the same time, to sow it five or six days earlier. See Cress.

It must be cut for use while young, and before the rough leaves appear, otherwise the pungency of the flavour is disagreeably increased. If the top is cut off, the plants will in general shoot again, though this second produce is always scanty, and not so mild or tender. For the production of seed, whether for manufacture of mustard or future sowing, the insertion must be made broadcast, thin, and regularly raked in. When the seedlings have attained four leaves, they should be hoed, and again after the lapse of a month, during dry weather, being set 8 or 9 inches apart. Throughout their growth they must be kept free from weeds, and, if dry weather occurs at the time of flowering, water may be applied with great advantage to their roots. The plants flower in June, and are fit for cutting when their pods have become devoid of verdure. They must be thoroughly dried before thrashing and storing. For forcing, the seed is most conveniently sown in boxes or pans, even if a hotbed is appropriated to the purpose. Pans of rotten tan are to be preferred to pots or boxes of mould. But whichever is employed, the seed must be sown thick, and other restrictions attended to as for the open-ground crops. The hotbed needed only be moderate. Air may be admitted as abundantly as circumstances will allow. (G. W. Johnson's Kitchen Garden.)

MUSTARD, FLOUR OF. The seeds of both black and white mustard are employed in making the ordinary flower of mustard for dietetical use. In the dry state, mustard is inodorous, and, were it possible to taste without the aid of moisture in the mouth, it would also be tasteless; the principle of its odour and taste not existing ready formed in the mustard, but requiring water for its development. The principles which swell the seeds, and also the mucilage, are not a water-soluble body, for they are not an acid, which has been named myronic acid, and is a compound of carbon, sulphur, hydrogen, nitrogen, and oxygen; the other a substance resembling vegetable albumen, which has been named emulsion, or myrosyne. When the myrosyne and the myronic acid, which is united with potassa in the form of a myronate of potassa in the mustard, act upon each other by the aid of water, the volatile oil of mustard is formed, and odour and pungency given to the mustard. It is the volatile oil which reddens and blisters when mustard pollicles are used; and it is important to know that vinegar checks the acrimony of the potlicles, and should not be used. Tepid water only is required.

MUTTON (Fr. mouton). The flesh of the sheep. Although, by recent extensive improvements, the breed of sheep have been diminished in size, yet the smallness of bone and symmetry of form which the animals have thus acquired, have considerably decreased the quantity of offal, and added largely to the dead weight of marketable flesh. Before that time the mutton of those coarse sheep rarely amounted to more than one-half of their live-weight; whereas now, the common average is more than two-thirds; and Dishley wethers, when well fattened, are said to be in the proportion of an ounce of bone to a pound of flesh. The best and most nutritious mutton is that of sheep which are at least three, but not more than six years old, and which have been reared on dry, sweet pastures. The meat afforded by such as have been fed on salt marshes, or near the sea-coast, is likewise sweet and wholesome; for they have acquired both firmness and a fine flavour from the saline particles abounding in such situations. A sheep, to be in high order for the palate of an epicure, should never be killed earlier than when five years old, at which age the mutton will be found firm and succulent, of a dark colour, and full of the richest gravy; whereas, if only two years old, it is flabby, pale, and savourless. To ascertain the age of mutton, Mr. Ellman directs: To observe the colour of the breast-bone when a sheep is dressed, that is, where the breast-bone is separated; which in a lamb, or before it is one year old, will be quite red; from one to two years old, the upper and lower bones will be changing to white, and a small circle of white will appear round the edge of the other bones, and the middle part of the breast-bone will yet continue red; at three years old, a very small streak of red will be seen in the middle of the four middle bones, and the others will be white; and at four years old, all the breast-bones will be of a white or glistly colour. South Down wether mutton, in point of delicacy and flavour, is thought equal to any that is killed; and in summer as preferable to some other fine-flavoured breeds, especially Norfolk mutton. This circumstance is attributed to the closeness of the grain, or the specific gravity.
NAVEW.

NAVEW. A provincial term applied to a horse, of a small size for the saddle; such a horse is very useful for many purposes, where light labour is required.

NAPIFORM. Formed like a turnip, tuberous.

NARCISUS (from narko, stupor, on account of the effects produced by the smell upon the nerves). This is an old and very popular flower of great beauty, and some of the species are highly fragrant.

NARCOTIC (Fr. narcotique). Substances having the double property of exciting in the first instance, and afterwards stupefying and producing sleep or torpor. In medicine the term comprehends opiates, anodynes, and other drugs which induce sleep and alnay pain.

NASTURTIUM (from nasus, the nose, and tortus, twisted). The acridity of N. officinallis affects the muscles of the nose. Few of these plants are worth cultivating; they are of the simplest culture. The seed of the annual kinds has only to be sown in the open ground in spring. See CRESS.

NAVE OF A WHEEL. The short, thick block in the centre of the wheel which receives the end of the axletree, and from which the spokes radiate: it is bound with hoops, called nave-bands, to strengthen it. It has likewise in each end of the hole through which the axletree passes, a ring of iron called the washer which saves the nave from wearing.

NAVEL-ILL. See CALF, DISEASES OF.

NAVEL-WORT, Cotyledon (from kotyle, a cavity; in allusion to the cup-like leaves). A numerous and rather ornamental genus of succulent herbs or shrubs, with very thick, juicy, alternate, simple, entire, or jagged leaves. In England, the native species are two in number: both are perennial in habit, flowering about June and July.

NAVEW. The common wild navew (Brassica campestris) belongs to the cabbage tribe, and is an annual plant, found in corn-fields, marshes, and about the banks of ditches and rivers. The root is tapering; stem erect, 2 feet high, leafy, branched, glaucous; rough in the lower part, with small bulbous spreading bristles; smooth upwards. Radical leaves lyrate, toothed, and jagged, rough; stem-leaves smooth, clasping, oblong, partly pinnatifid; all somewhat glaucous. Flowers blooming in June and July, yellow, corymbose, almost as large as those of the turnip. Pods on longish stalks, 1/2 inch long, nearly cylindrical, beaked. The roots are nourishing, containing a sweet juice, which is sometimes domestically used in coughs and asthma.
NAVICULAR. A botanical phrase, signifying boat-shaped.

NEAT CATTLE. See CATTLE.

NECTARY, in botany, is applied to those parts of a flower which secrete honey.

NECTARINE (Amygdalus Persica, var. Nectarina). A variety of the common peach, from which the fruit differs only in having a smoother rind and finer pulp. The culture is in every respect the same as the peach. The varieties of nectarines are numerous, nearly 70 being described in the catalogue of the Horticultural Society of London. Forsyth recommends for a small garden the following sorts:—Fairchild's Early, Eldridge's Scarlet, Newington, Red Roman, and Temple's. Nectarines, like peaches, are subdivided into free-stones and cling-stones.

NEP. See Catmint.

NERVES. In botany, the strong ribs upon leaves or flowers, which are bundles of vessels, chiefly spiral. Besides conveying the sap to the leaf, and returning the proper juice to the bark, they often afford distinctive characters to the leaf, as in distinguishing sorts.

NETTED. A botanical term, implying that the veins or membranes are reticulated on the leaf, or variously intersected.

NETTLE, Urtica (from uro, to burn; in reference to the stinging properties of most of the species). An extensive genus of herbaceous or shrubby plants of little beauty, and which are justly looked upon in the eyes of the agriculturist as mere weeds. The herbage in all the species is copiously armed with venous perforated bristles, each of which has a bag of liquid poison at its base. This liquor, by the slight pressure required to pierce the skin, is transmitted into it, causing great irritation. Many of the numerous exotic species have not this stinging property; but the sting of common nettles is not to be compared with that of some of the Indian species grown in the gardens of Europe. These are, however, all surpassed in virulence by one which in Timor is called duonn setan, or devil's leaf, the effects of which are said by the natives in many cases to cause death. In England, the indigenous species of nettle are three; viz. 1. Roman nettle (U. pilulifera), an annual plant, growing in waste ground amongst rubbish, chiefly near the sea. The herb is armed all over with peculiarly venous stings. The stem is branched, leafy, bluntly quadrangular, often purple, about 2 feet high. 2. The small nettle (U. aeneus) is found to be in all cultivated ground a troublesome weed, especially on a light soil. It is annual in habit, flowering from June till October, smaller than the last, and of a much brighter green; its copious stings hardly less virulent. The several parallel ribs of the leaves form its distinguishing character. The whole plant being refused by every kind of cattle, should be carefully extirpated from pastures. 3. The common or great nettle (U. dioica), which is a noxious perennial weed, growing almost everywhere, and flowering in July and August. The root is branching and creeping, with fleshy roots, and many fleshy radicles. The herb is of a duller green than the last, erect, 3 feet high, with less irritating stings.

Leaves large, heart-shaped, spreading, pointed, strongly serrated, veiny. The leaves are employed for feeding poultry, especially in the winter; when boiled, they are said to promote the laying of eggs. Asses devour nettles eagerly, but all other live-stock refuse them, unless they are dried. In the western islands of Scotland, a rennet is prepared by adding a quart of salt to 3 pints of a strong decoction of nettles; a tablespoonful of which is said to be sufficient to coagulate a bowl of milk. The young tops of the common and smaller nettles may be boiled as pothors during spring, and eaten as a substitute for greens; being not only nourishing, but mildly aromatic. The tough fibres of the stem may be manufactured like hemp, and are often found in winter naturally separated and bleached. The roots are astringent and diuretic. See Dead-Nettle.

NETTLE-HEMP. See Hemp-Nettle.

NETTLE TREE (Celtis). This is an ornamental genus of trees and shrubs, varying in height from 6 to 50 feet. The most of them do very well in any common garden soil, and are suitable for the back of shruberies and plantations. They are increased by seeds or layers.

NETTLE TREE, AMERICAN (Celtis occidentalis). Sugar-berry. This American tree, Michaux says, if not rare, is little multiplied in comparison with the oaks, the walnuts, and maples. As it is scattered thinly through the forest, it is difficult to fix the point at which it ceases towards the north, but it is believed not to extend beyond the Connecticut river. In the Middle, Western, and Southern States, it bears the name of nettle tree, whilst the French call it bois inconnu, or unknown wood. On the Savannah river trees are found 60 or 70 feet high, and 18 or 20 inches in diameter. In the Middle States it seldom grows above 10 or 15 feet in height. It is similar in its foliage and general appearance to the European nettle tree. The flowers are small and white, and open early in spring. The fruit consists of small berries disposed on stems singly, of a dull red colour, purplish when mature, and of a sweetish taste. (Michaux.)

NICKING. In farriery, an operation performed on the tails of horses to make them carry the hair in a set manner.

NIGHTSHADE. A very numerous, principally tropical genus of shrubs or herbs, more or less narcotic; though in some cases rendered eatable by cookery, as in our common potato. Some of the genus are very dangerous and highly virulent poisons. Two species only are indigenous to England,—1. The woody nightshade (S. dulcamara). See Bittersweet. 2. The common or garden nightshade (S. nigra). This is common everywhere, law as well as cultivated ground. The root is fibrous, annual in habit, occasionally perennial. Herb fetid, narcotic, bushy, with numerous angular or winged leafy branches. Stem herbaceous, without thorns. Leaves undivided, ovate, lengthened at the base, smooth. Umbels from the intermediate spaces between the leaves, lateral, drooping, solitary, stalked, simple, downy. Flowers white with a musky scent. The berries globular, black; some.
times, as it is reported, yellow. A grain or two of the dried leaf has sometimes been given to promote various secretions. Both its poisonous and medicinal powers depend on an alkaline principle, which can be procured in a separate state, and has been called solanias. It is a powerful narcotic, and the poisoning principle of the solanums.

**NIGHTSHADE, DEADLY, or DWALE (atropa belladona).** A plant with narcotic and dangerous qualities, found growing in hedges and waste ground on a calcareous soil, frequently about ancient ruins. The root is fleshy and creeping. Stems herbaceous, annual, 3 feet high, round, branched, leafy, slightly downy. Leaves lateral, mostly two together of unequal size, ovate, acute, undivided. Flowers solitary, stalked, drooping, dark dull purple in the border, paler downwards, about an inch long. Berry of a shining violet black, partially enveloped in the calyx, which is persistent, the size of a small cherry; sweetish, and not nauseous, so that children have often been tempted to eat it to their own destruction. The poisonous principle is an alkaloid named atropia.

**NIGHTSHADE, ENCHANTER’S.** See **ENCHANTER’S NIGHTSHADE.**

**NIGHT-SOIL.** In agriculture, a powerful manure. This valuable fertilizer has not been employed in England to the same extent as on the continent, although it is certainly one of the most valuable of the organic manures; and to this neglect many causes have contributed. Its disagreeable smell, 25 years since, as a very powerful manure, and very liable to decompose: a part of it is always soluble in water; and, in whatever state it is used, whether recent or fermented, it supplies abundance of food for plants.” *(Lectures, p. 229.)* The disagreeable smell, he adds, “may be destroyed by mixing it with quicklime; and if exposed to the atmosphere in thin layers in fine weather, and mixed with quicklime, it speedily dries, is easily pulverized, and, in this state, may be used in the same manner as rape-cake, and delivered into the furrow with the seed.”

Night-soil is a mixture of urine and feces; and these have been found to contain the following substances. Feces were analyzed by M. Berzelius: the products were—

The salts detected in this analysis, equal to 1-2 parts, were carbonate of soda, murate of soda, sulphate of soda, ammonia, and nitrate of lime. *(Gedea’s Journal, vol. vi. p. 536.)* To the same great chemist we are indebted for an analysis of human urine. He found 1000 parts to contain—

**Water**                         | 97.9  |
**Urea (peculiar animal matter)** | 9.1   |
**Sulphate of potash**            | 2.1   |
**Sulphate of soda**              | 2.4   |
**Phosphate of soda**             | 2.4   |
**Murate of soda (common salt)**  | 1.3   |

**Animal matter and urea**        | 13.7  |
**Earthly phosphates and fluoride of lime** | 1.1 |
**Mucus**                        | 0.35  |
**Silica (earth of silt)**        | 0.65  |

*(Annals of Philos. vol. xi. p. 422.)*

The very chemical composition, therefore, of this compost would indicate the powerful fertilizing effects which it is proved to produce. The mass of easy soluble and decomposable animal matters and salts of ammonia with which it abounds, its phosphate of lime, its carbonate of soda, are all by themselves excellent fertilizers, and must afford a copious supply of food to plants.

The history of the use of night-soil, as a manure, is attended with difficulties; for the very nature of the fertilizer predisposes every experimentalist, especially in this country, to be silent as to his knowledge of its powers. Many absurd prejudices are entertained by the labouring classes; such as to the imaginary taste it imparts to vegetables, when added to the soil; and, in the earliest of all authorities, it is mentioned with becoming reserve. The warmth of the climate would insure a regular attention to the removal of excrements of every kind. And amongst the virtues of the dung of the bullock slain in sacrifices was directed to be burned *(Exod. xxix. 14; Lev. iv. 11, viii. 17, xvi. 37; Num. xix. 5.)* and used as fuel; and, in periods of distress, even human dung *(Exod. iv. 12–15.)* Danuills were evidently formed *(Daniel ii. 5, iii. 9; Luke xiv. 35.)* and carried away *(1 Kings i. 10.)* to be spread on the surface of the earth *(Psalm lxxiii. 10; Jer. vii. 2, xvi. 14, xxv. 33; Zeph. i. 17.)* and straw was spread to increase the quantity of it *(Isa. xxv. 10.)* And Jerusalem had even a gate called the Dung Port, or Gate *(Neh. ii. 13, iii. 14, xii. 31.)* The inhabitants certainly applied dung to their fruit trees *(Luke xii. 8.)*

The account of eastern customs, furnished by modern travellers, illustrates very remarkably the notices of the sacred historians. “In Arabia, says Niebuhr *(vol. i. p. 91),* ‘the dung of asses and camels is chiefly used for fuel, because these are the most numerous and common. Little girls go about gathering dung in the streets, and in the highways; they mix it with cut straw; and of this mixture make cakes, which they place along the walls, or upon the declivity of some neighbouring eminence, to dry them in the sun.” *(Tourne 4 B 841)*
fort, speaking of Georgia, says, "All this fine country yields not a single tree; and they are forced to burn cows' dung." (Townelev, vol. iii. p. 137.) And again, when speaking of Erezon, he says, "You see neither tree nor bush, and their common fuel is cows' dung. And Le Bruyn speaks of the same custom as occurring in Persia:—"Wood is very dear, and is sold by weight; whence it is that they are obliged to make use of turf made of camels' dung, cows' dung, sheeps' dung, horses' dung, and asses' dung. They use it more particularly for heating of ovens, in which they bake most of their meats in this country. They even apply human dung in this way."

Long experience has taught many nations the value of this manure. In China it is preserved with the greatest care, mixed with a fat marl; and, according to Sir George Staunton, made into cakes, which, after being dried in the sun, constitute a regular article of traffic between the citizens and the cultivators of that singular empire. The same useful practice is carried on in Belgium. What we throw into our rivers the more thoughtful Belgians turn to account; what is a nuisance in London is a source of revenue at Brussels. To a report of my friend, Dr. Granville, I am indebted for an instance of the application of this manure to the purposes of another kingdom, namely, to this manure in the northern states of the continent; and this I will give chiefly in his own language. When describing a continental tour, made chiefly for the purpose of examining the mode of employing this description of manure in Germany, he says, "The kingdom of Württemberg is supplied with population, and land, consequently, is of such value, that every inch of it is progressively brought into a state of culture by dint of labour and manuring; no matter how ungrateful the soil, or its situation, may at first sight appear."

"The cultivation of the vine is one which requires, in certain arid and mountainous soils, a liberal use of the human manure. Wishing to ascertain this fact from my own observation, I undertook a journey through the principality of Nassau, and along both banks of the Rhine, examining many of the vine districts, as I descended that river for the purpose of visiting Holland. On my return, I took French Flanders in my way, looking particularly to the great flax districts of Tournois, Lille, Valenciennes, and Cambray, where the surprising results obtained from the application of human manure, like those obtained in Belgian Flanders by similar means, have induced agriculturists, within the last few years, to give to that species of manure the name of 'Flemish Manure.'"

And, when speaking of the little care taken in England of this fertilizer, he continues:—"In my part of France, Württemberg, Bavaria, Bohemia, Prussia, Saxony, the Confederated States of Germany, Holland, and Belgium, is there a city in which, as in London, the general mass of filth, of every description, created by a vast population, is first allowed to enter the river which may happen to traverse that city, and is then returned, diluted with the water of that river, to the houses of the inhabitants, to be used either for domestic or culinary purposes; although, by avoiding the latter disgusting alternative, foreign cities are less free from unpleasant smells than London is. In this respect, it may be truly said that foreigners smell too much of the city; but do not swallow it; whereas the Londoner swallows it, but seldom smells it."

"In no large city of that part of Europe which I have recently visited, possessing a river, is any portion of the contents of closets and cesspools suffered to find its way, or to be emptied into it, except at Amsterdam, Antwerp, Brussels, Stuttgard, and Leipzig; and even there only in a partial manner. In Paris the Seine is contaminated by one large drain only, conveying the urine from the large reservoirs of night-soil at Montfaucon, and by 2 smaller ones proceeding from cesspools. To convey generally, or to empty even partially any such matter into the river, is a practice against which the laws have provided by heavy fines and incarcerations. And such is the present feeling of all the governments on that subject, even in the great cities I have just enumerated as exceptions, that the superior authorities are seriously engaged in devising plans for preventing in future every possible infraction of those laws; not because it is desirable to preserve pure the water of such rivers (since no domestic use is made of it), but on account of the loss of a material, deemed most valuable, which such infractions must necessarily entail."

"Night-soil is husbanded in every part of the Continent I have visited, without exception, with a jealousy and care which prove how valuable it is considered by the people. In most of the cities of the second order, and the smaller capitals, night-soil is a source of profit, first, to the householder, next to a middleman, and, thirdly, to the farmer, who is the last purchaser, and employs it."

"In all the towns of the Grand Duchy of Baden, of the kingdom of Württemberg, of Bavaria (except Munich and Würzburgh), of the province of Salsburg, of Bohemia (except Prague), of Saxony (except Dresden), in some of the minor cities of Prussia, in all the federated principalities, in all the cities on both banks of the Rhine, particularly Strasburg, Mayence, Coblenz, Bonn, Cologne, Dusseldorf, Niemegen, &c., the householder disposes of the contents of his cesspool for a certain sum of money, besides getting the operation of emptying it performed gratuitously. By comparing the returns of the different prices paid in those cities for the commodity in question, one year with another, and equalizing them by an average price, the inhabitants appear to be benefited to the amount of 4 francs a head yearly, and the middlemen to at least 40 per cent. more on the sum he pays to the original seller. I will cite Strasburg as an example, since most of the other cities of the same extent (on the Rhine, and in many parts of Germany), and a few cities even larger presented the strongest analogy to the case I have selected. At Strasburg, a company of middlemen engage to empty the cesspools, of which every house has at least two (built air a.a.l. 842
NIGHT-SOIL.

Water-light, once a year for nothing, and pays, moreover, 6 francs per charrette, containing 96 bouquets, of the capacity of 4 gallons each. This quantity the company supplies afterwards to the farmers for ten francs. (The capacity of the charrette being that of a ton as 28,772 ounces are to 35,840, it follows that the price of a ton at Strasburg would be 10s.) Now, as there are 14,000 houses in Strasburg, 10,000 of which have cesspools affording the soil in question (which is always semi-liquid), supposing the latter to be emptied only once a year, and to furnish each 3 charrettes only, at six francs, we have 10,000 × 6 × 3 = 180,000 francs, which the company pays yearly to the inhabitants of a town having a population of 70,000 souls. But as the company resells to the farmer the said soil for manuring purposes, at ten francs per charrette, it follows that this article of traffic produces yearly at Strasburg 300,000 francs, or just about 4½ francs for each inhabitant.

The high prices paid for this manure by the Continental farmers betrays the estimation in which they hold it. "The contractor at Brussels, M. Champion," says Dr. Granville, "sells his manure for 13s. 4d. per ton—400 florins, or 33½. 6d. for a barge-load of 50 tons. M. Smet, the greatest trafficker, perhaps, in this material in East Flanders, gets for some of his 10s., and for the best and larger portion of it 15s., per ton; while the contractor at Antwerp disposes of all he flays of Flemish manure at 52 florins the put, or 624 florins the barge-load, equal to 52½, or 17½. 9d. per ton. But if we look to what takes place every day at Montfaucon, near Paris, where 200 cart-loads of the contents of the cesspools are daily deposited, to be converted into pourette, we find the latter (a dry and compound manure made from night-soil) to fetch a much higher price than all the rest."

"But by far the most important point of practical knowledge in this matter, put forward by the same great authorities, and the truth of which was afterwards confirmed to me by more than one great farmer in East Flanders, is, that while the manuring with human soil has produced 14 times the quantity sown, where horse-dung has only yielded 10, the proportion of the human or Flemish manure employed was, to that of the horse-dung, as 1 to 5 only; so that with 1 ton of the Flemish a larger produce is obtained than with 5 tons of stable manure." See MANURES APPLICABLE BY THE DRILL.

In Sweden the value of night-soil has been long well understood by the farmers. Nearly half a century since the Baron de Schulze, when writing to Sir John Sinclair, observed, "They have now ceased to spoil the fine harbour of Stockholm with nuisances of every kind. The contents of the privies are now collected, by undertakers, in barrels, of which they are obliged to have a double quantity to replace those deposited in the reservoirs, from which they are removed to the manure shed. My eldest son, who has changed the sword for the ploughshare, has, particularly attended to this manure, being favourably situated on the Lake Malar, 48 English miles from the capital; he conveys it in a covered boat, each loading of which is sufficient to dress about 3 acres of spring corn, and between 4 and 5 of winter corn and meadow ground. This manure, by the motion of the boat, becomes more liquid; and if it is conveyed from the hold of the vessel by a bucket at the end of a lever, through a spout into a close cart on shore drawn by two oxen. These carts are provided with a movable funnel, and with a strainer so regulated, by means of a pole, that the manure can be administered at pleasure by the driver, without further attention to spreading. That the land may not be over-dug, and the crop consequently lodged, care must be taken not to lay above 40 such cart-loads on the Swedish acre for spring corn; each cart containing 180 gal- lons English, or 1,200 lbs. Except that other powerful manure produced by the refuse of the herring oil-works, none can come into competition, for richness, with the contents of the privy mixed with urine. The effects of this manure, no doubt, diminish gradually; yet its operation may be plainly perceived in the fourth successive crop. When clover is meant to be sown with the spring corn, this species of manure is unsuitable; for although the seed be diminished to one-third, the straw becomes so thick and strong as to choke the clover. A mixture of lime is sometimes recommended for this manure, in order to dry it and correct the smell; but, besides that lime is not plentiful here, the process would be found to require a considerable time and expense. A little addition to the wages of the labourers or cottagers soon reconciles them to the inconvenience of the smell, and it becomes still less offensive to them if they are allowed to use part of it on their own little fields. If any particular impediment occurs, such as harvest work, this manure is then from the vessel conveyed to great pits, to be, after a mixture with other substances, driven to the field at a more convenient season." (Com. Board of Agr. vol. i. p. 326.) The prejudice which some English labourers entertain against the employment of night-soil is readily overcome by a little management. The stream which flows through the village of Eastbourn, in Sussex, had become, a few months since, much contaminated through the night-soil which had been deposited in it from the adjoining cottages, and it was in vain that their owners were advised to use it for their gardens; until an excellent lady of the place, who is ever ready to promote the comfort of her poorer neighbours, desired her bailiff to go round and propose to purchase it of them. His offer was, however, rejected, universally rejected; and ever since they have no longer suffered the contents of their privies to be wasted, but have carefully applied them, and with the best results, to their own gardens; remarking, that if it was worth a farmer's while to buy it of them, it was worth more to them for their gardens."

"By this term, night-soil," remarked the indefatigable Armer, when at London, is to be understood the collections there made of what a French marquis calls 'l'espece de fumier que la politesse empêche de nommer;' from which trait of him one would not have expected he should know so much of the value of it as he
NIGHT-SOIL.

really did. An Englishman says, "is more decent and better to let it alone; but as I conceive it perfectly decent and efficient, I shall consider human ordure as the very best manure that can be procured. But here, I must first consider the farmer's conduct at home, where his great object is to raise as much manure as possible without being obliged to depend on purchases, which are only to be made in certain situations. If the farmer manages his necessary-house in such a manner as to suffer nothing to run off from it, and frequently throws malt-dust, saw-dust, fine mould, or sand into it, he may, every year, manure from 1 to 2 acres of land.

"If the farmer is within reach of any considerable town, and there are scavengers or people who will collect this manure and keep it separate, the farmer can hardly purchase it at too high a price. In the last century, the ordure of the galley-slaves at Marseilles was all saved, and sold to the farmers as a dressing for grapes, olives, and figs; the last of which produced by it were the best in the world. At Nice it sells high, and every peasant has a house of office for passengers. In China it seems to be a manure, of all others, in the most request; and in Italy they are well acquainted with its value. At London it sells at from 3s. to 6s. a load; at 17 miles distant, with turnpikes and all expenses, it costs 25s. a wagon-load; yet it answered greatly. It should be laid by the scavengers in very light swamps (not too deep) in a grass field, and in summer trenches cut through it to drain; and then being thrown in heaps, it is of very light carriage. Three wagon-loads, or from 240 to 300 bushels, are enough for an acre of grass land, upon which I think it answers best; but mixed with marl, loam, turf, or dry pond mud, its use for that application is excellent. I have compared it with all other manures, and found that none of them I could procure equalled it by many degrees. It is a vulgar error to imagine that manuring a field with this substance will give a bad taste to plants. I dressed part of a pasture with it, fed the whole of that year with horses, cows, and young cattle, and I remarked to various gentlemen that saw it how close into the ground that part was constantly eaten, while there was much longer grass, &c., in every other part of the field."

"On October 20th, 1772," adds Arthur Young, "I marked divisions each of 4 square perches on a summer sallow; the soil a poor blue pebbly gravel, and manured these compartments as follows:—

"The effect of nig-t-soil," he continues, "was prodigious; it just trebles the produce. In all the experiments I have made with this manure, I have ever found this result almost uniform." (Annales d Agr, vol. III. p. 79.) It is evident, also, from the experiments of Arthur Young, which are entirely confirmed by those of the Essex farmers, and my own, that night-soil is an excellent manure for potatoes. The following table contains the result of Arthur Young's trials. The soil on which these experiments were made was a poor gravelly loam.

These experiments are useful, as indicating the comparative value of each fertilizer, although the quantities employed were evidently excessive. Mr. Hewitt Davis, of Spring Park, near Croydon, finds 6 tons of night-soil, mixed with peat, to be amply sufficient for an acre of ground. He thinks this manure the best for turnips. Night-soil is, however, in spite of all the obstacles of prejudice and inattention, much more extensively used in the neighbour-hood of the large manufacturing towns of the north of England than it was formerly. Mr. Dixon, of Hathershaw, in Lancashire, thus describes his mode of using it. "For the conveyance of night-soil and urine, we have the largest and strongest casks, such as oils are imported in; the top of each is provided with a funnel to put the matters through, and the casks are fixed on wheels like those of a common dung-cart. I am fully aware that there are many localities where neither peat nor night-soil can be readily obtained; but it is worth a farmer's while to go even more than 20 miles for the latter substance, provided he can have it without deterioration: the original cost is often trifling. On a farm where turnips or mangels are cultivated to some extent, the system here recommended will be almost incalculably advantageous. A single horse is sufficient for one carriage; mine holds upwards of a ton each; 6 tons of this manure in compost with peat, or, if that is not convenient, any other matters, such as ditch-scourings, or high headlands which have been properly prepared and laid dry in a heap for some time, would be amply sufficient for an acre of turnips or mangels. This manure is by far the most invigorating of any I have ever yet tried. Bones in any state will bear no comparison as a help for any crop; but it must be remembered that I write on the supposition that it has not been reduced in strength before it is fetched."

There have been various patents granted in France for the preparation of manure from night-soil, several of which have proved very successful. The pouderette, or dried night-soil, first prepared by M. Bridet, was found, after repeated trials, to be a very powerful dressing for land; 240 lbs. of this powder producing effects equal to 8 loads of stable manure. This substance has been recently examined by Professor Hermstout, who reports it to be a perfect substitute for common dung; that it is most
NITRATES.

NITRATES.

Efficacious in wet seasons; and that in dry seasons it is less useful upon sandy soils than upon greasy clays. There is no doubt but that very excellent composts may be made from night-soil; and, in fact, several are now prepared in London, on a very bold scale, for the service of the farmer; but the success of these is usually impeded by the preparers professing that their preparations may be used in quantities much too small. Then, again, one or two patent have been taken out in England for artificial manures, by persons who were evidently very grossly ignorant of what they professed to understand. (Johnson on the Fertilizers, p. 92.) See Farm-Yard Manure; Manures applicable by the Drill; Urine.

NIPPERS. A term applied to the four teeth in the fore part of the horse's mouth, two in the upper and two in the lower jaw: they are put forth between the second and third years. Nippers, in farriery, are the pincers which the smiths use in shoeing.

NITRATES OF POTASH AND SODA. Two salts lately much employed in agriculture. The first (nitrate of potash) is known in commerce under the name of saltpetre, and is principally procured from the East Indies, where it is found on the surface of the ground, especially in the district of Tihar, in Bengal. It also abounds in Ceylon, Persia, Egypt, and even in Spain; but that which is brought to England comes chiefly from India in an impure state, and contains about 70 per cent. of pure nitre. It, however, varies in quality; but the average loss in the purification is generally about 15 to 20 per cent. Nitre is also formed by artificial composts in various parts of Europe. When pure, nitre is composed of nitric acid 54.15 parts, or 1 equivalent; and potash 47.15 parts, or 1 equivalent; or 52.9 per cent. of acid + 47.1 of alkali = 100.

NITRATES. (Continued)

Nitrate of soda, which is known as cubie petre, is obtained chiefly from Peru, where it is found in a thick stratum, at an elevation of 3500 feet above the level of the Pacific Ocean. (Darwin's Researches, p. 443.) It is sold, it seems, at the ship's side on the coast of Peru, at 14s. per cwt. It is composed of nitric acid 62-1 parts, and potash 37-9 parts.

It is only in modern days that saltpetre has been extensively employed as a fertilizer; for it is not long that the nitre of commerce has been produced in quantities sufficiently large and reasonable to enable the farmer to profitably use it as a manure. That the knowledge of its enriching qualities, however, is not a modern discovery, is too self-evident to be doubted. Virgil (Georgics, lib. i. v. 193, 195) recommends it to the Italian farmers as an excellent addition to the drugs of olive oil, to form a steep to cause the seed-grain to swell and vegetate with vigour; and from his days to our own, hardly an agricultural writer has omitted to notice its powers. The very first English author who wrote upon husbandry, in 1532, Sir Anthony Fitzherbert, describes it as having the power to insure to the farmer the most abundant crops. And in 1570, a learned German counsellor, Heresbacius, in his Treatise upon Rural Affairs, describes the use of this salt as not an uncommon dressing in his time for coleworts. A century afterwards, Evelyn, in his Discourse on Earth, told the farmers of his age that if they could but obtain a plentiful supply of saltpetre, they would "need but little other compost to meliorate their ground." And even Jethro Tull, in the early part of the last century, who denied very zealously the necessary use of manures of all kinds—even Tull placed nitre at the head of his list of those substances which he deemed to be the essential food of plants.

Saltpetre, therefore, must not be regarded as a modern introduction into agriculture; for it has long been used in limited quantities by previous generations of cultivators, who, like us, were content to notice the effects which it produces, without being able to exactly comprehend its mode of action.

It is idle to merely substitute words in explanation of unknown effects, and to say that saltpetre is a stimulant, or that it yields nitrogen to the plant; and there is little evidence of its entering into the composition of any of the more commonly cultivated crops: there is, therefore, but a slight probability of its being a direct food of the plants to which the farmer usually applies it. The only common exception is that of barley, in which a minute portion of cubic petre (nitrate of soda) is found to exist.

But although these nitrates have not been detected in the farmer's crops, yet they are known to exist in many plants, most likely as essential ingredients. Thus saltpetre is found in the common horse-fish, in the nettle, and the sunflower. M. Chevalier discovered it in the Chenopodium albidum; M. Vanquelin in the deadly nightshade. Dr. John found it in the Mecusbyrthuthum crystallina; M. Chevreul in wood. The growth of the sunflower is materially promoted by watering it with a weak solution of this salt. It languishes in soils which do not naturally contain it; but when the salt is added to the earth, then it immediately makes its appearance in the plant in the usual proportions.

And although we are not aware of its existence in the ordinary field-crops, yet still it may beneficially exist in them, and exert a considerable influence at certain periods of their growth, although in minute proportions: and, notwithstanding we have no direct evidence of the fact, it is not unlikely that its presence may tend to vary, in the vegetable world, the essentially present combinations of nitrogen, in a way which the skilful investigations of the chemist have not yet succeeded in tracing. Such researches, however, have already proved that nitrogen (of which, with oxygen, the acid of saltpetre is formed) performs a much more important part in vegetable economy than was once supposed; and many facts are already apparent which should encourage us to persevere in the examination. For instance, it has been observed by the farmer that these two nitrates (the base of whose acid is nitrogen) have a very powerful effect in adding to the deep green colour of plants. Now, this is precisely the effect produced by other fertilizers, which also contain nitrogen; such as gelatine, urine, oils, blood, soot, fish, &c. In fact, I am not aware...
of any manure producing this rapid, darkly-green, luxuriant growth, from which nitrogen is absent. Saltpetre is naturally generated on the earth’s surface under favourable circumstances, and in situations much more frequent than the farmer is wont to suspect. Wherever ammonia is copiously generated, as in stables, farm-yards, &c., and wherever the nitrogen, which forms a component portion of ammonia, at the moment of its extrication has access to potash or calcareous and there saltpetre is usually formed. This is naturally done so copiously, in some of those situations in which the farmer is placed, as to form fine crystalline exudations on the walls; and it is in such places that those plants which abound in saltpetre, as the nettle, the horse-radish, &c., commonly flourish with uncommon luxuriance. It has been proved by those who gather the saltpetre from the earth’s surface in southern Africa and Hindostan, as well as by those who prepare the artificial saltpetre beds in Spain from the waste places of the province of Madrid, that nothing more is requisite for the formation of saltpetre in these beds of earth, than the presence of a certain proportion of decomposing animal and vegetable matters, with some potash, and calcareous matter. Now all these essentials for the formation of saltpetre must in many situations be afforded by the farmer’s own soils. There are, in fact, many lands in the cultivator’s possession where, especially in dry summers, the formation of saltpetre in minute proportions is continually taking place; where the putrefaction of animal matters must in small proportions be productive of ammonia; and where an abundance of potash is already existing in the soil to neutralize the nitric acid produced, and form with it nitrate of potash or saltpetre. For it has been ascertained that if, at the moment when nitrogen is evolved, it is presented with oxygen gas, that it combines with it, and forms nitric acid. Here, then, we have explained to us the origin of the acid of the nitre, and we know that its base, or potash, is to be found in some form or other in all cultivated soils. And if we admit that this must in some instances be the case, then we shall be furnished with a ready explanation of many of the difficulties and discordant results which have attended the recent very general application of these two nitrates, since the fact that saltpetre has commonly been found to produce the least results upon those deep, rich, alluvial soils which must abound in decomposing organic matters, in some degree counterbalances the conclusion, as does the smallness of the quantity of saltpetre applied; for, if once we concede the possibility of the soil, under favourable circumstances, being able to generate this salt, then it will be allowed that one cwt. per acre is not a large crop for the soil to produce. That in this way it is generated in some of the richest soils of the East, to such an extent as to cover the surface with a white incrustation, is known to every oriental traveller. To a still greater extent is the land in those countries impregnated in many situations with the nitrate of lime, a salt which, possessing the same acid as nitre and cubic nitre, has lime instead of potash or soda for its base; and from some experiments which I have made, I have little doubt but this nitrate, which is of much less cost than either the nitrates of potash or soda, will be found a valuable agent for the use of the cultivator. For its excessive deliquescent or moistening properties, which render it so unmanageable for many manufacturing purposes, make it more valuable to the cultivator of the poor, dry, thirsty soils, where artificial fertilizers are most in request. If nitrate of lime was imported at a reasonable rate, the farmer could readily, if he wished, make his own cubic petre, at a very low price, by mixing the nitrate of lime with glauber salts (sulphate of soda), by which means a rapid decomposition takes place, the result of which is nitrate of soda (cubic petre) and sulphate of lime (gypsum). The inferior, impure, refuse glauber salts, made by the cotton bleachers in the preparation of their bleaching powder, would answer for this purpose very well.

My experience of the enriching powers of saltpetre extends over several years. My earliest experiments were made in the kitchen and flower garden, in which I found very considerable advantage in increasing the beauty and in prolonging the bloom of several of the tenants of the latter; and in the former I found excellent results from applying it at the rate of 2 cwt. per acre to my beds of horse-radish, and in very small proportions, as one-eighth of an ounce per gallon, to the water with which I watered, to prevent mildew, &c., my early and late crops of pease, wall-fruit trees, &c. My experience with it as a field crop has been principally confined to the gravels of Essex and the chalks of Hampshire and Berkshire, in which, especially upon grass, I have obtained results exceedingly satisfactory. In 1840, I tried it upon the old clay grass soils of Knitbury, in Berkshire, with various other manures; 1st, at the rate of 1 cwt. per acre; 2d, nitrate of soda, 1\frac{1}{2} cwt. per acre; 3d, Pottevin’s manure, 14 bushels per acre; 4th, gypsum, 1\frac{1}{2} cwt. per acre; 5th, nitrate of soda, 1\frac{1}{2} cwt., and gypsum 1\frac{1}{2} cwt. per acre. These were all applied by hand in the month of April; but although they all produced a better crop than the soil simple, yet the extreme dryness of the season operated very materially against the success of almost all artificial dressings, and the produce of the whole plot was much below an average crop. Nos. 1, 4, and 5 were decidedly the best, producing at the rate of rather more than 2 tons of hay per acre; while the produce of the soil simple was less than 2\frac{1}{2} cwt. per acre. The grasses were of the ordinary kinds tenanting the upland pastures, mixed with a considerable portion of nearly worn-out roots of lucern, which, in the plot No. 4, gypsum alone, and in No. 5, gypsum and cubic petre mixed, was revived by the application to a very remarkable degree; its plants nearly doubling in height any other portion of the land.

In some experiments, at which I was present, on the barley and wheat land of the chalk formation in the neighbourhood of Winchester, the effect of the saltpetre was excellent; the green colour of the crops was rendered much.
more deep, and the increased produce far more than compensated for the expense of the salt-
petre. And the same success attended its appli-
cation to both red clover and sainfoin on the
down lands; but when I tried saltpetre at the
same rate per acre on the lawn of a rich old
garden, whose earth was also principally chalk,
there was no perceptible effect pro-
duced, even in the colour of the grass. This
soil abounded in decomposing organic matters,
was within reach of the soot and other amm-
niacal matters of the city of Winchester, and,
I have little doubt, in minute proportions al-
ready contained saltpetre. In fact, almost all the
successful experiments with saltpetre have
been made on light, poor land. Those of Mr.
Lightfoot were on the gravels of Hertfordshire,
which have a substratum of chalk; and yet he
produced with 1 cwt. per acre of saltpetre
effects more than equal to those produced by
folding the land with sheep. And when Mr.
Beadel, of Witham, tried it on the Essex clays,
it produced hardly any effect, except increasing
the colour of the wheat; but when he used the
same quantity (1 cwt. per acre) on his light
barley, he gave him heavier harvests than he
ever turned up before. The same effects were
found on a sandy field of oats, the in-
crease from its application was 20 bushels of
oats and half a load of straw. The successful
experiments of Mr. Kimberley, of Trotsworth,
on clover, in which he produced with 1 cwt.
per acre of nitre results fully equal to that from
25 cubic yards of horse-dung, were upon the
sandy lands of Surrey, “of moderate quality.”
Mr. Everitt, of North Creake, bears out en-
tirely these conclusions, when he applauds its
use “upon all light, warm soils,” but predicts
that, “on cold clay land, on an average of sea-
sons, it will not more than repay the outlay;”
and yet this excellent farmer had no reason to
dissatisfied with his success, having ob-
tained from an application of 1 cwt. of salt-
petre to “good light land,” an increase of 63
bushels of wheat. The experiments of Mr. R.
Harvey, of Harlstone, entirely confirm those of
Mr. Everitt; and in the Report of the Har-
stone Farmers’ Club, in 1839, it is stated to be
the unanimous opinion of the meeting;” that
saltpetre was excellent in its effects on heavy
clover layers, but that on light land it was
highly beneficial to “wheat, clover, and other
layers and tares.”

One of my neighbours, too, an excellent
farmer of Essex, in 1839, found on the fine,
light barley soils of his farm the following re-
sults from top-dressing his barley with 1 cwt.
per acre of saltpetre, compared with the soil
undressed, dressed with night-soil, with sprats,
and with farm-yard manure:—

| I have noticed, also (and the same remark applies to cubic petre), that the effect of saltpetre is the soonest apparent when it is finely powdered, and spread on the land in moist weather. The explanation of this must, perhaps, be found in the superior rapidity with which it mixes with the soil. The cultivator will remark that moist weather is also the best adapted for the application of other top-dressings, such as gypsum and soot. I have found in the application of crushed bones to grass lands, that they never produce such good effects as when rolled into the soil by a heavy roller, when the ground is softened by wet weather. The Staffordshire farmers will readily attest the same fact. If long-continued dry weather succeeds the application of the nitrates to clover, the leaves of the grass, whenever the powdered nitrate has fallen, become covered with yellowish spots.

The application, too, of either nitre or cubic
nitre to grass renders it much more attractive
to live-stock, who, if turned into a grass field
only partially dressed with either, will almost
invariably resort to the portion of the land
dressed with the nitrates. This is one argu-
ment in favour of the condition that these
salts are in minute proportions absorbed by the
crops to which they are applied. We know
that this is the case with other saline manures,
such as gypsum, (sulphate of lime) and com-
mon salt; and every cultivator who has dressed
his grass with either salt or gypsum will attest
how decidedly his live-stock prefer the grass so
reached to every other portion of the same field.

The effect of cubic petre as a fertilizer for
heavy soils, seems to be rather more favoura-
ble, as far as my observations extend, than that
of saltpetre; and in this I am confirmed by the
observations of many of my neighbours.

Yet still I am of opinion that, in the great ma-
Jority of instances, both the cubic petre and
the saltpetre will be found much more valu-
able top-dressings for light lands than for the
heavier soils; and I am not much inclined to
alter my opinion from the results of many of
the carefully observed experiments of the very
dry season of 1840; for in such periods it is
almost hopeless to expect that any kind of top-
dressing will produce results such as may
serve to guide us in our future practice. Thus,
in seasons such as the last, I have repeatedly
witnessed the failure of top-dressings of all
kinds; not only of the salts, such as lime and
salt, gypsum and soot, and malt coombs, but
even of the richest manure. My neighbours
in Essex know very well that if a dry summer
follows the application of their sprats (perhaps
the most powerful of all animal manures), the
application is entirely useless. In my own
experiments with nitrate of soda I have inva-
riably found the most excellent effects produced
by its application to barley at the rate of 1½ cwt.
per acre, sown broadcast, as finely divided as
possible, soon after the young plants were be-
inning to show themselves above ground.
The soils on which these experiments were
made were the barley soils of Hampshire and
Essex; and the same increase to the green
colour of the crop, and a similar large increase
to the produce of seed which my neighbours
experienced, resulted from my own experi-
ments. The clover also, which was sown with
the barley in most instances, seemed to derive
a considerable benefit from the dressing; and

847
I have noticed on more than one occasion, the advantage of sowing the cubic petre in moist weather. In the dry summer of 1840, the effect of the cubic petre was very inferior to that produced by it on similar land and crops in 1838 and 1839—affect which entirely supports my conclusions with regard to the inefficacy of all top-dressings in periods of long-continued dry weather. Of this opinion, too, is a very excellent and extensive farmer of Surrey.

Mr. Hewitt Davis noticed too the effect on some of the clays as well as the sands of Surrey in 1840,—that the effect of cubic petre upon young wheats at the rate of 1½ cwt. per acre was excellent, not only in producing a very deep green colour, but in inducing a very considerable rankness of growth. But then, in his experience and observations, he has noticed that the wheat thus dressed has a stronger tendency to blight than that growing on the adjoining lands. On his farm, however, this rankness of growth is not felt as an evil; for on such soils, heavy as well as light, he practises an excellent system of thin sowing, the effect of which, as I can attest, is excellent in producing most abundant crops; either on the poor, hungry, black gravels and sands of Ad-lington in Surrey, or on the tenacious clays of Sussex, he never drills more than 5 pecks of seed wheat per acre at intervals of 12 inches. It is true that by this plan the appearance of the wheat during the winter months is not so vigorous as many farmers would at first sight approve; but the plants gradually get together, stool out very abundantly, have all their ears of a uniform length; the produce is abundant, the sample generally excellent, and rarely subject to blight.

These valuable experiments of Mr. Davis entirely confirm those which I have been induced to make on several occasions, and may, in a great measure, perhaps, serve to explain some of the discordant results of the recent extensive, and, in the majority of instances, successful experiments, with nitrate of soda and saltpetre, as a top-dressing for wheat, barley, and oats. For in a great many instances where the cubic petre has failed to produce advantageous results; the seed has been sown in rather large quantities; the corn, therefore, by the action of the salt becomes darkly green, grows with great luxuriance—is perhaps too thick on the ground; and the farmer, as a natural consequence, finds that the nitrated corn has a tendency to mildew. In the first number of the second volume of the Journal of the Royal Agricultural Society of England, there is a mass of valuable information, collected by Mr. Barclay, which illustrates very consider-ably these observations on the advantages of thin sowing; such as the experiments of Mr. Barker, Mr. Hyett, and others. And although I am not prepared to contend that the effects of these two powerful salts will be in all cases the most apparent on thin-sown corn, yet I am much inclined to think that the farmer will find that this is very often indeed the case.

In most soils there is to be found a certain proportion of carbonate of potash, and in many it exists in sufficient quantity to decompose the nitrate of soda, and form nitrate of potash and carbonate of soda. This may, perhaps, serve to account, in some instances, for the varying results obtained in some apparently similar soils from the application of the nitrate of soda, and may be one reason amongst others why moisture is found to be so essentially necessary for the beneficial action of cubic nitre; for it is a chemical axiom, that to produce any chemical action between two substances, one of them must be in a fluid state, perfectly dry sub-stance hardly ever producing any chemical action on either.

Such, then, are the results of the long-continued experiments and observations upon nitre and cubic nitre which I have been able to make, and to suggest to others to re-examine and verify; and such, too, are, I think, the reasonable conclusions to be derived from our united experience.

In pursuing a path so novel, and so extensive, it need hardly astonish us that there are yet several sources of error to be avoided, deceptive appearances to be scrutinized, and additional experiments needed, before we can expect to arrive at the knowledge of the best and most economical modes of applying these two valuable nitrates. The soils to which they are best adapted, and the causes of their not always producing even on apparently similar soils the same powerful effects, are amongst the objects of inquiry to which I have alluded in this paper. The advocates, however, of these saline manures have no need to complain of the progress which they have made; for admitting that on some soils they have apparently produced but trifling effects, and on other soils hardly any, yet still in the multitude of instances they have amply repaid the farmer for his outlay. There is no other instance, perhaps, of such a rapid introduction of a saline manure into agriculture, as that of the modern, extensive, and increasing use of cubic petre by the farmers of Great Britain; and if we only pause to remember the difficulties of experimental researches like those, exposed, as all examinations of the process of vegetation of necessity are, to innumerable sources of error, we shall find no reason to complain of the success of its introduction, or of the talent and enterprise with which the farmers of England have conducted their valuable experiments.

There are many experiments with these two salts to be met with in the agricultural journals of the last few years.

1. Memorandum of saltpetre, nitrate of soda, and common salt, used as top-dressings in the south-east garden park, of a lightish land, well drained, 11th April, 1840, on pasture laid down with grain in 1839: one acre sown with 1½ cwt. of nitrate of soda, measured and marked as such; then a piece of one rood, without any dressing; again, one acre sown with 1½ cwt. of saltpetre; next to this half an acre dressed with three-fourths of a cwt. of common salt.

Result.—In little more than a fortnight after this, having had some favourable showers, there was an extraordinary change on the two distinct acres dressed with saltpetre and nitrate of soda, as compared with the rest of the field. The grass continued to grow on these divisions.
NITRATES OF POTASH AND SODA.

much stronger, close, and of an infinitely richer and darker colour; and the cattle lying much upon it, seemed to thrive and to gain by it. This superior appearance continued through May and June, and perhaps later. The grass was, after this, eaten so close that no difference could be noticed, if any existed; it was particularly and frequently observed in September, October, November, and now, 8th December; and no difference was then, or is now, perceptible between the ground dressed with saltpetre and what was not so dressed. The pasture seemed equally benefited by the nitrate of soda as by the saltpetre; and as the latter cost in proportion the former as 50s. to 30s. per cwt., there can be no question of preferring the nitrate of soda. No improvement could be perceived to have taken place from the dressings of common salt.

2. Another trial was made on pasture of the second year, in the lawn, on light land and dry, 14th April, 1840; one acre, measured and marked, sown with 1 1/2 cwt. of saltpetre; adjoining this, one acre sown with 1 1/2 cwt. of common salt; and next, one acre, measured and marked, sown with 1 1/2 cwt. of nitrate of soda.

Result.—Every remark applicable to the experiments in the south-east garden park applies equally to this. In both, in the different dressings sown by the cast of the hand where the two breadths joined, and the ground had got an extra quantity, the grass was richer and darker, showing that 1 1/2 cwt. per acre is not an over-dressing, whether of saltpetre or of nitrate of soda.

3. Memorandum of dressings of saltpetre, common salt, and of nitrate of soda, on the 16th of April, on oats already braided in Scott's Paud, partly on well drained, dry, and partly on light land; one acre and fifteen falls, measured and marked, sown with saltpetre at the rate of 1 1/2 cwt. per acre; next to this, one acre and fifteen falls, dressed with common salt in the same proportion; next to this, one acre and fifteen falls, sown at the same rate with the nitrate of soda.

Result.—It was long before any effect was perceived on any of the oats dressed as above. About the end of June a difference was perceived on the acre and fifteen falls sown with saltpetre, which had previously shown worming, and then came away darker and stronger, and became a heavy crop of oats and straw. The acre and fifteen falls dressed with nitrate of soda never seemed to be benefited by the dressing. Being an inferior, light, sandy soil, with a red, irony bottom, it was injured by the early drought, and never recovered; the salt here, as on the pastures, seemed to have no effect.

4. Memorandum of dressings of saltpetre and nitrate of soda, in Laughian Glenfield, principally strong clay, thorough-drained, and sub-soil-ploughed, 26th April, 1840, on red clover, &c., for green cutting: one acre, measured and marked, sown with saltpetre, at the rate of 1 1/2 cwt. and 2 1/2 cwt. of nitrate of soda, were sown here in the same proportion.

Result.—The clover, &c., seemed equally benefited by the saltpetre and by the nitrate of soda; and, compared with what was not dressed, the improvement was very perceptible in about a fortnight, and it became a much darker and healthier crop than in that part of the field not dressed, and it was ready for cutting fully ten days earlier. It was not weighed, but it is believed there was from one-third to one-half more on the ground dressed than where it was not. The second cutting did not show a better crop than where it was not dressed. Nearly an acre was dressed with nitrate of soda after the first cutting, on the 10th of August, where one had been before applied, but it did not seem to do much good.

5. Memorandum of dressing of saltpetre and nitrate of soda on one fifth of an acre of wheat in Bridge Park, on clay land, thorough-drained, and subsoil-ploughed, 50th April, 1840.

First Lot.—Twenty falls, measured and marked, dressed with 28 lbs. of nitrate of soda. 

Result : Wheat 7 bushels, 1 1/2 lbs., or per acre (by an acre a Scotch acre is meant throughout, and a Scotch acre is about one-fifth longer than a statute acre; and by " a fall," a perch of land), 58 bushels, 26 lbs.; straw 64 stones, 18 lbs., or per acre 518 stones. Weight of wheat per bushel, 28l. 23s. Sold to baker for 22s.

Second Lot.—Twenty falls, measured and marked, sown with 28 lbs. of saltpetre.

Result : Wheat 6 bushels, 38 lbs., or per acre 52 bushels, 24 lbs.; straw 95 stones, 12 lbs., or per acre 764 stones. Weight per bushel, 58 lbs. Sold to baker for 28s.

Third Lot.—Forty falls adjoining, measured and marked, without any dressing. 

Result : Wheat 11 bushels, 1 lb., or per acre 44 bushels, 4 lbs.; straw 79 stones, or per acre 316 stones. Weight 59 lbs. Sold for seed at 33s. per boll.

Fourth Lot.—A small quantity of oats adjoining to this winter wheat was dressed with saltpetre, which produced a great effect on the strength and colour of the oats; but the produce was not weighed or measured after being cut.

Fifth Lot.—Trial of nitrate of soda on six drills of potatoes, at the rate of 1 1/2 cwt. per acre, sown over the stems when 5 inches long, on 10th June. Result: The shaws (tops) seemed much finer and richer than those not thus treated; but the potatoes being sold, the comparative produce was not ascertained.

Six drills of Swedish turnips, dressed at the same rate, 10th June, on a healthy braid, followed by fine showers and warmth. 

Result : Both shaws and turnips much improved, as compared with those near them not thus dressed; in appearance improved by several tons to the acre, but no comparative weights were taken.

In the trial with nitrate of soda, in the same proportions, on mangel-wurzel and carrots, Walls, the overseer, could not observe any difference between those so dressed and those which were not; and saltpetre and cubic petre were also mixed in small proportions with the nitrate of soda on some hodded, and used in the garden for turnips, spinach, carrots, cauliflowers, asparagus, and onions, but without any apparent advantage.

Mr. S. Martin, of Warbleton, in Sussex, has given, in the Sussex Express, the following details of his experiments with nitrate of soda as a top-dressing for corn, on a four-acre field in: 819
his occupation:—"The soil of the field selected is a thin, gravelly loam, with a substratum of sandstone, and was a rye-grass ley, fed with sheep and beasts until the last week in May, 1839, when it was ploughed up, and afterwards twice sown and harrowed, and manured with 120 bushels of lime per acre, previously to its being sown with the wheat "golden drop" in the autumn. In the last week of April, this year, I applied 1 cwt. of nitrate of soda per acre over the whole field (with the exception of two lands in the middle of the field); in the second week in May, I applied to two lands adjoining those upon which none had been sown an additional 1 cwt. per acre. Previously to the application of the nitrate, the plants had a very sickly appearance, getting yellow in patches, and looking, as we call it here, "squeary," but in a very few days subsequent, its appearance was much altered, it having (with the exception of the two lands on which none had been sown, and which remained in a very sickly state) changed from a faint yellow to a luxuriant green; the two lands upon which the 2 cwt. per acre were sown were much darker in appearance than the other, and easily distinguishable from the remainder at a very considerable distance.

"At harvest I measured off exactly 8 rods of each, and had it reaped (having left stubble about 16 inches high), and carted and threshed separately; the result was as under:—8 rods without soda produced 1 bushel, 3 gallons, 1 pint, or 27 bushels, 6 gallons, 4 pints per acre; weight, 61 lbs. per bushel; straw 89 lbs., or 42 trusses, 16 lbs. per acre; 8 rods with 1 cwt. of soda per acre, 2 bushels, 1 gallon, or 42 bushels, 4 gallons, per acre; weight, 60½ lbs. per bushel; straw, 155 lbs., or 86 trusses, 4 lbs. per acre; 8 rods with 2 cwt. of soda per acre, 2 bushels, 2 gallons, 7 pints, or 47 bushels, 1 gallon, 4 pints per acre; weight, 60 lbs. per bushel; straw, 156 lbs., or 86 trusses, 24 lbs. per acre.

"On another piece of land, soil very thin and gravelly, sown with Talavera wheat in the autumn, I applied 1 cwt. per acre in the first week in May, and the result was equally satisfactory, the produce good, and weighed 64 lbs. per bushel.

"In an adjoining field of precisely the same description of soil, but which had been in hops for 11 years previously, and amply manured every year, I sowed on two rods at the end of one of the lands nitrate equal to 1½ cwt. per acre, which had a very prejudicial effect; the part with nitrate of soda being much more swelled and totally unfit for bread, while the straw on the remainder of the field was very bright and clean, and the grain full and handsome. I also used nitrate of soda on a meadow, 1 cwt. per acre, applied the last week in April; produce very trifling.

"As far as my experience goes, and from the effect of nitrate of soda on my neighbours' lands, I am of opinion that it is a very valuable manure for their light soils, exhausted by repeated croppings, particularly in districts where the arable lands have been repeatedly manured with lime; but I have great doubts whether it would answer for wheat on newly opened up or other land in a high state of cul

ment on the old hop ground, although the straw was much longer, with a blade broad and flaggy, the yield was miserably deficient, both in quantity and quality, compared with the rest of the field after harvest.

"In respect to its effect on the second crop, I can only observe, that a very thin, wornout field of 18 acres, with wheat in 1839, on which 1 cwt. per acre was used (one land of which had a double quantity), was sown this year half with oats and half with seeds, that both oats and seeds were fully equal to any I ever grew on that field; and that the land where the 2 cwt. per acre was sown produced fully as many plants, with longer straw and more grains, and was, as far as I could judge from appearances (I did not keep it separate), much superior to the other.

NITRIFICATION. See EREMACEAUS.

NODIL. In botany, the knots or swelled articulations of stems; the place where one joint is articulated with another.

NONE-SO-PRETTY. One of the names of the London-pride Saxifrage. See SAXIFRAGE.

NOUNSEUCH, or BLACK MEDICK. See MEDICK.

NOONINGS. A term provincially used to signify working during dinner-hours.

NORFOLK PLOUGH. See PLOUGHS.

NORTHERN LIGHTS, or AURORA BOREALIS. See LIGHTS, NORTHERN.

NOSE-BAND. That part of the head-stall of a bridle which comes over a horse's nose. It is sometimes termed maserole.

NUCLEUS (Lat.). Literally, any thing round which matter has accumulated, or to which it is affixed. In botany, it is used in various significations:—1. The central, fleshy, pulpy mass of an ovule. 2. That part of a seed contained within the testa, and consisting of either the embryo and albumen or of the embryo only. 3. In lichens, the disk of the shield, which contains the sporules and their cases. 4. In the language of the older botanists, what is now termed by gardeners a clove; that is, the secondary bulb of a bulbous plant.

NUISANCES, in English law, are of two kinds: public or common, which annoy the king's subjects in general; and private, which are defined "any thing done to the hurt or annoyance of the lands, tenements, or hereditaments of another." A nuisance may be defined to be any act done which renders the lives of the neighbours less comfortable than they were before. The remedies allowed by the law are in some cases summary, as when a gate is erected across a public highway, or cattle trespass on the land; and in which cases the passenger or owner of the land is justified in removing the nuisance: or in other cases, the general legal remedies are, indictment or presentment, for public nuisances; or by an action on the case for damages, for private nuisances.

Indictable Nuisances.—Of the number of public nuisances which are punishable by indictment are setting spring-guns and man-traps, which, by the 7 & 8 G. 4, c. 18, is declared to be a misdemeanor; but the act allows such to be set "from sunset to sunrise in dwelling-houses for the protection thereof." Other indictable nuisances are for erecting a privy or
NURSERY.

placing patrid carrion near a highway, or keeping hogs, and feeding them with offal near to a street; for keeping a dangerous bull in a field through which there is a public pathway (if the bull or other dangerous animal is purposely placed there to stop a disputed path, and death be the result of this suffering, or a frenzied dog; for baiing on the queen's highway a bull, &c. The punishment in any case of nuisance is fine or imprisonment, or both; and the court may order the defendant to pay the prosecutor his costs. It is no defence to prove that the nuisance has existed for a number of years; but in some cases the facts of the case may be taken into consideration by the jury, who are to determine whether the benefit derived by the public exceeds the annoyance. But in indictments for obstructing the highway by placing on it for a length of time carriages while loading and unloading, it is no defence to show that space was always left for two carriages to pass and repass on the other side of the street. The non-repair of a road or a bridge are also well-known nuisances, which are indictable.

Nuisances on which an Action on the Case is maintainable.—Accidents from the negligent use of loaded guns; placing baited traps so near to the premises of another, or the highway, that dogs are attracted into them and injured. For an injury by a vicious bull; and it is no defence by the owner of an animal that he has had notice of having done an injury, and has taken every precaution to prevent it doing so again. No action, however, lies for an injury by a dog let loose on the owner's closed premises at night for their protection; or on land on which the injured party has no right to go. If a person harbour a dog, or allows it to resort to his premises, he is liable for any damage it may cause. And the owner of a dog that destroys or injures sheep is, of course, liable to their owner. If the owner catch the dog in the act of worrying his fowls or sheep, he is justified in shooting him; but he must not follow the dog a sufficient distance, and then shoot him; nor may he shoot a dog merely trespassing; but he may if the dog is chasing deer in a park. And if any man do any thing on his own soil which is a nuisance to another, as by stopping a rivulet, and so diminishing the water used by him for his cattle, the party injured may enter on the soil of the other and abate the nuisance; and this right of abatement is not confined merely to nuisances to a house, to a mill, or to land.

NURSERY. In horticulture, a piece of land set apart and appropriated for rearing and preserving young plants and trees of different kinds, with a view to supply both gardens and plantations. The situation ought to be open and airy, and the soil of an average quality, neither too heavy nor too light, so as to be adapted to the majority of plants; but in a complete nursery there ought also to be shady borders for plants requiring shade, and beds or compartments of peat soil or other peculiar earths, for such plants as are not readily increased and grown in ordinary soils. Where tender plants are propagated, or where hardy plants are to be raised from seeds or struck from cuttings, which are not easily germinated or rooted in the open ground and in the ordinary manner, hotbeds, frames, and handglasses are also requisite. Every private garden of any extent requires a nursery to raise and bring forward young plants, as a reserve for supply in case of disease or accident in the general garden; and in every country where private gardens or plantations of trees are frequent, public or commercial nurseries are formed by persons who adopt nursery gardening as a business.

OAK.

Oak (Ger. eiche; Dut. eik; Dan. eeg; Sw. ek; Lat. Querceus; from the Celtic gwer, fine, and ence, a tree; others derive it from the Greek word choiros, a pig, because those animals feed on the acorns.)
The oak is indigenous throughout Britain, and in former ages, before the clearing away of the forests had commenced, apparently had covered a very large portion of its surface; for, even in districts where the natural or self-sown oak is now rarely seen, the remains of noble and gigantic trees are frequently met with, sometimes in the alluvial deposits on the margins of rivers, or in boggy places covered with a layer of peat-moss, which has been generated around them by the stagnation of the water caused by their fall.

A fine oak is one of the most stately and picturesque of trees; it conveys to the mind associations of strength and duration, which are very impressive. The oak stands up against the blast, and does not take, like other trees, a twisted form from the action of the winds. Except the cedar of Lebanon, no tree is so remarkable for the stoutness of its limbs; they do not exactly spring from the trunk, and thus it is sometimes difficult to know which is stem and which is branch.

English oak warps and twists much in drying, and in seasoning shrinks about 2/3 of its width. This wood is more durable than any other timber in water; and in a dry state it has been known to last nearly 1000 years. The more compact it is, and the smaller the pores are, the longer it will last; but the open, porous, and foxy-coloured oak, which grows in Lincolnshire and some other places, is not near so durable. The bark, leaves, and fruit of all the species abound in astringent matter, and in tannic acid. The bark in the spring contains more tannic acid, and is more easily separated, than at any other season: hence oaks are usually barked in May, June, and the beginning of July. When separated, the bark is dried by being set up in ranges, which are called loftes
In the greater part of North America, as well as in Europe, there is no tree so generally useful as the oak, which seems to have been multiplied in proportion to its utility.

Linnaeus, in the third edition of his Species Plantarum, published in 1774, described 14 species of oak, of which 9 only are natives of the New World. Since then, owing to the labours of those indefatigable naturalists, Humboldt, Bonpland, and especially Michaux, the father, the number of American species of oak has been increased to no less than 44, all of which are comprised between the 30th and 48th degrees of North latitude. In the Old Continents, only 30 species are enumerated, and these are scattered on both sides of the equator. The species and varieties of the oak added to those described by the Michaux, are chiefly found in the extreme Southern States, Texas, and Mexican possessions.

The following classification of American oaks was made by the elder Michaux, who includes in it three European species:

First Division.

Fructification annual.

First Section.—Leaves lobed.

1. White oak (Quercus alba).
2. Common European oak (Quercus robur).
3. European white oak (Quercus robur pedunculata).
5. Over-cup white oak (Quercus macrocarpa).
6. Post oak (Quercus obtusiloba).
7. Over-cup oak (Quercus lyrata).

Second Section.—Leaves toothed.

8. Swamp white oak (Quercus prinus discolor).
9. Chestnut white oak (Quercus prinus palustris).
10. Rock chestnut oak (Quercus prinus monticola).
11. Yellow oak (Quercus prinus acuminata).
12. Small chestnut oak (Quercus prinus chincapin).

Second Division.

Fructification biennial; leaves unlobed (except in the 13th species).

First Section.—Leaves obtuse or entire.

13. Live oak (Quercus virens).
15. Willow oak (Quercus phellos).
16. Laurel oak (Quercus imbricaria).
17. Upland willow oak (Quercus cinerea).
18. Running oak (Quercus pumila).

Second Section.—Leaves lobed.

20. Water oak (Quercus aquatica).
22. Bear oak (Quercus banisteri).

Third Section.—Leaves multifid or many-clefted.

23. Barren scrub oak (Quercus Catesbaei).
24. Spanish oak (Quercus falcata).
25. Black oak (Quercus tinctoria).
26. Scarlet oak (Quercus coccinea).
27. Gray oak (Quercus ampignus).
28. Pin oak (Quercus palustris).
29. Red oak (Quercus rubra).

The most valuable species of the American oaks is the white oak, which is found as far north as the small town of Trois Rivières, in Canada, lat. 46° 20', and the lower part of the river Kennebec, in Maine, and thence south on both sides of the Alleghanies down to the 28th degree of latitude. Its vegetation is repressed in the Northern States by the severity of the winters. In the lowermost Southern States it is found only on the borders of swamps, with a few other trees, which likewise shun a dry and barren soil. The white oak is observed to be uncommon on lands of extraordinary fertility, like those of Tennessee, Kentucky, and Genesee, and in all the spacious valleys watered by the western rivers. One may travel whole days in those states without seeing a single stock, though the few that exist, both there and in the Southern States, exhibit the most luxuriant vegetation.

The white oak abounds chiefly in the Middle States and in Virginia, particularly in that part of Pennsylvania and Virginia which lies between the Alleghanies and the Ohio. East of the mountains this tree is found in every exposure, and in every soil which is not extremely dry or subject to long inundations; but the largest stands are found in the western districts, where it composes entire forests, the face of the country is undulated, and the yellow soil, consisting partly of clay with a mixture of calcareous stones, yields abundant crops of wheat.

By the foregoing observations it appears that the severity of the climate, the fertility of the soil, its dryness or humidity, are the causes which render the white oak so rare over three-quarters of the United States that it is inadequate to supply the local demand, though the country contains but a small proportion of the population which it is capable of supporting.

Among the American oaks this species bears the greatest analogy to the European oak, especially to the variety called European white oak, Quercus pedunculata, which it resembles in foliage and in the qualities of its wood. The American white oak is 70 or 80 feet high, and 6 or 7 feet in diameter; but its proportions vary with the soil and climate.

The excellent properties of the white oak for the construction of houses, ships, and almost innumerable other purposes, are too well known to need any particular description in this place.

Great black oak (Quercus tinctoria). The wood of this tree is of a coarser grain than that of the white oak, and of a reddish colour. Between every year’s growth, also, it appears porous, yet when dry and seasoned, it becomes strong and durable. The bark has, for a long time, been in great repute for tanning, and for the very excellent yellow dye which it affords. Dr. Bancroft, of London, learned the use of the bark as a dye, when in this country, during the revolutionary war; and introduced it in the manufactories of England, to which country many ship-loads of the article, ground, have been annually shipped, under the name of Querci nëon bark.
Spanish oak (Quercus falcata, of Michaux); the bark of this species is somewhat rough, and light-coloured. The leaves are deeply and obtusely sinuate, and end in several acute, briskly points: the foot-stalks are pretty long. The timber is generally worm-eaten, or rotten at heart; but the bark is preferred to all other for tanning, and is much dearer.

Live oak (Quercus virginiana). This species is confined to Georgia, South Carolina, and Florida. The tree is of uncommon magnitude, and singularly beautiful. The moss hangs in lengths of several yards from the large branches of the old trees, and waving with the wind, gives the tree a venerable appearance. The wood is proverbial for its durability, when cut at a proper season, and is much used for ship timber. See ACOBN, DRY ROT, and PLANTATION.

OAK-APPLE. This is not to be confounded with those beautiful little excrescences so common upon the underside of the leaves of the oak, and known by the name of galls and spangles; they are the nidi of different species of Cynips, produced by the puncture of the ovi-positor of the female, upon the different parts where they are found. The oak-apples are also formed by the puncture of a cynips, upon the twigs of Q. pedunculata. It rises rapidly, is usually spheroidal, in size about 1 to 2 inches in diameter. Its texture is spongy. It has some resemblance to the Edeytree of the Eglantine, but is not so rough and fibrous on the surface. The oak-apples are very astringent, containing tannic acid, and may be used in dyeing, making ink, and staining.

The largest galls or oak-apples, found in the United States, grow on the leaves of the red oak. They are round and smooth, and measure from 1½ to 2 inches in diameter. This kind of gall is green and somewhat pulpy at first, but, when ripe, it consists of a thin and brittle shell, of a dirty drab colour, enclosing a quantity of brown spongy matter, in the middle of which is a woody kernel about as big as a pea. A single grub lives in the kernel, becomes a chrysalis in the autumn, when the oak-apple falls from the tree, changes to a fly in the spring, and makes its escape out of a small round hole which it gnaws through the kernel and shell. This, says Dr. Harris, is probably the usual course, but I have known this gall-fly to come out in another way. The name of this insect is Cynips confluens. Its head and thorax are black, and rough with numerous little pits and short hairs; the hind-body is smooth, and of a shining pitch colour; the legs are dull brownish-red; and the fore-wings have a brown spot near the middle of the outer edge. Its body is nearly one-quarter of an inch long, and its wings expand five-eighths of an inch.

Clusters of three or four round and smooth galls are often seen on the small twigs of the white oak. They are nearly as large as bullets, of a greenish colour on one side, and red on the other. They approach in hardness to the Aleppo galls, and perhaps might be put to the same use. Each one is the nest of a single insect, which turns to a fly and eats its way out in June and July, having passed the winter as a chrysalis, within the gall, lodged in a clay-coloured, egg-shaped case, about three-twentieths of an inch long, and with a brittle shell. These little cases appear to be cocoons, but are not made of silk or fibrous matter. Similar cocoons are found within many other galls, and I have some which were discovered under stones, and were not contained in galls, but produced gall-flies, the insects having left their galls to finish their transformations in the ground. The gall-fly of the white oak varies in colour. Sometimes it closely resembles the gall-fly of our oak-apple, differing from it only in size, and in wanting the brownish spot and dark-coloured veins on the fore-wings; and sometimes it is of a dull brownish-yellow colour, with a brown spot on the back. It is three-twentieths of an inch long, and its wings expand three-tenths of an inch. It is the Diplocleps, or more properly Cynips onurus of Dr. Harris's "Catalogue."

Galls of the size and colour of grapes are found on the leaves of some oaks. Each one contains a grub, which finishes its transformations in June. The winged insect is the Cynips nubilipes, or cloudy-winged Cynips, so named from the smoky cloud on the tips of its wings.

Except in some respects, it closely resembles the dark-coloured variety of Cynips onurus, and very little exceeds it in size.

One of our smallest gall-flies may be called Cynips seminator, or the sower. She lays a great number of eggs in a ring-like cluster around the small twigs of the white oak, and her punctures are followed by the growth of a rough or shaggy reddish gall, as large sometimes as a walnut. When this is ripe, it is like brittle sponge in texture, and contains numerous little seed-like bodies, adhering by one end around the sides of the central twig. These seeming seeds have a thin and tough hull, of a yellowish white colour; they are egg-shaped, pointed at one end, and are nearly one-eighth of an inch long. The gall-insects live singly, and undergo their transformations within these seeds; after which, in order to come out, they gnaw a small hole in the hull, and then easily work their way through the spongy ball wherein they are lodged. They are less than one-tenth of an inch long, are almost black, or of the colour of pitch, highly polished, especially on the abdomen, and their mouth, antennæ, and legs are cinnamon-coloured.

It has been observed that no tree in Europe yields so many different kinds of galls as the oak. Those described are not all that are found on oaks in the United States, and they seem to be sufficiently distinct from the galls of European oaks. (Harris)

OAK BARK. The cortical layer stripped from the oak tree. Oak bark is preferred to all other substances in the tanning of leather, and in Europe brings a high price afterwards as a manufacture. The exhausted bark is used by gardeners to produce a slight equable heat by its fermentation, and may be advantageously used as a manure. The tan-balls, or muddy sediments of tan-pits, are used for summer fuel. The bark contains different quantities of tannic acid, according as it is near to or distant from the wood. Thus, the inner part, or liber, according to Sir H. Davy's experiments, yields 3 C 853
about 77 per cent. of tannic acid; the cellular layer, lying upon the \textit{liver}, yields only 56 per cent; and the cuticle little or none. Dr. Higgins obtained 108 parts of tannic acid from the bark of an oak felled in the spring, and only 30 from an oak felled in winter. When the bark is set up to dry, the air, aided by moisture, acting upon the tannic acid, converts a portion of it into gallic acid, which is not originally a constituent of oak bark. See \textit{Tax} and \textit{Bark}.

\textbf{OAK PRUNER.} The ground beneath black and white oaks is, says Dr. Harris, often observed to be strewn with small branches, neatly severed from these trees, as if cut off with a saw. Upon splitting open the cut end of a branch, in the autumn or winter after it has fallen, it will be found to be perforated to the extent of six or eight inches in the course of the pith, and a slender grub, the author of the mischief, will be discovered therein. In the spring this grub is transformed to a pupa, and in June or July it is changed to a beetle, and comes out of the branch. The history of this insect was first made public by Professor Peck, who called it the oak-pruner, or \textit{Slenocorus}, \textit{Amphipteron} \textit{puntator}. See Pl. 16, 1. In its adult state it is a slender, long-horned beetle, of a dull brown colour, sprinkled with gray spots, composed of very short close hairs; the antennae are longer than the body, in the males, and equal to it in length in the other sex, and the third and fourth joints are tipped with a small spine or thorn; the thorax is barrel-shaped, and not spined at the sides; and the scutellum is yellowish-white. It varies in length from four and a half to six-tenths of an inch. It lays its eggs in July. Each egg is placed close to the axilla or joint of a leaf-stalk or of a small twig, near the extremity of a branch. The grub hatched from it penetrates at that spot to the pith, and then continues its course towards the body of the tree, devouring the pith, and thereby forming a cylindrical burrow, several inches in length, in the centre of the branch. Having reached its full size, which it does towards the end of the summer, it divides the branch at the lower end of its burrow, by gnawing away the wood transversely from within, leaving only the ring of bark untouched. It then retires backwards, stops up the end of its hole, near the transverse section, with fibres of the wood, and awaits the fall of the branch, which is usually broken off and precipitated to the ground by the autumnal winds. The leaves of the oak are rarely shed before the branch falls, and thus serve to break the shock. Branches of five or six feet in length and an inch in diameter, are thus severed by these insects, a kind of pruning that must be injurious to the trees, and should be guarded against, if possible. By collecting the fallen branches in the autumn, and burning them before the spring, we prevent the development of the beetles, while we derive some benefit from the branches as fuel.

Oak trees are also subjected to the attacks of insects, which destroy the leaves, deposit their eggs in the branches which they destroy, and others which devour the solid wood. See \textit{Beetles}, \textit{Borers}, \textit{Caterpillars}, \textit{Locusts}, \textit{&c.}

\textbf{OAT.} \textit{(Russ. ovce; Pol. owce; Dutch, haver; Fr. Avoine; Lat. Avena).} A very valuable cereal grass, of which several varieties are cultivated for their seeds: the chief of these are—\textit{1. The Avena sativa}, or common oat. Pl. 3, \textit{c}. 2. The \textit{A. orientalis}, or Tartar oat, \textit{f}. 3. \textit{A. striogosa}, or bristle-pointed oat. 4. \textit{A. brevis}, or short oat. 5. \textit{A. unda}, or naked oat.

The common oat is far the most important of these species. Its spikelets contain two or three seeds. Its florets are sometimes furnished with awns, and at other times are awnless. The oat is a native of cold climates: it flourishes in the temperate latitudes, but it degenerates, and at last refuses to yield profitable crops as it approaches the equator. It is, however, cultivated with success in Bengal, as low as the 25° of latitude. It flourishes remarkably well in Ireland and in Scotland, and constitutes the principal food of the inhabitants. In England it is cultivated to a very considerable extent in the ten districts of the eastern counties, as well as in the northern border districts, in which last the oats are considered to be very superior. By cultivation, difference of soil and climate, and other causes, the common oat \textit{(A. sativa)} has produced several varieties, which have been divided by some authors into three classes, the black, the gray, and the white. Those of the first class are commonly hardy, have small seeds, become early ripe, and are hence well adapted for cold hungry soils, such as those which are usually found on considerable elevations.

The gray, or dun-coloured oats, although possessing more valuable qualities than the black oat, are still inferior in quality to the white, but on some soils yield very remunerative crops.

The third and most valuable class of oats is the \textit{white}. “The most improved of these,” says Professor Low, “are without awns. They are the least hardy kinds, but they are of the greatest weight to the bushel, and the most productive of meal. In this class the potato oat is that which has possessed the greatest reputation for a time in the districts where it is cultivated. It is not so well suited to inferior soils as some of the other white and darker-coloured kinds; it is also less productive of straw, though the grain is more plump, weighs heavier, and yields a greater weight of meal. The hardier kinds, however, are better suited to certain situations than the finer, just as the hardier red wheats are better suited to certain situations than the thin-chaffed and white varieties. The potato oat was the discovery of accident, and the produce of a single plant. It has, in many cases, shown a tendency to degenerate, by the husks becoming thicker and the body less plump, and by the partial appearance of awns.”

The \textit{Polish} oat is another valuable cultivated variety of the white oat. It comes early to maturity, and is a prolific bearer. Its defects are a tendency to be deficient in straw, and a liability to shed its seeds.

Besides these there are several other varieties of the white oat, as the Dutch, or Friesland oat, the Hopetoun oat of East Lothian, &c.

The \textit{Hopetoun oat} was produced in 1824, by
Mr. P. Sherriff, of Mungo’s well, in the way he thus describes. “Having frequently had occasion to pass the gateway of a crop of potato oats, in the summer of 1824, a stalk of remarkable height attracted my attention. When the crop was reaped, the grains supported by this stalk and those upon a short one proceeding from the same root, were gathered and sown in the following spring. The crop from the grains of the gigantic stalk was again conspicuously tall, and after the crop of 1827 the new variety established its superiority.” In some comparative trials by Mr. Boswell, “on a good free black soil,” the Hopetoun exceeded the potato oat in produce, as, in some experiments by Mr. Forsyth, of Elgin, “on a rich loam,” it excelled the late Angus oat, and in those of Mr. Howden, at Traprain, in East Lothian, it proved superior to the grey Angus, the potato, and the early Angus oats.

The early Angus oat is well known for its early ripening, and the late Angus, says Mr. Sherriff, is also well known for its fine straw and grain; and although late in ripening, is the most esteemed species of oat in the early districts of Scotland, such as East Lothian and Morayshire. There is a difficulty, however (Mr. Sherriff very justly adds), of ascertaining the merits of different varieties of grain by experiment, from the many contingencies affecting the results, the most powerful of which is the nature of the season. Some kinds of oats grow rapidly in the early part of the season, and some attain their full height, such as the Polish and Georgian oats, both of which are stunted. Others grow slowly, and are later in arriving at their full height, such as the potato, Flemish, and early Angus oats, which are also short. Others continue to grow through the season, and are still later in arriving at their full height, as the Hopetoun and late Angus oats, which are taller than the others. When the early part of the summer proves wet, and is followed by drought, the Polish and Georgian oats have an advantage over other kinds, as they attain their full height before the drought commences. When the early part of the summer is very dry, and moisture succeeds, the Hopetoun and Angus oats benefit by the moisture, while the others mentioned do not. When the season proves wet throughout, and the different oats in consequence reach an extreme height, the smaller species have frequently an advantage over the larger in grain produce, in consequence of the straw of the latter becoming too luxuriant.

The Cumberland early oat, so named from being raised from a single head by a Cumberland gentleman, is of a longish grain, more like the early Angus variety than the potato; colour dark and dull. It is as much earlier than the potato oat as the latter is earlier than the Hopetoun, being ripe nearly a fortnight sooner than the Hopetoun.

Red oat.—There is a peculiar variety of oat (classed with the gray oats), called the red oat, which is a favourite in some districts, and is thus described by the celebrated William Dawson, of Progdon, in 1791:—“Happening to be at Linton, in Tweeddale, which is about the highest land kept in cultivation in the south of Scotland, I found the farmers complaining much of the loss they had by late harvests, and I asked if they had tried the Dutch oats, which were so much earlier than the common kinds. They told me that they had tried the Dutch oats, but that they had a kind in their own country which were as early as the Dutch, and were superior in some several respects; they were not so apt to shake even as the common oat; they suited every sort of soil if in good condition, and they yielded well in mealt; that they had been sown in that country for fifty years, but no one knew where they came from. Upon this information I commissioned a ball for a trial, and found them answer so well that I have sown no other sort for several years. They do not produce much straw, but what they do produce is very good. I saw a second crop of these oats upon the same land last year, which was good. I have found that they answer the character given of them at Linton fully. That they answer best upon land in good condition, but that they produce very little straw upon poor land; yet the produce of corn is not even in these situations inferior to any other oats. These properties give them a great superiority over every other kind known in this country, and grown in high situations, and cold climates and soils.” They are a kind of oat much relished by horses, who, if used to them, do not readily take to other, even richer kinds. Carters accustomed to them give them a decided preference.

The Georgian Oat was introduced about the year 1824, but it has not made much progress. In 1826, Mr. Wilson, of Preston, reported the following comparative trials between it and the potato oat (Trans. High. Soc. vol. i. p. 153), upon 2 English acres of equal land. The quantity sown upon an acre was 6 bushels, and of the potato 4 bushels. The Georgian was reaped 10 days earlier than the potato, but they might have been 14 days. The appearance of the Georgian was by far the most luxuriant during the summer, till the end of July, when the potato shot out considerably longer in the straw. They were carefully cut down, stacked, and threshed in March, 1826; the result was, in—

| Stones: Hr. | Weight of straw of the potato oats per acre | 317 | 6 |
| Weight of straw of the Georgian oats per acre | 235 | 12 |

The produce of the potato oats per acre was 69 Winchester bushels, and the Georgian 63.

| Stones: B. | Weight of meal from 6 bushels of the potato oats | 11 | 5 |
| Weight of meal from 6 bushels of Georgian oats | | 10 | 6 |

The Tartarian Oat is cultivated to some extent in England, but much more extensively in some portions of the Continent. “Its fascicle is contracted, and nods to one side, which distinguishes it from the common oat. The colour of its corolla is generally dark, but the plant improves by culture in a good soil, losing its awns, and that darkness of colour which appears to distinguish the oat in its less improved state.” The breadth of this oat annually cultivated in England has much increased within the last few years. It is the best description.
for the poorest exhausted soils, producing the most straw on those sorts of any other variety. The oat can be profitably cultivated upon, perhaps, a greater variety of soils than any other of the cereals. It may be grown, too, successfully with less preparation of the soil, and less manure. The oat plant, however, succeeds best in fresh soils, in newly broken up old pastures, and in those abounding in organic matters.

The organic manures by which the oat crop is best nourished, appear to be green manures; fish, especially those like sprats, abounding in oil, and, in fact, all those of a readily decomposable description. Recently-drained marshes, peaty soils after being dressed with lime, newly enclosed commons after being chalked, all usually yield large crops of oats.

The land intended for oats should be ploughed, if possible, especially on clay soils, in the previous winter, or at least as early in the spring as possible: this is a practice almost always adopted by the best farmers of our island. A still more common course of cropping is to sow oats after turnips, or other green crops, and especially on the four-shift system with grass-seeds.

A mingled custom still prevails in some parts of England, of taking two crops of oats in succession, or an oat crop after wheat or barley. Arthur Young long since denounced this as bad husbandry. After observing that white oats should be sown in March, in preference to any other season, he remarked, that “in the general custom of them the farmer should by all means avoid the common error of sowing after other corn crops, by which they exhaust the land. They should always receive the same preparation as barley, nor ought a good husbandman to think of their not paying him as well for such attention as that crop. It is a very mistaken idea to suppose it more profitable to sow barley on land in good order than oats. He was, from divers experiments, inclined to think that oats will equal, and in many cases exceed, barley. The superior quantity of the produce will ever be found to more than counterbalance the inferiority of the price; which, however, sometimes exceeds that of barley.”

Oats are commonly sown from March to April, but it is very probable that they might be advantageously sown much earlier in many situations, and when on grass leys generally broadcast: from 4 to 6 bushels per acre of seed is the ordinary quantity. By the drill, after turnips, a much less quantity will be sufficient. I have known from 10 to 11 quarters per acre grown year after year from only 2 bushels of seed.

They are usually cut in the south by the scythe—in the north and western portions of Britain by the sickle; and they should never be allowed to become perfectly ripe before they are cut. The usual produce varies from 25 to 60 bushels per acre. In the fens of Lincolnshire, and in Essex and Suffolk on land previously dressed with 35 or 40 bushels of sprats per acre, the yield is usually much more considerable.

The weight of a bushel of oats varies from 856

---

Oatmeal is a well-known article of food; it is the flour from which, in the northern portion of Great Britain, the bread of the working classes is partly procured. The oat-seed was examined by Sir H. Davy: he found in 1000 parts of Scotch oats 743 of soluble or nutritive matter, composed of 641 mucilage or starch, 15 saccharine matter, and 87 gluten or albumen. In 100 parts of oats from Sussex, 59 parts of starch, 6 of gluten, and 2 of saccharine matter, 33 husk.

The principal demand for oats in Great Britain is for horses. Its use for bread is chiefly confined to the northern districts. Meal is employed also for various domestic purposes, feeding pigs, dogs, &c.; and it has been used in brewing ale, and in the malt distilleries; but for this purpose its value is much inferior to that of barley.

The seeds were analyzed by Schraeder; he found in 227.8 grains of ashes, obtained from 2 lb. of oats—

Oats raised south of Philadelphia usually bring about 3 cents per bushel less than those raised in Pennsylvania and still further north, which are generally much heavier.

OAT-GRASS. See Avena.

OATMEAL. The meal or flour of the oat is used in Great Britain to make porridge, gruel, bread, and poutilies. In the mealing process, the oats, after being previously dried in a kiln, are made to pass through the mill-stone to divest them of their coarser husks or "shealings" before being ground. The kernels are then named "grits" or "groat's;" and are next ground over again into a coarse, rough meal, varying in its fineness according to the custom of different districts. This is afterwards either baked upon a heated iron, called a grate in Scotland, into thin, flat cakes, or made up with water into loaves, and baked. When gradually stirred into boiling water, and boiled into a thick consistence, it forms the porridge of Scotland. It is eaten either with skimmed milk, butter, molasses, or ale. It is thus very generally used as the common porridge for breakfast and supper of the greater portion of the peasantry of the northern parts of England, Scotland, and Ireland, and forms a very nutritive and healthy food. It is, however, apt to prove acceotant in some stomachs, and to cause catarrhal diseases. See GROATS.

OCHRE. See Fuller's Earth.

OIL-CAKE. The marc which remains after the oil has been expressed from the seeds of flax and rape. See Colza, Linseed Cake, Palm Christi, Rape.

OILS (Ger. oel; Lat. oleum). This term comprehends two substances that have very distinct properties, namely, volatile and fixed oils; but, in general language, the term oil is indicative of the latter. Fixed oils are unctuous, fluid bodies, which, when dropped upon paper, sink into it, and make it semi-transparent, or give it what is called a greasy stain. They are composed of carbon, oxygen, and hydrogen. Train oil has been sometimes used as a medicine, and is a powerful fertilizer. See Fissan. Linseed oil is a common food for live-stock. See Linseed Oil.

The following is the result of analysis of 100 parts of

Hydrogen Oxigen Carbon.

Olive oil | 12 30 | 9 47 | 77 213 = 100
Train oil | 10 1 | 12 03 | 68 87 = 100

Olive oil is chiefly imported into England from the Mediterranean. It is the produce of the Olea europea, a native of Greece, Africa, and the south of Europe. The oil is expressed from the ripe fruit, which resembles a small purple plum in size and appearance. The fruit is first bruised in a mill, and then pressed: the first which flows is termed virgin oil; after obtaining which the marc is broken up, moistened with hot water, and again submitted to the press to prepare an inferior oil. The oil is left for a considerable time, to enable it to deposit the feculenties, before it is ready for exportation or for use. Good olive oil is of a pale straw-yellow colour, perfectly inodorous and tasteless. There are several kinds in the market: that which comes from Provence is the best, next to it that from Florence; it is imported in flasks. Lucaca and Genoa oils are also good; but the greatest part of the olive oil brought into England is the production of Naples and Sicily, and known by the name of Gallipoli oil. Olive oil is used both dietetically and medicinally. It is superior to butter for many purposes of cookery.

OKRA (Hibiscus coccineus). This plant is cultivated extensively in the West Indies, from whence it has been introduced into the United States. The pods are gathered green, and used in soups. They form an important ingredient in the celebrated Gumbo soup of New Orleans and other southern places. The pods are filled with seeds and a mucilage of a bland and highly nutritious quality. Hence the okra is frequently recommended to persons afflicted with dysentery and other bowel complaints, either eaten boiled, or made into soup. When

\[ \text{OAT-GRASS.} \]

\[ \text{OKRA.} \]
buttered and spiced, they afford a rich dish, and with vinegar, they make a good pickle. The plant comes to maturity in the Middle States, and the pods are abundant in the Philadelphia market. Those who become once accustomed to this wholesome vegetable, contract a great fondness for its peculiar flavour.

In Louisiana and other southern states, a dinner is scarcely considered complete without okra cooked in some way or other, and the poor consider it one of their greatest blessings. Mr. Legare, editor of the Southern Agriculturist, has published the following recipe for making okra soup, after the celebrated method pursued in Charleston. The pods, he says, are of proper size when 2 or 3 inches long, but may be used as long as they remain tender. If fit for use, they will snap asunder at the ends, but if too old and woody, they must be rejected. One peck of the tender pods are to be cut crosswise into very thin slices, not exceeding one-eighth of an inch in thickness. To this quantity add about one-third of a peck of tomatoes, previously peeled and cut into pieces. The proportion of tomatoes may be varied to suit the taste. A coarse piece of beef (a shin is generally made use of) is placed in a pot or digester with about 2½ gallons of water, and a very small quantity of salt. This is permitted to boil at first moments, when the scum is taken off and the okra and tomatoes thrown in. With these ingredients the proportions mentioned, the soup made is remarkably fine. Still, some think it improved by additions of green corn, Lima beans, &c. The most essential thing to be attended to is the boiling, and the excellence of the soup depends almost entirely on this being done faithfully. For if it be not boiled enough, however well the ingredients may have been selected and proportioned, the soup will be very inferior, and give but little idea of the delightful flavour it possesses when well done. A properly constructed digester is decidedly the best vessel for boiling this or any other soup in; but where such a utensil is not at hand, an earthenware pot should be preferred; but on no account make use of an iron one, as it would turn the whole soup perfectly black, instead of the proper colour, namely, green, coloured with the rich yellow of tomatoes. The time usually required for boiling okra soup is about 5 hours, during which it should be occasionally stirred, and the ingredients mashed. When taken off, the original quantity will be reduced to about one-half, and the meat “done to rags;” the whole forming a homogeneous mass, of the consistence of thick porridge.

OLEANDER ( Nerium, from serene, humid; alluding to the habitat of the plants). This is a genus of noble evergreen shrubs, of easy culture, and flowering freely the greater part of the year. N. oleander and its varieties bear forcing remarkably well; and, although treated as green-house plants, yet they will not flower well unless they are kept in the stove. They grow well in any rich, light soils, and young cuttings root in any soil, if kept moist. The leaves of N. oleander contain tannic acid, and the leaves and bark of the root of N. odorata are applied externally as powerful repel-

ants by the Indian practitioners. N. indicum yields indigo. ( Paxton’s Ed. Dict.)

OLIVE (Olea). This is a very important genus of plants, on account of the oil, &c., which is obtained chiefly from the O. Europaea. It is an evergreen, small tree, with lanceolate leaves, of a deep-green on the upper, and nearly white or hoary on the under surface. The flowers are small and white. The fruit is an elliptical drupe, of a bluish-purple colour when ripe. The tree lives to an extreme old age, and continues to bear good olives. It is also much admired for the fragrance of its flowers, which render it worthy a place in every green-house collection. They grow well in loam and peat; ripened cuttings root readily in sand, under a glass. They may also be increased by grafting on the common privet. The unripe fruit of the olive, preserved in salt and water, is a well-known article for the dessert.

With regard to the capacity of a portion of the Southern United States to produce the olive, the following extract from a communication of John Couper, Esq., will give interesting information:—

"I had a very pretty grove of 260 olives, imported about 16 years since, their stems from 8 to 12 inches diameter, and perhaps averaging 20 to 25 feet high to the top; they have borne fruit for some years past, and had also near 600 trees, or plants, from 11 to 5 years old. From comparisons between the olive and orange, in previous severe frosts, where the orange was much hurt, the olive was uninjured. I have, therefore, no hesitation in believing the olive is well adapted to, and will succeed on our sea-coast, of both Carolina and Georgia.

"I have been personally acquainted with sour-orange trees, both on St. Simon’s and Jekyll, for 58 years, and believe they were planted near 100 years since; and have never been killed by frost until last February, when they were all destroyed. I therefore conclude, that since the first settlement of Georgia the olive would have succeeded. It occurs to me that, notwithstanding the immense value of the olive in France, they have been cut down in some severe frosts.

"The olive and orange seemed so completely destroyed, even to some depth under ground, that I cut them down, and planted corn in their place; on examination about a month since, the lower roots still appearing fresh. I concluded that opening the ground around them might encourage vegetation; and have now the satisfaction to see the olives pushing out abundance of fine, strong shoots, not one failing. The oranges are doing the same, though some appear dead, not yet decided; by returning the earth to the olive shoots, they will throw out roots, and furnish fine plants. In fact, I am better satisfied respecting the success of the olive than I was before the severe frost." (Farmer’s Register, vol. iii. p. 246.)

OLIVE, THE AMERICAN ( Olea America). This American tree belongs exclusively to the Southern States, the Floridas, and Louisiana. Like the live-oak and cabbage-tree, it is confined to the sea-shore. "It is so little multiplied," says Michaux, "that it has hitherto received no name from the inhabitants of the
ONIONS.

country, except on the banks of the river Sa-
vannah, where it is called Devil wood.

"This tree grows in soils and exposures ex-
tremely different: on the sea-shore it springs
with the live-oak in the most barren and sultry
spots; and in other places it is seen with the
big laurel, the umbrella tree, the sweet leaves, &c., in cool, fertile, and shaded situations.

"This tree, or, to speak more accurately, this
large shrub, is sometimes 30 or 35 feet high,
and 10 or 12 inches in diameter; but this size
is extraordinary; it commonly fructifies at the
height of 8, 10, or 12 feet. The leaves are 4
or 5 inches long, opposite and lanceolate, en-
tire at the edge, smooth and brilliant on the
upper surface, and of an agreeable light-green.
They are evergreen, or at least are partially
renewed only once in 4 or 5 years. The fer-
tile and barren flowers are on separate trees:
they are very small, strongly scented, of a pale
yellow, and axillary, or situated between the
petiole of the leaves and the branches. The
season of flowering, in the neighbourhood of
Charleston, is about the end of April. The
fruit is round, and about twice as large as a
common pea. When ripe, it is of a purple
colour, approaching to blue, and consists of a
hard stone thinly coated with pulp. As it re-
mains attached to the branches during a part
of the winter, its colour forms, at this season,
an agreeable contrast with the foliage.

"The bark which covers the trunk of the
devil wood is smooth and grayish. The wood
has a fine and compact grain, and, when per-
fectly dry, it is excessively hard and very dif-
cult to cut or split; hence is derived the name
of devil wood. It is, notwithstanding, neglect-
et in use. On laying bare the cellular integu-
ment of the bark, its natural yellow hue changes
instantaneously to a deep red, and the wood,
by contact with the air, assumes a rosy com-
pexion. Experiments should be made to de-
tect the nature of this active principle in the
bark, which causes it to change colour so sud-
denly by exposure to the air.

"From the temperature of the native skies
of this tree, we may conclude that it is capable
of resisting a greater degree of cold than the
common olive: it becomes, then, on account
of its beautiful foliage, its odoriferous flowers,
and its showy fruit, a valuable acquisition."  

(Michaux.)

ONIONS (Allium cepa). Of this genus, there
are eight individuals that demand the garden-
er's care.

They all require a rich, friable soil, on a dry
substratum; a situation enjoying the full influ-
ence of the sun, and entirely free from trees,
which are very inimical to them, especially to
those which have to stand the winter. If the
soil be poor, or exhausted, abundance of dung
should be applied in the preceding autumn or
winter, and the ground thrown into ridges. By
these means it becomes well decomposed and
incorporated with the soil; for rank, unreduced
dung is generally injurious, engendering de-
cay, and inducing maggots; if, therefore, the
application of manure is neglected until the
spring, it should be taken from an old hoed,
or other source whence it is to be had in a
thoroughly putrescent state, and turned in only
to a moderate depth. Sea-sand, particularly
if the ground is at all tenacious, is advanta-
gegously employed; coal-ashes, and especially
soot, are applied with particular benefit. In
digging over the ground, small spits only should
be turned over; at a time, that the texture may
be well broken and pulverized. A consider-
able degree of attention is required from the
difficulty of giving the requisite degree of firm-
ness to light soils, which, if rich, are well suit-
ed to the growth of these vegetables. Old, soft,
or light, sandy soils, Mr. A. Gorrie, of Rait,
recommends to be dug rough in October, and
about January to have a top-dressing of cow-
dung applied and left on, to have its fertilizing
matters washed in until the time of sowing,
then as much as can be is to be raked off, and,
without digging, the seed sown, trod in, and
covered with earth from the alleys. By this
management, soils will produce good crops
which before were annually destroyed by the
maggot. Onions for pickling, as well as those
to stand the winter, should be grown on light,
poor soils, which cause the first to be small in
the bulb, and the latter, not growing so luxu-
riantly, to withstand the winter better.

There are 14 distinct varieties of this vege-
table, as appears from the description given by
Mr. C. Strachan, gardener to the Horticultural
Society of London.

1. Silver-skinned onion. 2. Early silver-
skinned. 3. True Portugal. 4. Spanish. 5.
keeping onion. 9. Pale-red. 10. Yellow. 11.
Lisbon.

In England the onion is raised from seed,
which may be sown for the first main crop to-
wards the close of February, if dry, open wea-
ther, otherwise only a small portion, in a warm,
dry situation. The principal crop, however,
must be sown during March, it being kept in
mind that the close of February is to be pre-
ferred, for the earlier the seed is inserted, the
finer will be the bulbs; many carelesly be even
be inserted as late as the beginning of April,
and, at its close, a small sowing to draw young
in summer, and for small bulbs to pickle;
again in July and early in August for salads in
autumn; and, finally, in the last week of Au-
gust, or early in September, to stand the winter
for spring and beginning of summer. The seed
is sown thinly, broadcast, and regularly raked
in. An ounce of seed is abundantly sufficient
for a rood of ground, especially for the main
crops, as they should never be allowed to grow
to a size fit for salads without thinning. No
other seed ought to be sown with it, for the
practice of stealing a crop is detrimental to
both crops, without the slightest advantage to
compensate. The beds should be divided by
narrow alleys into portions about four feet
wide, for the convenience of cultivation. In
about six weeks after sowing, the plants will
be of sufficient size to allow the first thinning
and small hoeing, by which they are to be set
out about 2 inches apart; if this is per-
formed in dry weather, it will keep the beds
free of weeds for six weeks longer, when they
must be hoed a second time, and thinned to
4 inches apart; and now, where they have
failed, the vacancies may be filled up by transplanting some of those thinned out into the places; the best time for doing this is in the evening, and water must be given for several successive nights. In transplanting, the root only is to be inserted, and no part of the stem buried; for there is very good reason to believe that not only the whole root, but the whole shoot, lies partly or entirely upon the surface, and that growing within the mould is a great cause of their not keeping well. After the lapse of another month they must be thoroughly gone over for the last time, the weeds eradicated, and the plants thinned to 6 inches asunder; after this they in general only require to be weeded occasionally by hand; they must, however, be kept completely free from weeds, and the stirring of the surface which the hoe effects is very beneficial. In order to prevent their running too much to blade, it is a good practice early in July, before the tips change to a yellow hue, to bend the stems down flat upon the bed, which not only prevents the rapid growth of the blade, but causes the bulbs to become much larger than they otherwise would be. The bend should be made about 2 inches up the neck.

About the close of August the onions will have arrived at their full growth, which may be known by the withering of the foliage, by the shrinking of the necks, and by the ease with which they may be pulled up. As soon as these changes appear, this must be taken up, the bed being frequently leeked, especially if the whole crop is waited for, the farthestest, especially in moist seasons, are apt again to strike root. They should be spread on mats, &c., in the sun, frequently turned, and removed under shelter at night. In 2 or 3 weeks, when the roots and blades are perfectly withered and void of moisture, and the bulbs become firm, they are fit for storing, being housed in dry weather, and carefully preserved from bruising: previous to doing this, all mould and refuse must be removed from them, for these are apt to induce decay, and spread contagion to all near them. To prevent this as much as possible, all faulty ones should be rejected: in the store-house they must be laid as thin as may be, and looked over at least once a month. Notwithstanding every precaution, many will decay, and more sprout, especially in mild winters; therefore, to preserve some for late use, it is useful to bear the roots and the summits with a hot iron, care being taken not to search the bulb.

For the winter standing crop the only additional directions necessary are, to tread in the seed regularly before raking, if the soil, as it ought to be, is dry and light. They must be kept constantly clear of weeds, as well as of the fallen leaves of trees, which cause them to spinkle and become weak, but they need not be thinned, as they serve as protections for each other. Early in spring they are to be weeded, and, as may be necessary, transplanted for bulbung. There are several modes of cultivation lately introduced or revived, which produce onions of superior size and goodness. The great object of the bulb grows entirely from these. England is the want of a sufficient continuance of warm weather; or, at least, the inclemency of the early part of the year prevents the insertion of the seed until so late, that the most genial season to vegetation passes away whilst the plants are in their infancy; it is the obviating this unfavourable circumstance that causes the superiority of the several plans hereafter detailed.

It should be observed that originated in America, and which has met with the decided approval of Mr. Knight and others, to sow in May; to cultivate the plants as in the other crops; and, in October, the bulbs, being of the size of nuts, are to be taken up, dried, and housed, as directed for the full-grown bulbs. About the middle of the following March they must be planted out in rows 6 inches apart each way, and afterwards cultivated in the same manner as the other crops. If sown earlier than May, they run to seed when transplanted. Another mode of early as efficacious, and which, I understand, has been practised for a great length of time in the south of England, is to sow in the latter part of April, to stand the winter, and in March, early or late, according to the forward growth of the seedlings, to be planted out in rows at the before-directed distance, and cultivated as usual.

In Portugal they sow in a moderate hotbed during November or December, in a warm situation, with a few inches of mould upon it; and the plants are protected from frost by hoops and mats; in April or May, when of the size of a man's thumb, they are transplanted into a light, rich loam, well manured with old rotten dung, to bulb.

It would seem, from the practice of Mr. McDonald, gardener to the Duke of Buccleugh, at Dalkeith, that transplanting alone is of great benefit. “His soil,” he says, “is not very favourable to the growth of the onion, being light and thin; and it was not until after many experiments he was able to obtain fine bulbs, and which he at length accomplished by sowing in the end of February, and about April transplanting them at the usual distance in drills, first drawing the root into a puddle consisting of 1 part soil to 3 parts earth, mixed with water; the work being performed in moist weather.” The puddle, as is observed by Mr. Sinclair, can be of no other use than to assist the rooting of the plants.

To obtain seed, some old onions must be planted during February, or early in March. The finest and firmest bulbs being selected, and planted in rows 10 inches apart each way, either in drills or by a blunt-ended dibble, the soil to be rather poorer, if it differs at all from that in which they are cultivated for bulbung. They must be buried so deep that the mould just covers the crown. Early in spring their leaves will appear. If grown in large quantities, a path must be left 2 feet wide between every 3 or 4 rows, to allow the necessary cultivation. They must be kept thoroughly clear of weeds, and when in flower have stakes driven at intervals of 5 or 6 feet each side of every 2 rows, to which a string is to be fastened throughout the whole length, a few inches below the heads, to serve as a support, and prevent their being broken down. The seeds are ripe in August, which is intimated by the
husks becoming brownish: the heads must then be immediately cut, otherwise the receptacles will open and shed their contents. Being spread on cloths in the sun, during the day, and taken under cover every night and during inclement weather, they soon become perfectly dry, when the seed may be rubbed out, cleaned of the chaff, and, after remaining another day or two, finally stored. It is of the utmost consequence to employ seed of not more than one year old, otherwise not more than 1 in 50 seeds will vegetate.

The goodness of seed may be easily discovered by forcing a little of it in a hotbed or in warm water, a day or two before it is employed: a small white point will soon protrude if it is fertile.

Onions are raised in large quantities, in the town of Weathersfield, Connecticut, for exportation to the West Indies and Southern States. The business is there reduced to a perfect system. Early in spring the land is manured, by ploughing in fine manure from the stable or barn-yard, in the proportion of about 10 loads to the acre. That of neat cattle is preferred, as that of horses is considered to be of too heating a nature. It is then well harrowed and laid out into beds of 5 feet wide, by turning a furrow towards them each way; this raises the beds above the alleys, and allows the surplus water to run off. They are then well raked with an iron-toothed or common hay rake, and the alleys suffered to remain as left by the plough.

As early as the season will admit, the seed is sown in the following manner. A rake, with teeth a foot apart, is drawn crosswise of the beds, and drills made for the reception of the seed; it is then sown with the thumb and fingers and covered with the hand, allowing 10 or 12 lbs. to the acre. After the plants are up, they are kept clean of weeds, which generally requires four weedicings, using a hoe of suitable width to pass between the rows, which saves much labour. When ripe, they are pulled, and the tops cut off to a suitable length for tying them to the straw in roping. Three and a half pounds are required by a law of the state to be put in each rope; and the ordinary crop is from 6 to 8000 ropes to the acre.

Onions may be raised in the same way in the Middle and Southern States, though the more common practice is to grow them from small bulbs raised from seed the previous year, by sowing thickly in rows, about 9 or 10 inches apart, about the middle of spring; if sown too early, they are apt to run to seed when transplanted. Cultivate and preserve as for full-grown bulbs. Plant early in spring, in well manured ground, in rows about 6 inches apart, and 5 inches in the row, allowing about 18 inches after every fifth row as an alley for convenience in weeding.

If the land is at all light, it is a good practice to tread or roll well before sowing or transplanting, and be careful to disturb the bulbs as little as possible in weeding.

Potato, or under-ground Onion.—This species of *Allium* has received the above appellations, on account of its producing a cluster of bulbs or offsets, in number from 2 to 12, and even more, uniformly beneath the surface of the soil.

From being first introduced to public notice in Scotland, by Captain Burns of Edinburg, it is there also known as the Burn onion. There evidently appear to be two varieties of this vegetable, one of which bears bulbs on the summit of its stems, like the tree onion, and the other never throwing up flower-stems at all. One variety is much larger than the other, and this vegetables again as soon as ripe.

Both varieties are best propagated by offsets of the root, of moderate size; for if those are employed which the one variety produces on the summit of its stems, they seldom do more than increase in size the first year, but are prolific the next; this also occurs if very small offsets of the root are employed.

They may be planted during October or November, or as early in the spring as the season will allow, but not later than April. In the west of England, assisted by their genial climate, they plant on the shortest and take up on the longest day. They are either to be inserted in drills, or by a blunt dibble 8 inches apart each way, not buried entirely, but the top of the offset just level with the surface. Mr. Maher, gardener at Arundel Castle, merely places the sets on the surface, covering them with leaf mould, rotten dung, or other light compost. The beds they are grown in are better not more than 4 feet wide, for the convenience of cultivation.

The only cultivation required is to keep them clear of weeds. Their practice of earthing the mould over them when the stems have grown up is unnatural, and by so doing the bulbs are blanched and prevented ripening perfectly, on which their keeping depends. So far from following this plan, Mr. Wedgewood of Betley recommends the earth always to be cleared away down to the ring whence the fibres spring, as soon as the leaves have attained their full size and begin to be brown at the top, so that a kind of basin is formed round the bulb. As soon as they vegetate, they intimate the number of offsets that will be produced, by showing a shoot for each.

They may thus be brought towards the end of July, and become completely ripe in early September; for immediate use they may be taken up as they ripen, but for keeping, a little before they attain perfect maturity, which is demonstrated by the same symptoms as were mentioned in speaking of onion.

**Onion, the Welsh, or Ciboule.**

This is a perennial, which never forms a bulb, but is sown annually, to be drawn young for salads, &c.; on account of its strong taste, it is greatly inferior to the common onion for this purpose; but from its extreme hardness in withstanding the severest frost, it may be cultivated with advantage as a winter standing crop for spring use. In France two varieties are in cultivation, the white and the red; the first of which is the one in general use in England. As it may be sown at all times, in common with the onion, and is similarly cultivated, except that it may be sown thicker, and only thinned as wanted, the directions given for that vegetable will suffice. The blade usually dies away completely in winter, but fresh ones are thrown out again in February or March.
ONION, THE TREE.

To obtain seed, some of the roots must be planted out in March, 6 or 8 inches asunder. The first autumn they will produce but little seed; in the second and third, however, it will be produced abundantly. If care is taken to part and transplant the roots every two or three years, they may be multiplied, and will remain productive for many years, and afford much better seed than that from one-year old roots. There is good reason for concluding, as Mr. T. Milne, of Fulham, ingeniously explains, that by a confusion of names, arising from similarity of appearance, this vegetable is the true scallion of Miller and others, whilst the hollow leek of Wales is the true Welsh onion; for the description of scallion, as given by Miller, accords exactly with that of the Welsh onion; and as he describes it as a distinct variety, we are reduced to the dilemma of receiving this explanation, or considering the variety as lost; for from Miller's known accuracy it is impossible to consider that he was deceived. At present all onions that have refused to bulb, and formed lengthened necks and strong blades in spring and summer, are called scallions.

ONION, THE TREE, or CANADA (Allium Caucadeus). This, which is a very hardy perennial species, like the ciboule, is without a bulbous root, but throws out numerous offsets. Its top bulbs are greatly prized for pickling, being considered of superior flavour to the common onion for that purpose, as well as other in which that species is employed.

It is propagated both by the root offsets, which may be planted during March and April, or in September and October, and from the top bulbs, which are best planted in spring, and not before the latter end of April. The old roots are best to plant again for a crop of bulbs, as they are most certain to run to stems. If the bulbs be planted earlier than as above directed, they are apt to push up the same season, and exhaust themselves without producing either good offsets or bulbs; but on the other hand, by planting the old roots in the previous autumn, it is found that they produce good bulbs the same year. They must be inserted in rows 12 inches asunder, in holes 6 inches apart and 2 deep, a single offset or bulb being put in each. Those planted in autumn will shoot forth leaves early in the spring, and have their bulbs fit for gathering in June, or the beginning of July; those inserted in the spring will make their appearance later, and will be in production at the close of July or early in August: they must not, however, be gathered for keeping or planting until the stalks decay; at which time, or in the spring also, if only of one year's growth, the roots may be taken up and parted if required for planting; but when of two or three years' continuance, they must at all events be reduced in size, otherwise they grow in too large and sprawling bunches; but the best plan is to make a fresh plantation annually with single offsets. The only cultivation necessary is to keep them clear of weeds; and when the stems run up, to give them the support of stakes.

The bulbs, when gathered, must be gradually and carefully dried in a shady place; and if kept perfectly free from moisture, will continue in good state until the following May. (G. W. Johnson.)

OPEN. A term frequently applied to crows or heifers, signifying that they are not in calf.

OPEN CUTS. Such drains or gutters as are made in land by the spade, and left without being covered in. They are used in draining lands in particular cases. Open cuts, if efferent, are the best of all for forest draining, as they cannot be inconvenient, from the plough not being employed after the trees are planted. Cuts of this sort are found frequently useful in the practice of irrigation or watering of land.

OPHTHALMIA. See Sneeze, Diseases of.

ORACHE. (Atriplex; from atris, black). A genus of herbaceous or shrubby straggling plants of little beauty, and the simplest culture and propagation. There are in England several native species.

The A. hortensis is cooked and eaten in the same manner as spinach, to which it is much preferred by many persons, although it belongs to a tribe whose wholesomeness is very suspicious. It flourishes best in a rich, moist soil, and in an open compartment. Those, however, of the autumn sowing, require a rather drier soil. It is propagated by seed, which may be sown about the end of September, soon after it is ripe, and again in the spring, for succession; the sowing to be performed broadcast, the seeds being scattered thin. The plants soon make their appearance, being of quick growth. When they are about an inch high, they must be thinned to 4 inches asunder; and those removed may be planted out at the same distance in a similar situation, and watered occasionally until established. At the time of thinning, the best must be thoroughly cleared of weeds, and if they are again hoed during a dry day, when the plants are about 4 inches high, they will require no further attendance than an occasional weeding by hand.

For early production, a sowing may be performed in a moderate hotbed at the same times as those in the natural ground.

The seed gathered for use whilst young, otherwise they become stringy and worthless. To obtain seed, some plants of the spring sowing must be left ungathered from, and thinned to about 8 inches apart. The seeds ripen about the end of August, when the plants may be pulled up, and when perfectly dry, rubbed out for use.

ORANGE, OSAGE (Macura aurantiaca). This is an American deciduous tree, which grows wild in Arkansas and Louisiana, where it attains the height of a tree of the second or third class, but in the Middle States it seldom grows higher than 15 or 20 feet. It is very branching; each branch being armed with numerous sharp thorns. The wood is remarkably tough, and said to be very durable. The male and female flowers are on separate trees. The fertile or female tree bears fruit abundantly in a very few years. These are round, rough, and greenish-coloured, resembling somewhat an orange, and weighing from 12 to 18 ounces, containing from 100 to 250 seeds.

Recently this thorny tree has received very considerable attention, with a view to making it useful in the construction of live fences,
which purpose it is extensively cultivated in nurseries. "Its great merit," says Mr. T. S. Pleasants, of Virginia, "consists in the spreading manner of its growth, the denseness of its branches, and the armature with which they are furnished. Planted in hedge-rows, the malura would never become unmanageable on account of its size; at the same time its growth is sufficiently vigorous to make a fence in 3, 4, or at most 5 years, from the seed. It may be asserted with safety, that on land of tolerable fertility, the labour and expense of perfecting a system of hedges would not be greater than to keep ordinary enclosures in good condition for the time required to construct them."

"The Osage orange trees are readily raised from the seed, which, unlike those of the common thorn, require no preparation. On the contrary, they vegetate with certainty in 2 or 3 weeks after planting. With tolerable care the seedlings will grow 2 or 3 feet in height the first season; after which they are to be removed from the nursery rows to the place designed for the hedge. Fifty of the large orange-shaped berries yield at least a pound of seed, or from 8 to 10,000 grains. It is the usual practice to place the sets from 12 to 15 inches apart, in a single row."

"(Farmers' Register, vol. 5, p. 86.)"

Though originally from a southern locality, the Osage orange is so hardy as to stand the winters not only of the Middle, but of the Eastern States.

ORANGE TREE (Citrus). The genus to which the orange tree belongs consists of ornamental species of fruit trees, growing from 3 to 15 feet high. The leaves are on more or less dilated and winged footstalks; the flowers are large, white, and odoriferous, existing at the same time as the fruit, which is too well known to require description. Orange trees thrive best in a good loamy soil, mixed with a quantity of rotten dung. The different kinds are procured by budding or grafting on common stocks. Stocks for working upon are raised from any oranges, lemons, &c. They are sometimes raised from cuttings, in which case they produce fruit when very small plants. The flowers of the orange tree yield, by distillation, a fragrant volatile oil, known by the name of oil of Neroli. The fruit of the bignarroll or bitter orange makes one of the best preserves which can be eaten, namely, Scotch marmalade. The unripe fruit is used for flavouring the liquor called curaçoa. The ripe fruit is wholesome, and a useful refrigerant in fevers.

ORANGE, WILD. See Cerney, Wild.

ORCHARD (Gr.). In horticulture, an enclosure devoted to the culture of fruit trees. In England the surface of the soil in orchards is generally kept under pasture; which, while it prevents the earth from being washed away by rains, is favourable to the running of the roots immediately under the surface, by which they are sooner called into action by heat in spring, and sooner thrown into a torpid state by cold in autumn. The principal fruits grown in orchards of this description in Great Britain are the apple, the pear, the plum, and the cherry; and wherever wheat can be ripened in the plains, these fruits will arrive at perfection on declivities exposed to the south and south-east.

ORCHIDACEE (Orchis, one of the genera). A natural order of herbarious endomycetes, inhabiting all parts of the world, excepting those climates situated upon the verge of the frozen zone, or remarkable for their exceeding dryness. They are well known for the singular form of their flowers. Some of them grow in the earth, others inhabit rocks and the branches of trees, and a few appear to be true parasites. They all belong to the class Gymnandra of Linnaeus, are often very agreeably scented, and sometimes produce an aromatic fleshy fruit, as in the case of the vanilla, which contains a large quantity of benzoic acid. The nutritious substance called salep is prepared from the amylaceous tubers of the male orchis, merely drying them in ovens. They become semi-pellucid, and when pulverized, form a mucilage with boiling water. They are usually grown in the frame or hothouse, and thrive best in a mixture of loam, peat, and chalk, broken small. They can only be increased from seeds. It would be quite impossible to describe the characters of each species.

The species indigenous to England are—

OREGON ALDER (Alnus Oregona). A species of the alder genus, which, like the European alder, attains the height of 30 or 40 feet. (Nutall's Supplement to Mierswar.)

ORGANIC CHEMISTRY, is that portion of the science of chemistry which relates to animal and vegetable substances. "The object of organic chemistry," says M. Liebig, "is to discover the chemical conditions which are essential to the life and perfect development of animals and vegetables, and generally to investigate all those processes of organic nature which are due to the operation of chemical laws." In this article I shall confine myself principally to the results obtained by the analysis of vegetable and animal substances. Under the heads Atmosphere, Earth, Gases, Temperature, Water, &c., will be found an account of their respective uses to vegetation.
There is no branch of chemistry more difficult, and yet more interesting, than that of organic chemistry; for in this the chemist finds, added to his ordinary difficulties, and to his many sources of uncertainty, the presence, and very often the controlling influence, of a living principle, which in some instances seems to neutralize and overcome even the most powerful chemical affinities. "I would warn, therefore, the reader," to use the words of Dr. Thomson, "not to expect complete information in this branch of science: the wonders of the vegetable creation are still but very imperfectly explored; many of the organs of plants are too minute for our senses, and scarcely a single process can be completely traced. The multiplicity of operations continually going on in the vegetable at the same time, and the variety of different and even opposite substances formed out of the same ingredients, and almost at the same time, astonish and confound us; the order, too, and the skill with which every thing is conducted, are no less surprising; no two operations clash; there is no discord, no irregularity, no disturbance; every object is gained, and every thing is ready for its intended purpose. This is too wonderful to escape our observation, and of too much importance not to claim our attention. Many philosophers, according, distinguished equally by their industry and sagacity, have dedicated a great part of their lives to the study of vegetation. But hitherto their success has not been equal to their exertions. No person has been able to detect the formative agent in plants, nor even the principle which is always so busy in performing such wonders, nor to discover him at his work; nor have philosophers been much more fortunate in their attempts to ascertain the instruments which he employs in his operations." A great variety of curious and interesting facts, however, have been discovered. These I shall attempt to collect and arrange, to point out the resemblance, and deduce from each other, and to deduce such consequences as obviously result from the discoveries which have been hitherto made.

The farmer will, upon reflection, be able to call to mind many circumstances, showing the influence of the living principle upon the chemical substances of organic matter. He will remember, for instance, that the living substance flourishes in the very same position, and under the very same circumstances, where, when dead, it rapidly putrefies. Every plant grown on the soil, or on a unburnt dungheap, testifies to the fact. The living plant, which flourish in the same solution of a salt in which they are dissolved, when dead, prove the same thing in another way; and these proofs may be multiplied very easily on very slight reflection. And as regards animal life, the very same results are obtained; the very gastric juice which the living stomach holds for an age, dissolves that stomach when dead. Animals can sustain a temperature considerably greater than that where the putrefaction of animal substances rapidly proceeds; and men even can exist for a considerable period in an atmosphere heated considerably above boiling point of water.

In this sketch of organic chemistry, I shall principally confine myself to the vegetable branch of it, and briefly follow the progress of a plant through its several stages of germination, its growth, and its decay, leaving the reader to refer to other heads of this work for the information he may need.

Germination. That all plants arise from seeds is now, I believe, undisputed by every person, notwithstanding the very many puzzling phenomena which occasionally occur; such as the profusion of some of the grasses, occasioned by the application of certain natures. Thus, "by dressing certain soils with bones and wood ashes, the white clover, which contains this salt, appears in great quantities. Now, phosphat of lime abounds in bones and in the ashes of wood; other plants, it is probable, require the same food. Thus, after the great fire of London, says Mr. Playfair, large quantities of the Erysimum latifolium were observed growing on the spots where a fire had taken place. On a similar occasion, the Bellis capitatum was seen at Copenhagen, the Senecio vicosus in Nassau, and the Spartium scoparium in Languedoc. After the burnings of forest pine in North America, poplars, according to Franklin, grew on the same soil. (Liebig's Org. Chem. p. 152.) Seeds, therefore, the farmer may rest assured, are essential to the production of plants. Now, the first movement of the seeds towards the production of plants is denominated their germination. To this certain requisites are essentially necessary; such as moisture, moderate heat, and oxygen gas. That all seeds require a certain degree of moisture before they will vegetate, is known to every one: where there is no moisture, there can be no germination. This, however, varies according to the nature of the plant. Some of the mosses, for instance, will germinate on walls and other places where the supply is very limited; others, such as the water plants, will only grow immersed in water. The seedling of rice in its growth is abounding with water, which would be destructive to all the grain crops of the English farmer. The water-meadow grasses of our own country illustrate the same position. The plant, too, has the power of decomposing water, and assimilating its hydrogen in the formation of its own substances. Water is composed of hydrogen and oxygen, and these substances are always essential ingredients in vegetables.

Heat is also necessary to germination: thus few plants will vegetate below the freezing point of water; nevertheless, this low temperature does not destroy their vitality, for every farmer is aware that frozen seeds will vegetate after they have been thawed. As, however, there is a peculiar degree of moisture on which every plant vegetates with the greatest advantage, so there is a temperature peculiarly favourable to the growth of every plant. The ivy, the elder, and the honeysuckle, for instance, invariably produce their leaves long before any other English plant has felt the warm reviving influence of spring.

And, again, if the soil is not supplied with oxygen gas, the most favourable supplies of moisture and heat will not induce it to germi
nate. Ray tried this in the vacuum of an air-pump with some lettuce seed; they did not germinate in vacuo, but they grew very well when the atmospheric air (which contains 21 per cent. of this gas) was admitted. It is for this reason that the farmer is careful not to bury his seed-corn so deep in the ground as to be out of the influence of the oxygen of the atmosphere. Beyond a certain depth, which varies with different plants, no seeds, in fact, will vegetate. Seeds have been buried deep in the earth for centuries, and when, afterwards, they have been accidentally thrown upon the surface, have vegetated. There is reason for believing that it is not the entire atmospheric air, but only its oxygen, which is essential to germination. In the experiments of M. Saussure, the quantity of oxygen consumed by various plants during their germination varied very considerably in amount. Wheat and barley, weight, for weight, consumed less oxygen than peas; and peas less than beans and kidney-beans. The oxygen consumed by wheat and barley amounts to between 10 and 11 parts of their weight, while that consumed by beans and kidney-beans may amount to 11 parts of their weight. The oxygen absorbed by the seed is in all probability combined with the carbon of the plant, and emitted during its germination, in the state of carbonic acid gas. This gas is composed entirely of carbon and oxygen, in the proportion of 6:12 parts of the former and 16 of the latter; and the quantity of it emitted is exactly equal in amount to the quantity of oxygen absorbed by the seed that should unite with the carbon of the plant, to form the carbonic acid gas, and a certain quantity of carbon is always lost by the seed during vegetation.

When once a plant has vegetated, its growth proceeds with more or less rapidity; none that I am aware of remain stationary; indeed, it cannot remain stationary, and live. They increase in size, require a supply of various substances as food, and the examination of the nature of this nutriment constitutes one of the most valuable branches of organic chemistry; for under this head are included the assistance afforded to plants by the gases of the atmospHERE. In the examination of the food of plants will also be illustrated the important questions of rotation, of fertilizers, and of various other important questions, which in this work will be found treated of under their respective heads; and it will be useless to repeat what I have there at some length endeavoured to illustrate. That the atmosphere yields its carbon and its oxygen; the soil its silica, alumina, and magnesia, with various saline matters; and that water yields both hydrogen and oxygen for the service of the plant, is pretty well established by many valuable experiments which I have there given; and it is impossible to observe the results of the analysis of a perfect plant without being struck with the number of its ingredients, and perceiving at once the probable sources from whence it drew its supply. Take, for instance, the analysis by M. Cadet of the solid matters or ashes of the common garlic. From 172 parts of these he obtained of

| Potash   | 33.44  |
| Sulphate and muriate of potash | 58.26  |
| Alumina | 2.38   |
| Phosphate of lime | 15.64  |
| Oxide of iron | 1.56   |
| Magnesia | 0.46   |
| Lime    | 1.48   |
| Silica  | 8.5    |

All these substances, there is little doubt, were absorbed by the plant from soil in which it grew; but in the fresh or unburnt garlic these are combined with about eight times their weight of muclage, albumen, sulphur, vegetable fibre, and water. Now the three first of these must have been formed during the growth of the plant, from either the atmosphere or from water; the first (the atmosphere) being composed of oxygen, nitrogen, and carbonic acid; and the latter (water) of hydrogen and oxygen. Muclage was found by M. Berzelius to be composed of

| Oxygen | 51.96  |
| Carbon | 41.96  |
| Hydrogen | 6.788  |

Albumen contains, according to the analysis of MM. Gay Lussac and Thenard,

| Carbon | 52.882  |
| Oxygen | 22.873  |
| Hydrogen | 7.519  |
| Nitrogen | 17.73  |

The same excellent chemists have shown woolly fibre to be composed of

| Oxygen | 48.25  |
| Carbon | 59.56  |
| Hydrogen | 5.75  |

The chief vegetable matters of the garlic, therefore, the student will remark (and the same conclusion applies to other vegetables), are composed entirely of two or three principal ingredients. The composition of all plants is, in fact, much more similar than is commonly supposed. For instance, all the vegetable acids, such as vinegar (acetic acid), sugar, gum, starch, woody fibre, &c., are composed of three substances, viz., carbon, oxygen, and hydrogen, arranged in different proportions, as may be seen from the following table:

| Acetic acid (vinegar) | 26.566 | 33.841 | 41.474 | 5.629 |
| Citric acid (lemons) | 33.841 | 59.859 | 6.320 |
| Oxalic acid (green sorrel) | 28.533 | 70.699 | 9.745 |
| Sugar | 42.47 | 50.63 | 6.90 |
| Starch | 43.69 | 49.69 | 6.77 |
| Gums | 42.23 | 50.84 | 6.92 |
| Woody fibre of the oak | 35.53 | 41.75 | 5.69 |
| Woody fibre of the beech | 51.45 | 48.73 | 5.82 |

The decomposition of vegetable substances.—All dead vegetable substances, when left to themselves, under favourable circumstances, speedily decay, or decompose, and are resolved into their constituents. This is commonly effected in two ways, either by fermentation or by putrefaction.

4 D 965
fraction; to this last phenomenon several requisites are necessary; moisture must be present, and the temperature must not be below 32° of Fahrenheit; in fact, it proceeds with extreme slowness at a temperature below 45°. It is retarded in its progress by the absence of the atmospheric air, but its presence is not essential: when water, however, is entirely absent, putrefaction cannot proceed.

The disagreeable odour which is emitted during putrefaction is owing to the gaseous substances which are generated. Those plants which contain nitrogen emit ammonia: onions produce phosphuretted hydrogen. By all of them carbonic acid gas and carburetted hydrogen gas are emitted in considerable quantities. These gases, being, when presented to the roots and leaves of plants, exceedingly invigorating, are one of the causes of the increased luxuriance of all crops manured with green vegetable matters. When the putrefaction of the vegetable substance is at an end, the carbon, hydrogen, and oxygen, of which it is composed, are gone and only remains but the earths and salts with which the purely vegetable matters were once combined in the plant. The ashes which are left when putrefaction ceases, are in fact nearly the same as those left after combustion. See Putrefaction.

Animal substances.—The analysis of animal substances is attended with all the difficulties to which I have alluded as attendant upon the examination of vegetable substances; and the progress of chemical philosophy has not yet succeeded in demonstrating the composition of any great proportion of the many substances met with in the animal world. The great mass of animal matters contain nitrogen, and this is the chief general chemical difference between animal and vegetable substances; hence, when animal substances purify, ammonia is disengaged, for this alkali is composed of nitrogen and hydrogen.

The following analysis of several animal matters will show how generally present is nitrogen in this class of substances:

<table>
<thead>

These are the chief animal substances of which most others are compounded. Thus the principal solid matter of animal muscle is fibrin. The outer skin or cuticle of animals is composed of from 93 to 95 per cent. of albumen. The solid matter of the blood is chiefly composed of the same substance. Under the heads Animal Manures, Fish, Bones, Gelatin, &c., the reader will find all the animal chemistry bearing upon farming and rural affairs, with which I am acquainted. The relative proportions of the inorganic constituents of vegetable substances forms a topic of great interest; and Professor G. F. W. Johnston's lectures upon the subject, just published, will be read with satis-

fraction. See Lect. IX, on the Application of Chemistry and Geology to Agriculture.

ORNITHOLOGY (Gr.). The science which teaches the natural history and arrangement of birds.

OSIER. The name given to various species of willow or salix, chiefly employed in basket-making. Although under the heads Sallow and Willow are noticed most of the species of this genus, it may be well to describe in this place, a few of which are more generally known under the name osier. Osiers differ fromallows in their long, straight, flexible, and mostly tough twigs; thin, generally sessile germs, and elongated styles and stigmas. The osier forms a hardy and useful hedge for excluding boisterous winds; and as it flourishes in wet situations is frequently planted with a view to prevent the banks of rivers being washed away by the force of the current. Osiers are divided into two classes: the first is known by their blunt and downy or mealy leaves, which in the other are more pointed, smooth, and green, resembling the myrtle.

The common osier (S. viminalis) is one of the most abundant species. This tree is found growing in wet meadows, osier-holts, the banks of rivers, and other moist situations. The branches are straight, erect, wand-like, very long and slender, round, polished, downy when young, with fine silky hairs. Leaves on short foot-stalks, almost upright, about a span long, and half an inch wide. The value of the common osier for various kinds of basket-work is universally known.

There is a variety much esteemed, called the velvet osier, in which no external difference is discernible, but the twigs are said to be more pliant. There are also various species as well as varieties comprehended under the name of osiers, some of which, having smooth leaves, are noticed under the articles Sallow and Willow.

The silky-leaved osier (S. smithiana) is a shrub found growing in meadows and osier grounds, the branches of which are brittle and unfit for basket-work. It is therefore important for cultivators of osiers to distinguish carefully between this and the velvet osier; for while the latter is, for some sorts of work, greatly esteemed, the silky-leaved osier proves of no utility.

The auricled osier (S. stipularis) is a common species in osier-holts, hedges, and woods, and is easily known at first sight by its coarse, tall habit, and conspicuous stipules, but not worthy of cultivation for any economical purpose. The twigs are upright, tall, soft, and downy, of a pale reddish-brown, brittle, and of little or no use as an osier.

The fine basket osier (S. Forbiana) is a shrub grown in the meadows and osier-holts of the eastern part of England. The stem is erect, bushy, with upright, slender, smooth twigs, very flexible and tough, of a grayish-yellow, not purple hue, highly esteemed and much cultivated for the finer kinds of basket-work.

Green-leaved osier (S. rubra). This is a small tree, with long, upright, smooth, grayish or purplish, more frequently tawny branches, very tough and pliant, this being one of the
most valuable osiers when cut down annually. The very long and narrow leaves of this rather rare species agree in shape with the common osier (*S. viminalis*), but want its dense white pubescence.

In the fens of the east of England many harts (as they are provincially called) or plantations of osiers are raised, which beautify the country, keep the stock warm in the winter, and provide much useful wood for baskets and all kinds of wicker-work. The mode of planting is very simple; it is, first, to dig the land from 6 to 12 inches deep, and then to prick down cuttings of 4 years' growth, and mark them with bricks, long, at about 3 feet distance from each other. The soil may be moor or clay, or any that is low and wet.

These harts or osier plantations must be fenced round, either with dikes, which are most common, or with hedges. The proper season for making them (they seldom fail of growing at any time), is from the fall of the leaf till very late in the spring.

**OSIER, GOLDEN, or YELLOW WILLOW.**

See WILLOW.

**OUZE.** A deposit made by the sea.

**OVEN.** A domestic furnace used for baking bread, pies, tarts, &c. Ovens are generally constructed of brick-work in a semicircular form, with a very low roof, and the bottom of which is laid with stone: in the front is a small aperture and door, by the shutting of which the heat is confined while the bread is baking. They are usually heated by means of dry faggots, wood, &c. As these ovens, however, are not calculated for small families, on account of the quantity of fuel they consume, others have been contrived, on a more diminutive scale: these are usually formed of cast or hammered iron, and may be heated by the same fire which serves for the cooking of other provisions; but for baking bread these ovens are inferior to the brick ovens.

**OVERLAND FARM.** A provincial phrase usually applied to a parcel of land without any building or house attached to it.

**OVER-REACH.** See Clicking.

**OVER-YEARS.** A country term applied to such bullocks as are not finished fattening at three years old when home-breeds, or the first winter after buying in; but kept through the following summer to be finished the next winter.

**OVIPOSITOR** (Lat. *ovum*, an egg; and *peno*, I place). In entomology, is the instrument by which an insect conducts its eggs to their appropriate nidus, and often bores a way to it; the same instrument is in some genera used as a weapon of offence, whence it is called the "aculeus." In the gall insect, and some others, the ovipositor is furnished at its root with a sac containing an acid secretion, which is deposited in the wound made by the ovipositor at the same time as the eggs.

**OWLING.** In law, so called from its being generally committed during the night. An offence consisting in conveying sheep or wool to the sea-side, in order to export them clandestinely. The offence was formerly capital, particularly if the offender neglected to surrender after proclamation made for that purpose.

**OWLS.** A tribe of reptorial birds, including those which fly by night, and have the eyes directed forwards. The owl, although frequently held in disrepute, should never be destroyed by the farmer, to whom he is a great friend; for his diet consists chiefly of field-mice, of which he consumes large numbers. The owls are usually arranged into two principal groups: one in which all the species exhibit two tufts of feathers on the head, which have been called horns, ears, and egrets; in the second group, the heads are smooth and round, without tufts.

**OX.** Synonymous with the generic name *Ovis*; in a more restricted sense, it signifies the castrated male of the domestic variety. See CATTLE.

**OXALIC ACID.** See Acids.

**OXALIS CRENATA.** A perennial ornamental plant, native of Chili, lately discovered by Mr. Douglas. The flowers are beautiful, of a yellow colour, and in umbels; the stalks and leaves are succulent, of an acid taste, and useful as salads; the roots or tubers are produced in clusters; their taste, when boiled, somewhat resembles a chestnut. They are raised from the tubers, are extraordinarily productive, as easily cultivated as the potato, and decidedly superior in flavour. They require a rich soil, and, like the potato, are stored during winter in cellars. (Kenrick.)

**OX-BOOSE.** Provinciall, a stall or place where oxen stand in the winter to be fed or fattened.

**OX-EYE** (*Chrysanthemum*, from *chrysos*, gold, and *anthemum*, a flower; alluding to the colour of some of the flowers). The great white ox-eye mauve-wort, or moor daisy (*C. leucanthemum*), Pl. 10, is very common in pastures, fields, and by way-sides. The flavour of the whole plant is herbaceous, slightly, not pleasantly, aromatic. Its properties are not important; like many other herbs, mixed with grasses, it makes a part of the hay crop. The root is branched, tough, and woody, with many fibres. Stem erect, simple, or branched, according to the soil, from one to two feet high. Leaves deep-green, clasping the stem, oblong, obuse, cut, pinnatifid at the base; radical ones obovate, stalked. Flowers large, terminal, solitary, not inelegant, with a broad yellow disk, and brilliant white radius. See DAISY.

Another wild indigenous species, the yellow ox-eye (*C. segementum*), has already been noticed under the head CORN MARIGOLD.

**OX-FEET.** A term applied to the feet of horses when the horn of the hind feet cleaves just in the middle of the fore part of the hoof, from the coronet to the shoe: they are not common, but very troublesome.

**OX-HARROW.** A term applied to a very large sort of harrow, called in some counties of England a drag.

**OX-LIP.** See COWSLIP.

**OX-LIP GAS.** A simple or undecomposed substance, discovered in 1774 by Dr. Priestley. It constitutes 21 per cent. of the atmosphere, and it is that portion of it which supports animal life and combustion. It is emitted by plants growing in the light, and is absorbed by them during the night. It is found in combination with hydrogen and carbon, and
less often with nitrogen, in all vegetable and animal substances. It unites with various bases, and forms alcalies, acids, and metallic oxides. It is tasteless, and soluble in water, which at a temperature of 60° absorbs about \( \frac{3}{2} \) of its bulk. One hundred cubic inches of this gas weighs about 34 grains. See Gases, their Uses to Vegetation.

**OYSTER SHELLS.**

As a manure, the use of crushed oyster shells has never been so extensive in England as in Ireland; and for this neglect several causes have contributed. They are composed principally of carbonate of lime, chalk, and a memhraneous substance; are in consequence not nearly so valuable as crushed bones, which contain the phosphate of lime; are not to be obtained but at particular seasons of the year; and, unless pulverized, are not sufficiently quick in their effects to encourage the farmer to use them unbroken. In England they have been, therefore, little employed; even in those districts, such as the clay and sand formation, where, from the absence of carbonate of lime in the soil, the calcareous matters of the oyster shells would be a very valuable addition. In Ireland, which is almost entirely destitute of chalk, the use of the broken oyster shells has been more considerable than in England; and in Dublin the parish authorities, in hard seasons, are glad to set the paupers to work to collect and break the shells which are thrown away as rubbish; and I am informed that the money received for the powdered shells affords a very tolerable remuneration for the labour bestowed in their preparation. The mother-of-pearl with which the oyster shells are lined is similar in composition to the outer shell or crust. This has been analyzed by M. Merat Guillot, who found in 100 parts of mother-of-pearl,

Powdered oyster shells should always, if possible, be drilled in with the seed; for, by thus coming into close contact with the plant, all the volatile and earthy constituents of the decomposing shell are absorbed by its roots and leaves with the greater readiness, from being placed more immediately in contact with them. In this way they have been found to answer very well on the light, sandy soils of Norfolk, when drilled in with the turnip seed, as will be seen from the following account of Mr. Blakie, in a letter to Sir John Sinclair, dated Sept. 18, 1818:—"Oyster shells pounded or bruised (without having been burned) were first used upon Mr. Coke's farm as a manure in the year 1816. In the summer of that year, the experiment was tried upon a hungry, light, sandy soil, which had been cleared for turnips. The oyster shell dust, or powder, was drilled in the usual way, upon 27-inch ridges, at the rate of 40 bushels per acre (without any other manure), was slightly covered with earth, and the turnip seed sown upon it. Another part of the same field, quality of land equal, was manured with farm-yard dung, at the rate of 8 tons per acre, put into the same sized ridges, and sown with turnip seed as before described, no other manure having been applied. The turnips proved a good crop on both pieces; nor was there any perceptible difference in the bulk, but the produce was not weighed. The turnips were all eaten upon the ground by sheep; and the succeeding crop, barley, was good on both, and apparently equal, as the produce was not thrashed separate. The seeds or layer crop of clover, in the present season, 1818, is a good plant, and appears equally so. In this experiment, so far as it goes, it appears that 40 bushels of oyster-shell powder are equal in virtue as a manure to 8 tons of farm-yard dung, at least for the purpose to which it was applied.

In the autumn of 1816, powdered oyster shells were tried as a manure for wheat, in competition with rape-cake powdered. The experiment was upon a one year's clover layer; the wheat sown after one ploughing; the soil a kind, light, gravelly loam. Oyster-shell powder, at the rate of 4 cwt. per acre, was drilled with the wheat seed on one part of the field; and on another part, of the same quality, rape-cake dust was drilled with the wheat at the same rate per acre as the shell powder; no other manure was applied to either part. The crop of wheat was good, nor was there any perceptible difference upon the ground; but the produce was not thrashed separate. A similar experiment was tried upon the same wheat field, the manure applied at spring; the operation as follows: the wheat seed was sown without any manure in the autumn of 1816, and in the spring of 1817 rape-cake dust, at the rate of 4 cwt. per acre, was drilled between the rows of wheat; at the same time an equal weight of shell powder was applied in like manner to another part of the field. The result of this was similar to the autumn experiment, viz., there did not appear to be any difference in the crop produced upon the shell manure from that of the rape-cake. The success of these experiments was such that the oyster shell manure is now in turnips, a good crop, and exhibits no difference where the manure, as before stated, had been applied for the wheat crop. These experiments are satisfactory, so far as they go, but certainly not conclusive; because the produce was in no one instance either weighed or measured. This I very much regret; but it appears to be almost impossible to conduct such experiments with a requisite degree of accuracy upon a farm establishment of such magnitude as that of Mr. Coke. At this place, during the hurry incident to collecting the harvest, the farm manager has so many important concerns to attend to, that he cannot devote any portion of his time to superintending experimental objects; and were he to depute the management of such concerns to the labourers, it is not to be expected that they would pay the attention requisite. The oyster shells are here broken to pieces by passing them through the oil-cake crusher; or are bruised by repeatedly drawing a heavy iron roller over them when spread upon a stone or hard-burned brick or edge floor. To give it as an opinion, that oyster-shell manure is likely to answer for gardens, particularly to rake in with onions and other
PACANENUT. See Hickory.

PACE. In horsemanship, the peculiar manner of motion, or progression, in the horse or other animal. The natural paces of the horse are, a walk, a trot, and a gallop, to which some add an amble, as some horses have it naturally. See Canter, Gallop, &c.

PACK RAG-DAY. A provincial term in England signifying the day after Martinmas day, the time of changing farm servants.

PADDLE-STAFF. An implement used by ploughmen to free the share from stubble, earth, &c.

PADDOCK. A small field or enclosure. It also signifies a large toad.

PAIL. A wooden bucket in which milk, water, or other fluids are usually carried.

PAIL-BRUSH. A hard brush, furnished with bristles at the end, to clean out the angles of the vessels more fully.

PALM. An ancient measure of length taken from the extent of the hand. The English palm is understood to be three inches.

PALMATE. In botany, divided so as to resemble a hand spread open.

PALMA CHRISTI. See Castor Oil Plant.

The cake left after the expression of castor oil is very advantageously applied to land as a manure for wheat and other crops. An interesting communication on another subject may be found in the first volume of the Farmer's Register, from T. G. Peachy, Esq., of Williamsburg, Va., the results of whose experiments show the great value of the article. In one experiment he applied from 50 to 60 bushels per acre on 7½ acres of land sown with 10 bushels of wheat, and the product was 26 bushels of wheat per acre. In this case the land was so poor that not over 5 bushels could be expected from it without the dressing. He recommends about 40 bushels as an ordinary dressing. Mr. Peachy does not think the common impression correct, that the chief efficacy of the cake resides in the portion of oil which it retains. His press, he says, "is a very powerful one, and

leaves a very small portion of oil in the cake. There is, moreover, other refuse matter in such an establishment as ours, which contains a vast deal more oil than the cake, which I have used as manure, and been uniformly disappointed in its effects. Accident has enabled me, however, to solve this difficulty, and the I declare my belief that the fertilizing qualities of the oil-cake reside chiefly in the farina it contains. Some time last year a vessel laden with flour was stranded near Jamestown, and the flour ruined. Mr. John Mann, who owns a farm in the neighbourhood, took two or three of the barrels and top-dressed a small portion of his wheat with it. I was not an eye-witness of its effects; but I was informed it produced as great an increase of that portion of his crop as my oil cake would have done. "By experiment, I find that 50 bushels of the cake will weigh 1800 lbs. ; and of this quantity I have discovered that ⅓ is farina or flour—equal to 5 barrels of flour. The cotton seed, I fancy, contains more farina, in proportion to the oil, than the castor bean, and, I believe, would produce as great an effect after being deprived of its oil, as it would do in its original state. I should be much obliged to you to give us your opinion on this subject." See Linseed Cake, Rape Cake, &c.

PALMETTO (Chamaeps palmetto). Cabbage tree. This American tree belongs to the genus of the palms, and is found farther north than any other species in America. From its lofty height it is reckoned in the United States as a tree. It is first seen about Cape Hatteras, in the 34th degree of latitude, from which it spreads to the extremity of the Florida peninsula, and thence around the Gulf of Mexico. In the extreme south the palmetto is not entirely confined to the immediate vicinity of the sea. Its stem or trunk is erect, and rises 80 or 90 feet, embellished at top by a globe of plumed leaves, each adorned with a sharp point, and plumes in the same manner, each frond, with its stipes or stem, 30 feet in length; the frond, or expanded part of the leaf, 15 feet over. There are six species of the palm in Carolina and Florida, all of which have flabelli-formed leaves or fronds.

It is the central part of this vast plant at top which stands erect, like a sharp cone or sugar-loaf, surrounded by the expanding leaves, which is eaten roasted or boiled, like cabbage; and consists of the young frond, rudiments of fronds, with all the succeeding appendages of the future growth, involuted together, white and tender as a curd, as rich, and of the like pleasant flavour.

A well grown palm stands perfectly erect, on a shaft or column of 60 or 80 feet high, its base 3 feet diameter, having 3 or 4 rings and circular mouldings, 3 or 4 feet upwards; from thence upwards to the top it diminishes almost imperceptibly, forming a model of a pillar for the architect, almost inimitable. A tree produces but one cabbage, and as soon as that is cut off, this glorious production of nature is destroyed. But though the tree dies, yet it ceases not to be useful; the exterior ligneous part, of three-fourths inch thickness, is as hard as bone when dry, and the interior
spongy consistency being rooted out, or devoured by worms, it makes excellent trunks or conduits for draining off water, being almost incorruptible under ground. These shafts also, split in two, and set upright in the ground, make strong and durable palisades; and we are informed that they answered a very good purpose in South Carolina, at the time of the revolutionary war, particularly at Sullivan's Island. The raspberries of the fortifications being lined with the trunks of the cabbage tree, split in two, and set upright against the wall; their smooth, firm, and elastic surface, together with their spongy interior, united to repel the shot of their assailants.

The stems are also used in Charleston, S. C., for the facing of wharfs, as the salt-water worm never touches them. Pieces of the spongy part of the stem afford a very good substitute for scrubbing-brushes, and are even preferred for whitening floors.

The leaves of the smaller species afford excellent and durable thatch for covering barns and out-houses; and the younger leaves of the cabbage tree are manufactured by the negroes into beautiful, light, and durable hats, called Bermudian hats. The repent caudex of the saw-palmetto, being torn from the surface of the earth, cut into proper lengths, dried, and burned to ashes, produce the greatest quantity of potash of any known vegetable. And the drupes, or large berries of this species, which are of the size and figure of dates, and as sweet, afford good and nourishing food to the Indians and hunters. They are not palatable to white people till they become accustomed to them.

PALMS. A natural order of arborescent endogens, chiefly inhabiting the tropics; distinguished by their fleshy, colourless, six-parted flowers, enclosed within spathes; their minute embryo lying in the midst of albumen, and remote from the hilum; and rigid plaited or pinuate inarticulated leaves, sometimes called fronds.

Palms is a common name for the male flowers of the willow.

PALSY. In the horse this nervous disease is usually confined to the hinder limbs. Old carriage-horses, and horses of draught of every kind, although not absolutely paralyzed, have often great stiffness in their gait, and difficulty of turning. These are evident injuries of the spine. Bleeding, phsysicking, animonial medicines, and stimulating embrocations are the most likely means of cure for palsy. See SICKNESS DISEASES OF.

PAMBINA. A species of North American bush cranberry, discovered on the Columbia river.

PAN. A term applied to the bed or flooring upon which the cultivated soil lies or is placed. See MOORHANK PAN.

PANICAL-GRASS (Pennisetum). This is a very extensive genus of large, coarse grasses, mostly annual in Europe, of no agricultural use: the inflorescence spikcd or panicked; the seeds in some instances used for food. There are three indigenous species: the rough, the green, and the loose panic-grass (P. verticillatum, viride, and Crus-galli). See MILLET GRASS.

PAPAW. In botany, a form of inflorescence in which the primary axis develops secondary axes, which themselves produce tertiary; or, in other words, a raceme bearing branches of flowers, in place of simple ones.

PANNAGE. An old manorial term applied to the food which swine consume in woods, as acorns, and the mast of beech. It also signifies the money taken by the king's agistors, for the privilege of feeding hogs in the king's forest.

PANSY. A term applied chiefly to the garden varieties of Viola tricolor, and others which are usually cultivated under the name of heart's-ease. See VIOLET.

PAPAW (Anona triloba). An American plant, which, though most frequently appearing in the form of a shrub, sometimes attains the size of a tree of the third order. By the French of Upper Louisiana the papaw is called Asimineer. It is not found north of the Schuykill river, in the vicinity of Philadelphia; and it appears to be unknown, or extremely rare, in the low and maritime parts of the Southern States. "It is not uncommon," says Michaux, "in the bottoms which stretch along the rivers of the Middle States; but it is most abundant in the rich valleys intersected by the western waters, where, at intervals, it forms thickets exclusively occupying several acres. In Kentucky, and in the western part of Tennessee, it is sometimes seen also in forests where the soil is luxuriantly fertile; of which its presence is an infallible proof. In these forests it attains the height of 30 feet, and the diameter of 6 or 8 inches, though it generally stops short of half this elevation.

"The leaves are borne on short petioles, and are alternate, 5 or 6 inches in length, and of an elongated form, widening from the base to the summit. They are of a fine texture, and the superior surface is smooth and brilliant. The flowers, which are attached by short peduncles, are pendent, and of a purple hue.

When the fruit is ripe, which takes place towards the beginning of August, it is about 3 inches long, and 1½ inches thick, of a yellowish colour, and of an oval form, irregular and swelling into inequalities. Its pulp is soft, and of an insipid taste, and it contains several large, triangular stones. It is never brought into the markets, and is sought in the woods only by children. At Pittsburgh some persons have succeeded in making from it a spirituous liquor; but, notwithstanding this experiment, very feeble hopes can be entertained of cultivating the tree with profit for this purpose.

"The trunk of the papaw is covered with a silver-gray bark, which is smooth, and even polished. The wood is spongy, extremely soft, destitute of strength, and applicable to no use in the mechanical arts. I have noticed that the cellular integument of the bark, and particularly that of the roots, exhales in summer a nauseous odour, so strong as to occasion sickness if it is long respired in confined air. (Michaux's Am. Syllae.)"

The papaw belongs to the custard-apple genus, which in the tropics produces several kinds of fruit highly esteemed. Among these is the
celebrated Cherimoyer (Anona cherimolia) found in perfection in Mexico, Peru, and Brazil; the Alligator pear (C. palustris), the Sweet sapote (C. aquamarina), all esteemed West India fruits, about as large as a middle-sized apple, and filled with a soft, rich, delicious pulp.

**PARASITICAL PLANTS** are those which grow into the tissue of other species, and feed upon their juices. Of this kind is the mistletoe, the broom-rape (Orobanche), the Lathraea, &c. Such species have no proper roots. The term parasitical is, however, often applied to mosses, Orchidaceous plants, Tillandsias and the like, which are mostly epiphytes, growing upon the bark of trees, but deriving their food from the air, by means of their own roots.

**PARING AND BURNING.** This well-known operation of agriculture, once much more extensively practised in England than at present, consists in paring off the turf to a depth of two or three inches, generally with a breast-plough worked by a labourer, or by a turf-paring plough drawn by a horse; allowing it to dry, and then burning it in heaps. It is commonly best performed in the months of April and May. It is a practice now rarely adopted on sandy or calcareous soils, although productive of good results on peat, and some kind of clay soil; but even there it is very doubtful whether it is the best mode of treating the land.

The practice is certainly as old as the days of Virgil, who mentions it in the first book of the Georgics. Endless have been the theories brought forward to account for its operation. Dr. Home thought it dispelled "a sour juice" from the land. (Prin. of Agr.) Dr. Darwin considered it produced "a nitrous sal" in the ashes. "Many such obscure causes," says Davy, "have been referred to for the purpose of explaining the effects of paring and burning, but I believe they may be referred entirely to the diminution of the coherence and tenacity of clays, and to the destruction of inert and useless vegetable matter, and its conversion into a manure. All soils that contain too much dead vegetable fibre, and which consequently lose from one-third to one-half of their weight by incineration, and all such as contain their earthy constituents in an impalpable state of division, such as the stiff clays and marls, are improved by burning; but in coarse sands, or rich soils, containing a great mixture of the earths, and in all cases in which the texture is already sufficiently loose, or the organizable matter sufficiently soluble, the process of torffaction cannot be useful. All pure silicious sands," adds Davy, "must be injured by it;" and here practice is found to accord with theory. Arthur Young found "burning injured sand;" and an intelligent farmer in Mount's Bay told me that he had pared and burned a small field, several years ago, which he had not been able to bring again into good condition. I examined the spot; the grass was very poor and scanty, and the soil a silicious sand.

The process of paring and burning, therefore, seems to be most adapted for peaty or clay lands; for, as Davy continues, "the process of burning renders the soil less compact, less tenacious and retentive of moisture; and when properly applied, may convert a matter that was stiff, damp, and in consequence cold, into one powdery, dry, and warm, and much more proper as a bed for vegetable life."

Davy examined three specimens of the ashes from different lands that had undergone paring and burning. (See Asiks, anté, p. 115.) "The great objection," he adds, "to this operation is that it destroys vegetable and animal matter, or the manure in the soil: but in cases in which the texture of its earthy ingredients is permanently improved, there is more than a compensation for this temporary disadvantage. And in some soils where there is an excess of inert vegetable matter, the destruction of it must be beneficial; and the carbonaceous matter remaining in the ashes may be more useful to the crop than the vegetable fibre from which it was produced." (Agr. Chem. p. 344.)

Liebig thinks that all the benefit of burning the soil is attributable to its thus obtaining increased powers for the absorption of ammonia. He says, "Soils which contain oxides of iron, and burned clay, must absorb ammonia, which is favoured by their porous condition; they further prevent the escape of the ammonia once absorbed by their chemical properties. The ammonia absorbed by the clay, or ferruginous oxides, is separated by every shower of rain, and conveyed in solution to the soil. Powdery charcoal possesses a similar action, but surpasses all other substances in the power which it possesses of condensing ammonia within its pores, particularly when it has been previously heated to redness. Charcoal absorbs ninety times its volume of ammoniacal gas, which may be again separated by simply moistening it with water." (Organic Chem.)

And it is evident, from the experiments which Liebig gives, that charcoal powder is a very fertilizing application to some plants. The practice, however, of paring and burning is evidently one whose advantages the farmer and the chemist admit with reluctance. And it is very probable, that by other means, such as the use of lime, &c., most soils may be cultivated with more advantage to the farmer by the avoidance of this expensive and destructive process. "My practice," remarks Mr. Pearson, "in the use of turf for various purposes, convinces me that all lands must be injured by paring and burning, save those lands, which are few and far between, that possess too much inert vegetable matter; or, in other words, lands that grow their crops to such a state of luxuriance, as to prevent the desired intent of the cultivator. Those lands which possess too much inert vegetable matter might also be improved by having part of their
PARSNIP.

Leaflets but the it poses. Finally to known it. Usually is much unnecessary of winter weather. Seed, in Chervil. PARSLEY. PARK. It is cultivated for its root, which attains the size of a middling parsley, boiling exceedingly tender and palatable. It is eaten both as a sauce to flesh-meat and in soups, &c. It is propagated by seed, which may be sown at monthly intervals from February until the middle of June. It is sown either thinly in drills, 9 inches apart, or broadcast and raked in. The plants appear in about a month after sowing, and when of tolerable growth require to be thinned to 9 inches asunder, and cleared from weeds either by hand or the hoe; which latter operation being performed as often as weeds appear, is the only cultivation required. By the end of July or during August, the earliest sowings will have acquired a sufficient size for occasional use; but they seldom attain their full growth until Michaelmas; and the latest crops not until the following year. On the arrival of frost some of them must be taken up, and after the removal of the superfluous fibres, decayed leaves, &c., buried in sand, in a dry situation, under cover.

To obtain seed, some plants must be left where grown, and allowed to run in May; their produce will ripen in July or August, when it must be cut, and, when perfectly dry, beaten out and stored.

PARSLEY-PIERT. See Ladies Mantle.

PARSLEY, SMALLAGE, or WILD CELERY (Apium graveolens). This wild plant, the seeds and herbage of which in its native ditches are acrid and dangerous, with a peculiar strong taste and smell, by culture becomes the mild and grateful garden celery, for which and its name we are indebted to the Italians, and which has now supplantcd our native Alexanders. It is biennial, and flowers in August and September. The root is tap-shaped, and the herbage smooth and shining. The plant grows in ditches and marshy ground, especially towards the sea. The stems are widely spreading or floating, long, branched, furrowed. Leaves bright-green, pinnate, or ternate; leaflets wedge-shaped, entire at their base, but variously notched above. Flowers in terminal and lateral umbels, small, numerous, greenish-white. Fruit almost globular, with permanent, wide-spreading, straight styles.

PARSNIP (Pastinaca, from pastinum, a dibble, in allusion to the form of the root). The common wild parsnip (P. sativa) is the well-known culinary root; the other species are unworthy of cultivation. The original is a biennial plant, and found in England growing wild about the borders of fields, on hillocks, and dry banks, in a chalky soil, the root being spindle-shaped, white, aromatic, mucilaginous, and sweet, with a degree of acrimony, which it loses by cultivation. The stem reaches to a yard high, erect, branched, deeply furrowed. Leaves oblong, simply pinnate, downy beneath; leaflets serrated and cut, bright-green. Umbels terminal, erect, of several unequal, angular, downy rays. Flowers small, yellow, appearing in July. Fruit large, pale-brown when quite ripe.
**Parsnip.**

The field Culture of the Parsnip.—Colonel Le Couteur describes this valuable field crop as thriving in any deep land, whether stiff or light. It succeeds in the island of Jersey admirably on the mixture of granite or schistus, or argilaceous schists, on red clay, or on a gravelly bottom; or almost pure sand, if mixed with a light coating of earth, and on soils derived from pudding-stones, or white and red felspar. This includes most of the British islands, exclusive of the chalky or limestone ranges. Some persons cultivate it on poor black heath soil, not above 7 or 8 inches deep, and by means of heavy dressings of manure raise a good crop; but the parsnip in such situations forms a large sward, and forks away into fingers when near the hard subsoil, whereas, in very deep land, it will run down a foot or two of a good size.

An old grass lay is broken up by some persons in September, by others just before the parsnip seed is sown; the former I consider to be the best mode. When the turf is well rolled, 20 tons per acre of stable manure are spread over the land. A trench is then opened through the centre of the field between 2 and 3 feet wide, and where the soil will admit of it, from 1 foot to 1½ inches deep. A small two-horse plough then turns the manure and about 3 inches of soil into the trench, and is immediately followed by a large trench plough, with 3 or 4, and, in many cases, with 8 or 10 horses, which turns a foot or more of clean soil upon the manure and scurf when the land has been recently skim-ploughed. The soil is then harrowed, and the parsnip seed, which should be new, is sown at the rate of 3 or 4 pounds to the acre. The plants, when they are an inch high, are weeded, and are thinned out to 6 inches apart, and, according to the soil, should be again thinned out to 9 inches or more at the second hoeing. In September, when the fine aftermath begins to appear, some of this crop may be taken up for milk cows; as from 12 to 25 pounds of them given at milking-time will have a surprising effect on the cream, and produce fine yellow butter, which will keep admirably, if properly salted and prepared, preserving an excellent and superior flavour.

They are taken up with a fork, or ploughed up in October or November. The average produce per statute acre, is 9 to 11 tons. The dry leaves of the parsnip are given to cows. The parsnip will fatten pigs (or poultry if boiled) in an extraordinary manner, and it is certainly one of the best preparatory crops for wheat. It will keep in store until April, and it is advisable to remove the leaves before the roots are stored. The parsnip being a very hardy vegetable, the frost does not injure the seed or the young plant; and, if thought desirable, the former may be sown as soon as they are ripe in autumn. There are only 1 or 2 varieties of parsnips, of which the common species is the best for field culture. 1000 parts of the parsnip yielded Davy 90 parts of saccharine matter, and 9 parts of mucilage.

Garden Culture.—The soil in which the parsnip succeeds best is a rich, dry, sandy loam, and the deeper the better. The most inimical to it are gravel or clay. It is always beneficial to trench the ground 2 spades deep, a little manure being turned in with the bottom spit. If the soil is suitable to them, they are not much benefited by the general application of manure at the time of sowing; but a consequence of numerous fibres being induced. D. Macculloch says, that in the island of Guernsey, which has long been celebrated for the fineness of its parsnips, sea-weed is the manure chiefly employed. Of excrementitious manure, that of pigeons is the best. Decayed leaves are also very favourable to its growth. The situation cannot be too open.

It is propagated by seed. The usual time for sowing is from the end of February to the beginning of April, but the earlier the better. It has been recommended in field cultivation to sow them in September; in the garden, when sown at this season, they also obtain a finer flavour, but many of them in general run to seed. In the isle of Guernsey they regulate their time of sowing according to the soil; in the most favourable soils they sow in January; or if the soil is wet or stiff, they do not insert the seed until the latter end of March.

The seed is sown broadcast, rather thin, and well raised. In the compartment being laid out in beds, not more than 4 feet wide, for the convenience of weeding, &c. When the seedlings are 2 or 3 inches high, they are carefully thinned to 10 inches apart, and the weeds removed both by hand and small-hoeing. The beds require to be frequently looked over to remove all seedlings that may spring up afresh, as well as to be frequently hoed, until the plants so cover the ground as to render it impracticable. The roots may be taken up as wanted, in September, but they do not attain maturity till October, and which is intimated by the decay of the leaves. In November, part of the crop may be taken up, and the tops being cut close off, laid in alternate layers, with sand, for use in frosty weather. The remainder may be left in the ground, and taken up as required, as they are never injured by the most intense frost, but, on the contrary, rendered sweeter. In February or March, however, any remaining must be extracted, otherwise they will vegetate. Being preserved in sand, they continue good until the end of April or May.

For the production of seed, some of the finest roots are best allowed to remain where grown; or else, being raised in February, planted in a situation open, but sheltered from violent winds. Seed should never be employed that is more than a twelvemonth old, as it has generally lost its vegetative power when of a greater age.

**Parsnip.**

See COW-PARSNIP. PARSNIP, THE SEA, or PrICKLY SAMPHIRE.

**Parsnip, the Water.** See Water-Parsnip.

**Parterre** (Fr.). In gardening, a system of beds of different shapes and sizes, in which flowers are cultivated, with intervening spaces of gravel or turf for walking on.

**Partition.** See Abortion, Calving of Cows, Gestation, Pregnancy, &c.

**Passion-flower** (Passiflora, from passio, passion; and flos, a flower; in allusion to...
the filamentous appendages or rays bearing a resemblance to the cross; the emblem of the passion of Christ. The species of this interesting and elegant genus are admirably adapted for stove and greenhouse climbers, being of easy culture, free growers, and, if allowed plenty of room, producing abundance of beautiful flowers. Many of the kinds produce fruit freely, from which, through impregnation, several fine hybrids have been raised. The fruit of some, as P. edulis, P. laurifolia, and P. quadrangularis, or granadilla, are eaten; the succulent pulp which surrounds the seeds is found to be fragrant, cooling, and pleasant, agreeably acid, and admirably adapted for allaying thirst in hot climates.

All the species will thrive well in a mixture of loam and peat, and are easily increased by cuttings planted in sand. The hardy kinds should be planted in sheltered situations.

PASTERN OF A HORSE. The distance that intervenes between the joint of that name and the coronet of the hoof.

PASTURE (Fr.). Ground on which cattle feed. I have heard Grass, gone at some length into the question of the grasses best adapted for different soils. The pastures of England and Ireland exceed in extent and productiveness those of any other country of similar extent. "The excellence of pastures," observes the author of The British Husbandry, vol. i. p. 478, "depends greatly both upon their position and the different species of animals for whose support they are intended. Thus, uplands which are elevated, open, and dry, are the best adapted for the feeding of sheep, while a heavy stock is fed with more advantage on ground which is lower in point of situation, as well as better enclosed. The soil of uplands, particularly if it be of a chalky nature, bears a sweet, though a short bite of grass, which is so favourable to the pasturage of the smaller breeds of sheep, that although it will support but a scanty stock, it yet produces the finest species of mutton. These flocks of sheep, too, by the folding system, keep in cultivation many a poor, thin soil, which would otherwise be worthless. There is an excellent paper, by Mr. Magillivray, on the natural pastures of Scotland, which I refer to, in which the natural grasses which are found on the highest elevations down to the valleys and sea-shore. "The bleak summits of these mountains," he remarks, "exposed to the depressing influence of a low temperature, boisterous winds, and abundant rains, covered for a great part of the year with snow, and presenting either bare rock or a shallow, gritty soil, produce few plants of any description, and hardly a dozen of those which are selected by sheep as their food. These latter consist of 3 or 4 carices or hard grasses, 1 or 2 junci or rushes, some tufts of the common club-rush, together with the Festuca vivipara, and 1 or 2 other grasses. The extreme heights scarcely present any other vegetation than Silene acaulis, Salix herbacea, and Statica armeria. Farther down the mountains, extending downwards to about 3000 feet above the level of the sea, we find a vegetation still poor and stunted, but by no means deficient in beauty, and perhaps affording better pasturage than some of the lower grounds. We here find irregular patches of verdure, consisting chiefly of Carices and Scirpus caspiotos, which, however, are also eaten by sheep; by the streamlets are several species of Alpine plants. Farther down the mountains, Aira flexuosa grows in tufts, and of a large size. Several carices form a tolerable sward in many places; the Agrostis vulgaris, &c., occasionally occurs. Calluna vulgaris, or common heath, first makes its appearance. As we proceed downwards, and arrive at the places where the mountains begin to expand, we enter upon the pastures of Ireland, one of which is the Calluna vulgaris, mingled with Erica cinerea (the gray-leaved heath); the vegetation becomes more vigorous; various grasses present themselves. The valleys of this region, in which flow the streamlets, are generally more verdant than the open ground. The heaths are less abundant, and the pasturage consists chiefly of carices and graminee, intermingled with many of the plants of ordinary pasture ground, such as Lotus corniculatus, Polygala vulgaris, &c. The general aspect of the vegetation, however, is healthy, and continues so until we reach the vicinity of the river." For every information, however, relating to the formation of pastures, and the cultivation of the grasses, the farmer cannot consult a better authority than the Hortus Gram. Woburnensis of the late Mr. George Sinclair.

In feeding pastures, it is usual with those fields which are shut up from stock at Candlemas, to graze them in the succeeding May. Those which are fed until April may, after being shut up, be grazed again at Midsummer. If it is intended to feed a pasture during the winter, it should be allowed to rest in the months of October and November. See MEADOW and GRASSES.

PEA, THE. (Pisum sativum, Fr. pois, Span. pe-soles. The English is evidently a corruption of the Latin name). This valuable plant is supposed to be a native of the south of Europe, and was cultivated by the Greeks and Romans. It is said by Acton to have been brought to England in 1548. There are only one or two kinds of pea; the grey pea, (P. arvense,) and the pea cultivated as a vegetable in gardens (P. sativum). Of the last, however, the varieties are endless.

Of field peas, the varieties are distinguished as the early and the late ripening. The common early are small and dark-coloured. The grey pea of this class is the most common.

The later sown varieties are generally similar in their characters to garden peas; they differ, however, from them in having usually purple flowers. The most common kinds are the white, the early Charlton, and the pearl. Field peas, especially where there is a considerable demand for them, as in the neighbourhood of large towns, are a very profitable crop to be gathered green, since there is time after the peas are gathered, in the month of June, to prepare the land for a crop of turnips.

Where they are grown for their seeds, the white peas are those generally cultivated for the purpose of boiling, the gray as food for animals.
The pea will succeed pretty well on both heavy and light soils; but it certainly does best on the latter, especially if the land abounds with carbonate of lime. It is an excellent crop to interpose between corn crops, for it affords considerable facilities to the cleansing of the land, and is not otherwise an exhausting crop. In many parts of England a pea crop is dilled on the clover and grass leys, and afterwards a corn crop is taken with great advantage. In others a crop of oats is taken, and then a crop of peas. When this latter mode is adopted, the land is commonly ploughed in the autumn, and by cross-ploughing and harrowing in the spring, brought into some degree of tilth, and then the seed may be sown with the ordinary drill. The quantity of seed employed is about 3 bushels per acre, and the rows are usually from 9 to 27 inches apart. There is every facility afforded for the use of the horse-hoe. This instrument, with the early and occasional use of the hand-hoe, will cleanse the land; to which end the crop of peas will, as they approach maturity, materially assist, by overpowering and stilling the weeds.

Peas are usually one of the most uncertain of the English farmer's crops. They are subject to many accidents—disease, blight, and, as above Harlequin, to the ravages of a variety of insects, such as the grub, which devours the roots; lice, aphides, &c., which haunt the leaves; and a small beetle, the Brachus granarius, lays its eggs in the green pods, which produce a grub that devours its seeds. Then, again, it is frequently injured by the weather, in very dry, or in continued wet, or late harvests; and hence in the east of England it is often designated by the farmers as "a gentleman farmer's crop." This crop, however, is too often mismanaged in the way to which Arthur Young so well alluded, when he told the careless farmers of his day that they were "too apt to sow this pulse when the land would yield nothing else. They have a proverb among them," he adds, "which signifies that the season does as much for peas as good husbandry; and they from thence take care that good crops shall be owing to season alone. Hence arises the general idea of peas being the most uncertain crop of all others. This is owing to their being scarcely ever sown on land that is in good order. Let," he continues, "the good husbandman lay it down as a maxim, that he should sow no crop on land that is not in good order; not merely in respect of fine tilth at the time of sowing, but also of the soil being in good heart, and clear of weeds. He would not, however, here be understood to rank all these crops together; because beans and peas will admit of cleaning while they grow. On that account, if a farmer comes to a field which his predecessor has filled with weeds, a horse-hoe crop of beans will be expedient, when a barley crop would be utterly improper; and, after land has yielded one crop of barley, certainly another should not be sown, but one of pulse substituted. If these ideas are well executed, the peas and beans, in every course, will find the land in heart enough for barley, the soil will always be clean, and the crop good. Peas, when managed in a spirited manner, will not have the reputation of being so very uncertain a crop, which character has, he thinks, in some measure been owing to ill conduct." Peas do not need any particular dressings with manure; in fact, few crops require it so little; and in many situations manure produces the ill effect of rendering the plant too luxuriant. Von Thaer found, by several experiments, that the dung applied to the pea crop is the most profitable when used as a top-dressing. And, moreover, he contends that on sandy loams it produces in this way a much better effect in the succeeding crop. Lime and sot are, perhaps, the best dressings for peas; and these may operate to some degree by killing the insects of the soil, which might otherwise prey upon them; besides, the pea plant seems to delight in every situation where it can have access to calcareous matter. The crop is commonly cut with a hook at the end of a staff, or the half of an old seythe in a handle. By these the peas are severed, and made up into small bundles, called wads or wisps, and these remain on the ground until they are sufficiently dry to be carried. The straw of peas is very useful for the stock of the farm-yard: cows eat it, when it has been well gathered, with considerable appetite.

1000 parts of peas grown in Norfolk afforded Davey 501 parts of starch, 22 of saccharine matter, 35 of albuminous matter, and 16 parts of extract. The ashes obtained by burning the pea plant in flower and when ripe were examined by M. Saussure: he found in 100 parts of these ashes, procured from the Pisum sativum in flower, of soluble salts 49-8 parts, of earthy phosphates 17-25, earthy carbonates 6, silica 2-3, metallic oxides 1, and loss 24-65 parts. And from the ashes of the ripe plant, soluble salts 34-25 parts, earthy phosphates 32, earthy carbonates 14, silica 11, metallic oxides 2-5, and loss 17-25 parts.

The average price of peas in England, per Winchester quarter, was in

757
Garden Culture of the Pea.—Of the numerous varieties, which differ much in their hardiness, yield, height, &c., we may enumerate the following:—Cormack's early dwarf-pea, early Charlton, early golden Charlton, early Nichol's golden Charlton, common Charlton, Reading hotspur, early single-blossomed, early War-wick, early dwarf frame, early double-blossom-ed frame, dwarf marrowfat, tall marrowfat, green or Patagonia marrowfat, early green nonpareil, Knight's marrowfat or wrinkled pea, Spanish moratto, imperial blue, Prussian blue, egg-white Rouncival, grey Rouncival, green Rouncival, blue Rouncival, tall sugar (the sugar-peas are eaten like kidney-beans), crown or rose, Leadman's dwarf, dwarf sugar, dwarf Spanish, sickle pea.

A soil moderately rich and moulidy is best suited to this vegetable; rather inclining to aluminous for the lofty growers and main crops, but for the early and late ones, light and dry if naturally otherwise, rendered so by the admixture of drift-sand with the earth of the drills. Dwarf varieties will grow on poorer and lighter soils than others. In an extremely rich soil they grow luxuriant but unproductive. They are rather injured than benefited by the application of unreduced dung at the time of sowing. Road dirt and rotted leaves form the best compost for them. For the early and late crops, that is, from October until the close of January, and during June and July, the sowings must be performed in sheltered situations, as south borders. In December, the rows are best drawn parallel with and within a foot of the fence. At other seasons their site cannot be too open.

They are propagated by seed, the sowing of which commences with the year. In January they may be inserted in sheltered borders, and large supplies in an open compartment, and thence continued throughout February and until July, once every two or three weeks. During this last month, and in the first week of August, the last sowings must be made for production the same year. For the first production in the following year, a small sowing may be performed at the close of October, and repeated about the middle of November and December, though it often happens that these are scarcely a week forwarder than those inserted in the following February. The necessary extent of the various sowings may be determined with tolerable exactness from the experiments of Bradley; he found on the average that 3 rods of ground, containing 18 double rows, afforded 36 quarts of shelled peas.

The seed must be inserted in drills, or by the dibble, in rows at a distance proportionate to the height to which the variety grows, as well as according to the season.

When the plants have advanced to a height of 2 or 3 inches, they are to be hoed, the weeds cleared away, and earth drawn round the stems. This should be performed twice or three times gradually as they ascend, previous to the sticks being placed. It should be performed in dry weather, and the leaves never covered, or in wet weather they decay. For the winter standing crops it should be especially attended to, as it protects them greatly from frost. Peas are always best supported by sticks; if it is neglected, even for the dwarf varieties, they not only produce less, but sooner decay, are inconvenient to cultivate and gather from, and never so fine. Sticking is not required until the plants are 6 inches in height, or show their tendrils. If, during the time of blossoming, or swelling of the fruit, continued drought should occur, water may be very beneficially applied, it being poured between the rows, if they are in pairs, or otherwise in a shallow trench on one side of each. Watering the leaves is rather injurious. Failures in the rows of the earliest crops, whether from mice or other causes, may be rectified by transplanting. This is best performed in March; the plants thus removed must be watered until they have taken root, and also shaded, if the weather is hot. It is a good practice to nip off the top of the leading shoots of the early and late crops as soon as they are in blossom, as it greatly accelerates the setting and maturity of the fruit. Too much care cannot be taken when the pods are gathered, not to injure the stems. I have heard it stated from a man of much experience, that if the pods are cut off with scissors, the plants produced one-fourth more than when roughly gathered from. Bradley makes nearly a similar observation. From the main crops, or where there is no necessity for precipitation on account of bringing them to table early, the pods should not be gathered until the peas have become plump and moderately firm, yet green and tender. The more regularly the plants are gathered from, the longer they continue in production, as the later pods never attain maturity if the earlier ones are allowed to grow old before they are gathered.

In very severe weather the winter standing crops require the shelter of litter or other light covering, supported as much as possible from the plants by means of branches laid between the rows. Mr. J. Laird, gardener, at Portmore, N. B., employs straw ropes or twisted bands for this purpose, which he fixes along each side of the rows with wooden pins, driven into the ground. Whatever mode of shelter is adopted, it must be always removed in mild weather, otherwise the plants will be spindled, and rendered weaker. For the imperial blue, frame, and other dwarf varieties, the sticks need not be more than 3 feet high; for the Prussian blue, hotspur, and other middle-sized varieties, about 5; for the Knight's marrowfat, and other tall ones, at least 7; and for the Patagonian, not less than 8. The best wood for this purpose is the brush, or fan-shaped branches of the hazel, &c. Before they are employed, the ends that are thrust into the ground should be charred, or moderately burnt, which effectually preserves them from decay. If this is attended to, and, when no longer required, the sticks, if thoroughly dry, on a fine day are stored in a dry shed, they will last for three or more years.

For the production of seed, leave some rows that are in production during July, or sow purposely in March. Care must be taken, however, that no two varieties are in blossom near each other at the same time, but a lapse of at least three weeks should occur, otherwise no
PEA.

Perfect variety can be obtained. We are much in want of observations on this point. If hot-spurs and marrowfats are sown on the same week, the latter will not bloom for nearly four weeks after the first. If the frame variety and the moratto are similarly inserted, the latter will succeed the first in about five weeks. The plants intended for seed ought never to be gathered from. When in blossom, all plants which do not appear to belong to the variety among which they are growing should be removed. They are fit for harvesting as soon as the pods become brownish and dry. When perfectly free from moisture, they should be beaten out, otherwise, if hot, showery weather occurs, they will open and shed their seed. Seed-peas preserve their power of germinating for eight or ten years.

Forcing commences in December, in the early part of which month they may be sown in a hotbed to remain, or thick, to transplant during the succeeding month into others for growth. These may be repeated in January and the transplanting take place in February. It is also a common practice to sow in a warm border during October, and the plants being cultivated as a natural ground crop, are removed into a hot-bed during January.

The temperature employed in forcing may be either progressive, beginning at 40° and 50°, for the extremes, at the time of sowing, rising to 52° and 60° when in blossom, and to 53° and 70° while the fruit is swelling; or the temperature may be uniformly kept up throughout their growth, having 50° for the minimum and 70° for their maximum.

In New York and some other of the Northern and Eastern States, the pea forms a highly valuable crop, not only for its intrinsic value, but as useful in preparing the land for the reception of wheat, and other grain, for which purpose it is considered on a par with the turnip and other root crops of England. The soil best adapted to the pea is one that is good for wheat, and where that grain is certain, peas may be considered so. The preparation of the soil demands nothing peculiar; it must only be made in good order for seed, in the manner required for other spring crops, by being well ploughed, harrowed, and if necessary, manured. If manured too highly, however, the vine or hauml is apt to be too abundant, and the pea itself inferior in quantity and quality. In this, as in most other cases, too great a growth of vine or straw is incompatible with great crops of pulse or grain. Lime in all countries has been found an essential ingredient of pea or wheat soils; and where it does not naturally exist in them, should be applied previous to attempting the culture of these crops.

The kinds of pea most usually cultivated as a field-crop, are the small yellow pea and the marrowfat. We prefer the latter; as it is equally certain with the other, is excellent for the table as well as for feeding, is as nutritious for animals, and generally more productive. In some situations, or in exhausted soils, the small yellow pea may however be preferable. From 30 to 40 bushels per acre is not an uncommon crop, and this highest amount is often exceeded. The quantity of seed required per acre may be stated at 2½ bushels, although some use only 2, and some put on 3 bushels per acre. For covering the pea the cultivator is a very good implement, as it gives them more earth than the harrow and less than the common plough. The ground should be left smooth by the roller or otherwise, as the ease of gathering is greatly depending on the state of the surface.

In harvesting the pea, some farmers hook them up with a scythe, some rake them by hand with the common hay-rake, but the most expeditious method by far, is to use the horse-rake in gathering this crop. In whatever way peas are gathered, it is necessary they should be ripe, and of course, if very dry at the time, there will be some loss by shelling, but not perhaps more by the horse-rake than by the other methods, and four-fifths of the time required by the two first methods is saved. This, where the land is to be put into wheat, is frequently done in March. Out of the peas there is no crop so easily thrashed and prepared for market as the pea, and few that better reward the cultivator.

There is no plant cultivated which will bring pigs forward more rapidly than the pea, if the feeding is commenced as soon as the peas begin to harden, and the whole plant is fed out to them. When gathered and hard, two methods of feeding have been adopted, both of which are far preferable to the barbarous practice of giving swine the pea without any preparation. The first is to soak and swell the pea in milk, if it can be had, if not, in water, and feed it to them in that state. The second is to grind the pea, either alone or with other coarse grain, and feed it to animals in that way. This is preferable to feeding whole, as in corn or any other food, the finer it is made the more readily it will be assimilated, and in all cases, if cooked into pudding the advantage will be decisive. In England, where corn cannot be grown, a mixture of peas and barley is considered superior to any other food for making pork; here, closing the process of fattening with Indian corn, as giving more firmness to the pork, is preferred.

In the Southern States, a kind of pea, called there the Cow Pea, is cultivated for the purpose of making into hay, and for being ploughed under as a fallow crop, like clover.

PEA-BUG or BEETLE. In the spring of the year we often find, among seed-peas, many that have holes in them; and, if the peas have not been exposed to the light and air, we see a little insect peeping out of each of these holes, and waiting apparently for an opportunity to come forth and make its escape. If we turn out the creature from its cell, we perceive it to be a small oval beetle, rather more than one-tenth of an inch long, of a rusty black colour, with a white spot on the hinder part of the thorax, 4 or 5 white dots behind the middle of each wing-cover, and a white spot, shaped like the letter T, on the exposed extremity of the body. This little insect is the Bruchus Plat of Linnaeus, the pea-Bruchus, or pea-weevil, better known in America by the incorrect name of pea-bug. The original meaning of
the word Bruchina is a devourer, and the insects to which it is applied well deserve this name, for, in the larva state, they devour the interior of seeds, often leaving but little more than the hull untouched. They belong to a family of the great weevil tribe called Bruchidae, and are distinguished from other weevils by the following characters. The body is oval, and slightly convex; the head is bent downwards, so that the broad muzzles, when the insects are not eating, rest upon the breast.

The habits of the Bruchians and their larvae are similar to those of the pea-weevil, which remain to be described. It may be well, however, to state here that these beetles frequent the leguminous or pod-bearing plants, such as the pea, Gleditsia, Robinia, Mimosa, Cassia, &c., during and immediately after the flowering season; they pierce the tender pods of these plants, and commonly lay only one egg in each seed, the pulp of which suffices for the food of the little maggot-like grub hatched therein.

The persons who cultivate a luxury of early green peas, are aware how many insects they unconsciously swallow. When the pods are carefully examined, small, discoloured spots may be seen within them, each one corresponding to a similar spot on the opposite pea. If this spot in the pea be opened, a minute whitish grub, destitute of feet, will be found therein. It is the weevil in its larval form, which lives upon the marrow of the pea, and arrives at its full size by the time that the pea becomes dry. This larva or grub then bores a round hole from the hollow in the centre of the pea, and the latter and generally the germ of the future sprout untouched. Hence, these buggy peas, as they are called by seedsmen and gardeners, will frequently sprout and grow when planted. The grub is changed to a pupa within its hole in the pea in the autumn, and before the spring casts its skin again, becomes a beetle, and gnaws a hole through the thin hull in order to make its escape into the air, which frequently does not happen before the peas are planted for an early crop. After the pea-vines have flowered, and while the pods are young and tender, and the peas within them are just beginning to swell, the beetles gather upon them, pierce the pods, and deposit their tiny eggs in the punctures. This is done only during the night, or in cloudy weather. Each egg is always placed opposite to a pea; the grubs, as soon as they are hatched, penetrate the pod and bury themselves in the peas; and the holes through which they pass are so fine as hardly to be perceived, and are soon closed. Sometimes every pea in a pod will be found to contain a weevil-grub; and so great has been the injury to the crop in some parts of the country, that the inhabitants have been obliged to give up the cultivation of this vegetable. These insects, as Mr. Deane has observed, diminish the weight of the peas in which they lodge nearly one-half, and their leaving are fit only for the food of swine. This occasions a great loss, where peas are raised for feeding stock or for family use, as they are in many places. Those persons who eat very few peas in the winter after they are raised, run the risk of eating the weevils also; but if the peas are kept till they are a year old, the insects will entirely leave them.

The pea-weevil is supposed to be a native of the United States. It seems to have been first noticed in Pennsylvania, many years ago; and has gradually spread from thence to New Jersey, New York, Connecticut, Rhode Island, and Massachusetts. It is yet rare in New Hampshire, and I believe has not appeared in the eastern parts of Maine. It is unknown in the north of Europe, as we learn from the interesting account given of it by Kalm, the Swedish traveller, who tells us of the fear with which he was filled, on finding some of these weevils in a parcel of peas which he had carried home from America, having in view the whole damage which his beloved country would have suffered, if only two or three of these noxious insects had escaped him. They are now common in the south of Europe and in England, whither they may have been carried from this country. As the cultivated pea is not native in America, it would be interesting to ascertain what plants the pea-weevil formerly inhabited. That it should have preferred the prolific exotic pea to any of our indigenous and less productive pulse, is not a matter of surprise, analogous facts being of common occurrence; but that for so many years a rational method for checking its ravages should not have been practised, is somewhat remarkable. An exceedingly simple one is recommended by Deane, but to be successful it should be universally adopted.

It consists merely in keeping seed-peas in tight vessels over one year before planting them. Latreille and others recommend putting them, just before they are to be planted, into hot water for a minute or two, by which means the weevils will be killed, and the sprouting of the peas will be quickened. The insect is limited to a certain period for depositing its eggs; late-sown peas therefore escape its attack. The late Colonel Pickering observed that those sown in Pennsylvania as late as the 20th of May, were entirely free from weevils; Mr. Worthington, of Rensselaer county, New York, who sowed his peas on the 10th of June, 6 years in succession, never found an insect in them during that period. (Harris.)

PEA-COW. The plant called by this common name in lower Virginia and the Carolinas, is there extensively cultivated. In some parts of Virginia it is called the Yentman pea, from the person by whom it was introduced from the Eastern Shore. The pea is of a yellowish colour, is very productive both in vine and seed, usually hardy in remaining uninjured by rain, after becoming ripe, and for table use is much esteemed. But it is chiefly cultivated, in common with several varieties of Indian peas, in fields, to plough under for the benefit of successive crops, as a substitute for clover, buckwheat, and other plants not so well adapted to southern culture. The vines of this and the varieties of the Indian pea, all make excellent long forage for common work-horses, oxen, milch-cows, or sheep. The curing of the vine is sometimes difficult, as it requires a longer time than most other forage plants. Some stack it away with layers of dry straw,
as is practised in the moist climate of England with clever.

PEA, EVERLASTING. See EVERLASTING PEA and LATHYRUS.

PEAS and OATS. These, in the Eastern and Northern States, are often sown together broad-cast, producing a mixed crop called Medley. The components are proportions of peas to three-fourths of oats. The pea commonly sown is the green pea from Canada, which ripens about the time of the oats, and for which, while growing, the oats act as supporters. Peas and oats are usually ground together as feed for their fattening cattle, and are deemed valuable, though not so good or so much relished as Indian meal without mixture. Forty bushels of peas and oats per acre would be regarded a large crop. This has been produced, however, on nine acres, in Deerfield meadows. Some farmers sow at the rate of one-third peas and two-thirds oats.

PEA, PARTRIDGE. The Cassia Chameriste of Beek; a native of the Middle and Southern States, where it goes by the common names of Sensitive pea and Magothbay bean. The stem is 1 to 2 feet high, rather erect, firm, and much branched, downy, and often purplish. Leaves 8, 10, or 12 pairs, 3 to 4 inches in length and 2 to 3 lines wide. Petals of the flowers, deep bright-yellow, obovate, 2 or 3 of them with a purple spot at base. Stamens 10, unequal, all fertile; anthers very long, 4 of them yellowish and 6 purple. Legume about 2 inches long and 3 to 4 of an inch wide, with a short, abrupt, oblique acumination, hairy along the sutures.

See Wild Sensitive Plant.

PEACH (Fr. pêche ; Lat. Amygdalus, derived from amyso, to lacerate, in allusion to the fissured shell). The tall and coarse portion of the ornamental, early flowering plants, of which the peach forms a species, may be advantageously disposed of in large plantations, and the dwarf kinds in small shrubberies at the front of the houses. In England the common way of increasing them is by budding on the plum stock or the bitter almond. Rich mould is a proper medium for them. They are most valued for producing their showy pink blossoms early in the season, sooner than almost any other shrubs. The peach is now one of the most esteemed fruits: nearly 300 varieties are enumerated in the London Horticultural Society’s Catalogue.

Although the peach is raised in the open air, in every part of the United States, it succeeds best in the states of New Jersey, Delaware, Maryland, Virginia, and some of the Western States in similar latitudes. The flavour of the peaches of the United States is far superior to that of the same kind of fruit in Europe. In the vicinity of the large cities, or where facilities of quick transportation to these are furnished, the culture of the peach is a source of great profit.

Mr. Thomas Hancock, a very intelligent nurseryman, near Burlington, New Jersey, gives the following description of the mode practised by him in planting and training peach orchards. “When it is intended to plant out a good orchard of trees, we generally select an elevated position, entirely unprotected by any timber or shelter of any kind; if a situation can be selected near the bank of a river, the crop is more certain, as the trees better withstand the frosts, which occasionally do much damage.

“Plough, and put the land in good condition for corn or vegetables, and plant the trees 20 feet apart each way: continue to till the land, taking care not to injure the roots of beans, potatoes, or something that does not grow with the peach. Or, if they are left fallow, a wheat, rye, and oats are very injurious, and should not be planted. The land must not remain without tillage, as the trees would soon be injured: indeed, nothing will destroy a fine peach orchard sooner than to let it lie in swart.

“The trees should be 2 years old on the stock from seed, and 1 year from the bud, the year after budding. This is considered as the best age for transplanting. If the water stands near the surface of the soil, or if the land has springs near the top of the ground, I should not deem it advisable to plant with the expectation of very certain crops. I have lost two orchards planted in this manner, while in an adjoining field, where the land, or a part of it, was high, with a dry subsoil, the trees flourished and produced abundant crops.

“Light sandy soil, or light loam, we consider the most preferable for planting out peach orchards, and I should judge that on many of the elevated knolls, in the vicinity of Boston, the peach might be cultivated to good advantage, particularly the earlier varieties. It is at least well worthy of trial.” (Orchardist’s Companion.)

The peach crop is, however, limited in a great degree by the destruction of the trees effected by a worm which attacks the inner bark of the root about the crown, and by a disease of uncertain origin, generally termed the yellows. In some parts of the country where the peach was formerly very extensively raised, the culture has been abandoned in consequence of the destruction of the trees from these two causes. Mr. Samuel Hubbard of Eggem, New Jersey, very advantageously known as a nurseryman, says that the attacks of the peach-worm may be obviated or the insect destroyed by frequently examining the root at the surface of the ground while the tree is in a state of vegetation, removing the insects, as far as possible, and then washing the tree at the earth’s surface with strong soap-suds, every week or two. Rubbing the trunk and main branches with soap-suds several times a year, is also highly conducive to keeping the tree in a healthy state. The ground should be kept free from grass around the peach tree. (Orchardist’s Companion.)

The application of a mixture of common salt and saltpetre has been recommended by a gentleman in Maryland, as successful in preserving peach trees against the attacks of worms. The proportions are, 1 part of salt-petre to 8 parts of common salt. Half a pound of this mixture to a tree of 7 years old and upwards, is to be strewed upon the surface of the ground around and in immediate contact with the trunk and branches. The mixture is also recommended to be sown over the orchard in the proportion of 2 bushels to the acre. By this means, it is said, the fruit is improved.
in size and flavour, the worms destroyed, and the yellows prevented.

The Yellows. The immediate cause of this fatal disease with which the peach tree is so often stated to be a matter involved in great obscurity. The following observations by Mr. Robert Sinclair, of Claimont Nursery, near Baltimore, Maryland, contains the views of a person of great intelligence and experience, in regard to the disease in question.

As I have, for about 30 years, occasionally had my attention drawn to this subject, I am willing, says Mr. Sinclair, to throw in my mite of experience. I am fully satisfied that the complaint exists. Some persons say that the worm at the root is the cause of the yellows. I acknowledge that any disorder that destroys the trees will cause the leaves to turn yellow, but the complaint I call the yellows will kill a whole orchard, without any visible wounds, on or before the third or fourth full crop. I think where any neighbourhood abounds with peach orchards, it will be nearly impossible to keep clear of the disease.

On planting out young peach trees on the site of a peach nursery, two years after the nursery was removed, and although the ground was in other respects well suited for the growth of the peach tree, yet by the next autumn many of them were dead, and the balance so sickly that I had them all dug up, and there was no sign of the worm at their roots. From this, and other similar experiments, I think the disease may be generated by planting too near where a nursery or orchard of peach trees has been, or where the latter is; consequently, where a neighbourhood abounds with peach trees, there is danger of its becoming over-spread with disease, without greater care than is usually taken to prevent it.

I think I have seen evidences of its being in some degree contagious. Richard Cromwell, the respectable and worthy peach raiser, near Baltimore, has for upwards of 30 years supplied that city with peaches of the best quality, on a large scale. Some time since, when I was walking with Mr. Cromwell through his peach orchard, when the trees were hanging full of ripe fruit: he pointed out a tree that he said had the yellows, having a full crop upon it, at that time worth one dollar per peck, and to me it appeared healthy; but he observed to me, "as soon as I take the fruit from the tree, I shall dig it up, in order to prevent the disease spreading any farther, for I expect the side of the adjoining trees next to it will be affected next season." I had occasion to pass through Mr. Cromwell's orchard the next fruiting time, and the sickly tree had been dug up, but, as had been predicted, parts of the four neighbouring trees were evidently much affected, but only the sides next to the diseased tree, which made it the more striking, and convincing of the contagion, if this is a proper term.

On another occasion, I had a favourite early purple peach, before I had a nursery, that I suspected was partially affected by the yellows, and being desirous of preserving the variety, I cut the healthiest branch I could get, and I had 12 buds inserted in healthy peach stocks; but when they had grown about 3 feet, they showed the disease so plainly, that in order to prevent it from spreading, I pulled up all the trees and had them burnt.

From these cases, it seems to me the disease may be generated by planting old peach orchards or nurseries too soon after the removal of the old trees, and also by planting too near those already affected with the disease; and if cuttings or scions are taken from diseased trees, their product will be also diseased. I also think the yellows may be communicated to young trees by planting seeds taken from diseased peach trees. (Hovey's Magazine of Horticulture.)

Drying Peaches. Several modes of effecting this are pursued. When done in-doors, furnaces should be placed in the cellar from which the heated air may rise into the building suitably provided with shelves, &c.

In some of the Southern States, says Mr. Kenrick, the process is facilitated by a previous scalding. This is effected by immersing baskets of the fruit a few minutes in kettles of boiling water. They are afterwards halved, the stone separated, and being laid with the skins downwards, the drying is effected in the sun in three days of good weather. Then may be stored in boxes.

In France, we are informed, peaches and other fruits are thus dried whole. The peaches or other fruits, being pared, are boiled for a few minutes in a syrup consisting of 1 pound of sugar dissolved in 3 quarts of water, and after being drained by being laid singly on board dishes, they are placed in the oven after the bread is taken out, and when sufficiently dry they are packed in boxes. The following is the mode of drying practised by Mr. Thomas Bellangee, of Egg Harbour, New Jersey. He has a small house provided with a stove, and drawers in the sides of the house lathed at their bottoms, with void intervals. The peaches should be ripe, and cut in two, not peeled, and laid in a single layer on the laths, with their skins downward, to save the juice. On shovelling in the drawer, they are soon dried by the hot air produced by the stove. In this way great quantities may successively, in a single season, be prepared, with a very little expense in the preparation of the building, and in fuel.

PEACH TREE BORER. Pl. 16, fig. 8. The following interesting description of the peach tree worm, with a mode of protecting against its ravages, is from Dr. Harris's Treatise on Destructive Insects.

The pernicious borer, which, during many years past, has proved very destructive to peach trees throughout the United States, is a species of Agrion, named exitiosa, or the destructive, by Mr. Say, who first scientifically described it in the third volume of the Journal of the Academy of Natural Sciences of Philadelph, and subsequently gave a representation and account of it in his American Entomology. In the fifth volume of the New England Farmer, I have given the history of this insect, have mentioned the principal authors who have noticed it, and recommended preventive measures, which have been found effectual in protecting the peach tree from its most serious attacks. The eggs, from which
PEACH TREE BORER.

these borers are hatched, are deposited, in the course of the summer, upon the trunk of the tree near the root; the borers penetrate the bark, and devour the inner bark and sap-wood. The seat of their operations is known by the castings and gum which issue from the holes in the tree. When these borers are nearly one year old, they make their cocoons either under the bark of the trunk or of the root, or in the earth and gum contiguous to the base of the tree; soon afterwards they are transformed to chrysalids, and finally come forth in the winged state, and lay the eggs for another generation of borers. The last transformation takes place, from June to September. Frequently, however, during the month of July, in the state of Massachusetts. Here, although there are several broods produced by a succession of hatches, there is but one rotation of metamorphoses consummated within a year. Hence borers, of all sizes, will be found in the trees throughout the year, although it seems to be necessary that all of them, whether more or less advanced, should pass through one winter before they appear in the winged state. Under its last form, this insect is a slender, dark-blue, four-winged moth, having a slight resemblance to a wasp or hornet-fly, to which it is sometimes likened. The two sexes differ greatly from each other, so much so as to have caused them to be mistaken for two distinct species. The male, which is much smaller than the female, has all the wings transparent, but bordered and veined with steel-blue, which is the general colour of the body in both sexes; the palpi or feelers, the edges of the collar, of the shoulder-covers, of the rings of the abdomen, and of the brush on the tail, are pale yellow; and there are two rings of the same yellow colour on the shins. It expands about 1 inch. The fore-wings of the female are blue, and opaque, the hind-wings transparent, and bordered and veined like those of the male, and the middle of the abdomen is encircled by a broad orange-coloured belt. It expands 1½ inch or more. This insect does not confine its attacks to the peach tree. I have repeatedly obtained both sexes from borers inhabiting the excrecences which are found on the trunks and limbs of the cherry tree; and moreover, I have frequently taken them in connection on the trunks of cherry and of peach trees. They sometimes deposit their eggs in the crotches of the branches of the tree, where the borers will subsequently be found; but the injury, sustained by their operations in such parts, bears no comparison to that resulting from their attacks at the base of the tree, which they too often completely girdle, and thus cause its premature decay and death. The following plan, which was recommended by me in the year 1826, and has been tried with complete success by several persons in this vicinity, will effectually protect the neck, or most vital part of the tree, from injury. Remove the earth around the base of the tree, crush and destroy the cocoons and borers which may be found in it, and under the bark, cover the wounded parts with the common clay composition, and surround the trunk with a strip of sheathing paper 8 or 9 inches wide, which should extend 2

PEAR TREE.

inches below the level of the soil, and be secured with strings of matting above. Fresh mortar should then be placed around the root, so as to confine the paper and prevent access beneath it, and the remaining cavity may be filled with new or unexhausted loam. This operation should be performed in the spring or during the month of June. In the winter the strings may be removed, and in the following spring the trees should again be examined for any borers that may have escaped search before, and the protecting applications should be renewed.

PEACOCK (Paeo crispatus). The peacock is not rarely be mentioned as a bird of economical use. Peacocks and peahens, indeed, are occasionally used for food, but this splendid creature is, and ought to be, regarded solely as an object of beauty. The advantages to be derived from rearing it for food are not to be thought of. See FOWL, THE PEACOCK.

PEARI-WORT (Sagina; from sagina, fatness; in allusion to its presumed nourishing qualities for sheep). These are hardy annual weeds, growing in any soil. There are in England three indigenous species.

PEAR TREE (Pyrus, from περας, the Celtic word for pear). Like other species of cultivated fruit, there are now a very great number of varieties, more than 600 being enumerated in the Horticultural Society's catalogue. A deep, rich loam is necessary for pear trees. They are increased by seeds, or by budding and grafting, which is the more common method, upon stocks of their own kind, or upon the quince. The established kinds are multiplied by grafting the chooser on the common kinds. Almost the same treatment is required in pruning and training the pear as the apple. When we reflect on the labours of the horticulturists, who have by cultivation made the pear tree forget its natural thorns, and instead of an acerb berry, produce us a fruit so fair and nectarous, we find our warmest gratitude an insufficient return.

The wild pear tree (P. communis) is a tall, handsome tree, growing in woods and hedges, with thorny branches, and simple, ovate, serrated leaves; downy beneath, and fringed with soft, white hairs. The flowers are copious, terminal, in corymbs, snow-white, with pink anthers. Fruit obovate, generally hard and astringent, but liable, even in a wild state, to many of the pests, and sometimes eatable. The wood is light, of a reddish brown, and durable. It is used by turners to make joiner's tools and picture-frames to be dyed black, and is also frequently stained and substituted for ebony. The white wild pear tree (P. arietina), we have already noticed under the head BEAN TREE. The expressed juice of the pear, when fermented in the manner of cider, constitutes the well-known beverage, perry.

Grafting and Incubating.—In Europe it is very common to set the pear on a quince stock for clayey and light soils, whilst for trees intended for sandy and calcareous soils, the free stock is preferred. Grafted on the white thorn (which, like the quince, renders them dwarfish), pears come very early into bearing, continue prolific, and, in respect to soil, will thrive.
well on a strong clay, which is considered unsuitable to those on quinces and wildings. But they are supposed to have an unfavourable influence upon the fruit, in rendering it small and hard. The following observations relating to the pear tree, its fruit, diseases, and insect enemies, are from the *New American Orchardist*, by Mr. Kenrick, whose list of fruits is valuable.

By grafting or inoculating on the quince, pear trees come much sooner into bearing, their productiveness is increased, the good quality of the fruit is not changed, but the size and longevity of the tree are diminished. Such pear trees are termed dwarfs. This mode is extensively adopted in France; but all kinds of pears will not grow on the quince stock. Those dwarfs trained in the form of a distaff, are called in that country *Quercules*.

The pear tree is of an extreme hardihood, exceeding that of the quince, and is seldom answered by the borers. The quince, when exposed, is liable to danger from the borer in the same degree as the apple tree. Their attacks always commence in the parts exposed above ground, or at the surface of the earth, and never beneath. In transplanting the pears, therefore, the quince stock must always be completely buried more than an inch beneath the soil. Thus situated and protected, the quince stock, from its nature, will strike root suddenly, new and numerous roots being produced on all sides, quite to the junction of the pear. Such is the mode adopted in practice by S. G. Perkins, Esq., and by other experienced cultivators, for the complete protection of the quince stock from all dangers of every kind.

**Soil and Distance.**—The pear flourishes in rich soils and gentle declivities; they will succeed in the most common, deep, dry soil, and throw out numerous lateral shoots. But they do not flourish in moist situations; in a cold, strong, moist soil, with a clayey subsoil, they throw out very few lateral roots, the fruit is not so fair, or of so good a quality, and the trees are not so long-lived. They will even grow in poor soils, and in the clefts of rocks.

With respect to distance, the same observations to be found under the head of *Apple* may here apply. But the pear, from its pyramidal form, requires much less space. 20 feet, in suitable soils, is a good distance; but less answers in poorer soils. *Quercules* are found to answer even at 4 or 5 feet distance, producing large crops; and, as they occupy but little space, and come suddenly into bearing, they are, for profit, extensively cultivated in France. The specimen pear trees at the Jardin du Roi, or Garden of Plants at Paris, in the autumn of 1840, were under the particular care and management of Mons. Dalbret, the pupil of Thouin, and himself the author of a most valuable work on pruning. These trees were kept in the most perfect *Quercules* or pyramidal form, from the summit quite down to the ground, by the system of short or spur pruning; and although at the distance of but about 7 feet asunder, yet they appeared to have ample space, and bore most abundant crops. But M. Dalbret then stated that 10 feet was the most suitable distance. *In the climate of the United States, and with more heat and sunshine, and finer skies, less distance might suffice.* Pears produced on quince stocks are found to be much improved in flavour; all but some particular winter kinds, which are said in some cases to become worse.

The young, luxuriant shoots of the pear tree, by being bent downwards, generally produced the finest possible bearing wood for the second year; and, by grafting on the quince, and bending the branches, fruit may be produced from a seedling pear in the third or fourth year from the seed, which, in the common course, would require from 7 to 14 years. That system of rendering trees productive is fully described in Mr. Kenrick's *Orchardist.* He believes it to be the best system of all others.

As to standards, very little other pruning is necessary, except taking out those few limbs that interfere in keeping the tree well balanced.

The *blight*, or, as it is sometimes called, *fire-blight*, is a malady which sometimes affects the pear tree during the months of June and July, causing the tree, or a portion of its branches, suddenly to turn black, with a mortal affection; its leaves wither at once, as by a stroke of the sun, and in a few hours become of a brown or black colour. Mr. Lowell is of opinion that this disease is caused by an insect called the *Scolytus pyri.* He observes, "On the first appearance of this disease, I instantly saw off all the limbs affected, and proceeded to examine them. I found at last the enemy, not at the place where death ensued, but some inches below it. The insect was very small, and apparently incapable of such extensive mischief; but the effect was certain, and the manner of producing that effect was obvious. It had eaten a complete circle of the alburnum, or sap-wood, not exceeding the size of a knitting-needle, so as completely to intercept the passage of the sap." This insect was shown by Mr. Lowell to the late Professor Peck, and in the account of the insect which was soon after published in the *Massachusetts Agricultural Repository*, the professor observed, that the mischievous effects of this insect may be observed in June and July, and that the dead part of the branches should be cut off without delay and burned. Mr. Lowell has stated (New England Farmer, vol. v. p. 2), that by steadily pursuing the system of cutting off the limbs many inches below the apparent injury, and burning them, the insects have been extirpated from his estate.

The account of Professor Peck was republished in the *New England Farmer*, vol. ii. p. 42. Some writers have attributed this disease to a stroke of the sun; others attribute it to manuring too high; some to excessive moisture at the roots, and too much pruning, which is supposed to cause a surfeit and produce a stagnation. But all agree that the only remedy is to saw off the limb. *Kenrick's Am. Orchardist.*

Some years ago, it was ascertained that a species of *Egeria* inhabited the pear tree in the State of Massachusetts, and it is said that considerable injury has resulted from it. An infested tree may be known by the castings thrown out of the small perforations made by the borers.
which live under the bark of the trunk, and subsist chiefly upon the inner bark. They make their cocoons under the bark, and change to chrysalids in the latter part of the summer. The winged insects appear in the autumn, having, like others of this kind, left their chrysalis skins projecting from the orifice of the holes which they had previously made. In its winged form, this Egeria is very much like that which inhabits the currant-bush; but it is a smaller species. It was described by Dr. Harris in the year 1830, under the name of Egeria pyri, the pear tree Egeria; and his account of it will be found on the second page of the ninth volume of the New England Farmer. Its wings expand rather more than half an inch; are transparent, but veined, bordered, and fringed with purplish black, and across the tips of the fore-wings is a broad, dark band, glossed with coppery tints; the prevailing colour of the upper side of the body is purple-black; but most of the under-side is golden-yellow, as are the edges of the collar, of the shoulder-covers, and of the fan-shaped brush on the tail; and there is a broad yellow band across the middle of the abdomen, preceded by two narrow bands of the same colour. (Harris.)

**Drying Pears.** When dried in ovens, the fruit will keep for years. This mode of preserving is common in France. Bosc has described two modes of drying pears, and adds, that, in some of the cantons of that country, the cultivators annually preserve, by these means, supplies of subsistence extremely agreeable and wholesome during winter and spring. He invites cultivators not to neglect this resource. In this mode of drying, those varieties of middle size, melting and sweet, are preferred. After the bread is drawn from the oven, they are placed on the swept hearth, or on hurdles or boards. This operation is repeated a second, a third, and even a fourth time, according to their size and the degree of heat. The heat must not be so great as to scorch, and the fruit must not be dried to hardness. Lastly, they are placed in bags, and preserved in a dry place. The second mode of preserving is practised chiefly on the Rousselets and finest-flavoured varieties. Bosc states that he has tried them after three years' preservation, and found them still good; but they are better during the first year. They are gathered a little before their maturity, and after being half-boiled in a small quantity of water, they are peeled and drawn. They are next carried on hurdles to the oven, after the bread is drawn, or the oven is heated to a suitable degree; here they remain twelve hours; after which they are steeped in the syrup, to which have been added sugar, cinnamon, cloves, and brandy. They are again returned to the oven, which is now heated to a less degree than at first. This operation is thrice repeated, until they are sufficiently dried, or of a clear brown colour, and firm, transparent flesh; and finally they are packed in boxes lined with paper. (Kewrick's Orchardist.)

**PEAT.** A collection of vegetable remains, commonly collected together in considerable masses, either on the surface of the earth, or in strata, at various depths. Owing to the changes which the plants composing it have undergone, it contains much tannic acid, which preserves the vegetable matter from further decomposition. It contains elements for the formation of the richest manure when substances are added to it to decompose the tannic acid, and hasten the decomposition of the vegetable matters, such as lime or marl. Peat has been found, when used alone as manure, not to possess any fertilizing qualities, as might be expected from its nature; but it has been advantageously employed as a mixture with compost. See Farm-Yard Manures.

It often happens that in extensive agricultural districts at a distance from cities and other places from which they cannot obtain supplies of animal manures, the domestic resources of the farm-yards are entirely inadequate to preserve the fertility of the extensive fields. It becomes a question of deep interest whether it be possible to enrich barren fields without the aid of animals and the resources of the farm-yard. Under the head of Farm-Yard Manures it will be seen that by Lord Meadowbank, Mr. Dickson, and other English agriculturists of high reputation, one load of dung has, by judicious mixture with peat and other matters, been made into six loads of manure, capable of fertilizing the whole field.

The regular peat formation of geologists, so extensive in Britain, can hardly be said to exist in the United States. But a substance is found in abundance in bogs and marshes throughout the Union, sufficiently analogous in composition to answer most, if not all, the valuable purposes of European peat.

Dr. Samuel L. Dana, of Lowell, Massachusetts, has published a work of the highest interest to agriculturists, under the title of A Muck Manual for Farmers. After treating of the various matters relating to soil, its elements, and the agencies brought to act upon it, he introduces, under the head of Artificial Manures, chiefly consisting of geine, the subject of swamp-muck, mud, or peat.

Peat, he states, is the result of a spontaneous change in vegetable matter, which ends in the production of geine, a term which he applies to designate humus and humic acid. Among manures, consisting chiefly of geine, peat, he says, is what bone-dust is among manures, consisting of animal matter. Peat is highly concentrated vegetable food. Under the general name of peat, Dr. Dana comprises several varieties distinguished as, 1st. Peat, the compact substance generally known and used as fuel, under this name. 2d. Turf, or swamp muck, by which is to be understood the paring removed before the peat is dug. It is a less compact variety of peat, common in all meadow swamps, and includes the hassocks or tussacks. It includes also the mud of salt marshes. 3d. Pond mud, the slushy material found at the bottom of ponds when dry, or in low grounds, the wash of higher lands. This seldom contains more than 20 per cent. of geine. These varieties comprise probably a fair sample of all the peat, and swamp muck, and pond mud, which occur in the various parts of the country. Dr. Dana has given analyses of 12 specimens representing the different varieties.
The average of the 10 best being per 100 parts, dried at a temperature of 300° Fahrenheit,—by which process it loses 73 to 97 per cent. of water,—soluble geine, 29.46; insoluble geine, 55.03; total geine, 83.97; silicates and silicate, 15.59. The poorest varieties of pond mud gave only 5 to 8 per cent. soluble geine, 6 to 9 per cent. insoluble geine, or about 14 per cent. total of geine, and 85 of salts and silicates.

When. fresh-dug peat, of average quality, is analyzed in its wet state, it is found to contain:

<table>
<thead>
<tr>
<th>Component</th>
<th>Amount</th>
<th>Amount</th>

</tr>
</tbody>
</table>

It is an interesting fact that this result differs very little from the result of the analyses of fresh cow dung, so far as the proportions of geine, water, and salts are concerned.

When allowed to drain as dry as it will, pond-mud still contains about two-thirds of its weight of water. It shrinks from two-thirds to three-fourths of its bulk, a cubic yard wet becoming one-fourth to one-third of a yard when dry.

A cord of pond mud weighs, when dug, 6117 lbs., and contains solid matter, 5495 lbs.; composed of geine, 450 lbs.; of silicates and salts, 3005 lbs.

The salts and geine of a cord of peat are equal to the manure of one cow for three months. It is certainly a very curious coincidence of results, that nature herself should have prepared a substance, whose agricultural value approaches so near cow dung, the type of manures. The power of producing alkaline action on the insoluble geine, is alone wanted to make peat good cow dung.

The great question comes, how is to be given to peat, a substance which in all other respects is so nearly allied to cow dung, that lacking element, ammonia, without which cow dung would be no better than peat, nay, not so good, since in peat nearly one-half of the geine or humus is already in a soluble state. It is well understood that the various matters used as manure, either solid or liquid, from whatever source derived, all possess a common property of generating ammonia. Peat in its ordinary state contains traces of ammonia, which is evolved freely on the addition of caustic potash or common ashes. Peat, then, is a source of nitrogen, since this with hydrogen constitutes ammonia. Without going into all the nice chemical reasoning of which Dr. Dana avails himself, we will simply state his main conclusion, namely: that by the addition of alkali to peat, it is put into the state which ammonia gives to dung.

With regard to the quantity of alkali required to be added to swamp-muck or peat, in order to bring it to an equality with cow dung, "It is found," says Dr. Dana, "that

52 parts of ammonia are equal to
58 parts of soda, or white ash, or to
63 parts of 1st quality pot or pearlash, or
65 parts of 2d quality pot or pearlash.

For all agricultural purposes, it may be considered, that salts of hartshorn, or carbonate of ammonia, and white or soda ash, are equal, pound for pound, and that pots and pearl ashes may be taken at one-half more.

"If all the nitrogen in dung becomes ammonia, then each 100 lbs. affords 2 lbs. 2 oz. Hence, if to 100 lbs. fresh-dug peat, there are added 2 lbs. of soda ash, or 3 lbs. of pot or pearl ashes, all the good effects of real cow dung will be produced. Peat or muck thus requires 2 per cent. of soda ash, or 3 per cent. of potash.

A cord of green peat weighs 9216 lbs.; 2 per cent. is 184 lbs. Hence, a cord requires that amount of soda ash, or 276 lbs. of potash. But if the peat is quite dry, so as to have lost $3$ of its bulk, then 736 lbs. of soda ash, or 1104 lbs. potash will be necessary. Two per cent. of alkali seems enormous. It is stated, in the hope that it may lead to experiments on the free use of alkali. But as it will be hereafter shown, that this is to be reduced by mixing with loam or other matter, this quantity, even if applied to one acre, will probably produce very good effects.

"There are other practical facts, which may help to solve a solution of the question, how much alkali is to be added to a cord of peat. According to the experience of Mr. Phinney, of Lexington, an authority which may not be questioned, a cord of green dung converts twice its bulk of peat into a manure of equal value to itself—that is, a cord of clear stable dung, composted with two of peat, forms a manure of equal value to three cords of green dung. Indeed, the permanent effects of this compost, according to Mr. Phinney, exceed those of stable dung. On this fact, 2 lbs. of ammonia in 100 lbs. of cow dung should convert 200 lbs. of fresh-dug peat into good cow dung. The equivalents of these, as has been shown, are 2 lbs. of soda ash, or 3 lbs. of potash. Allowing the gaseous ammonia to be divided equally among the 300 lbs. of dung and peat, this is in proportion of 103 oz. of soda ash, or 1 lb. of potash to 100 lbs. of fresh peat. Now this calculation, deduced from actual experiment, confirms the theoretical proportions, supposing only 1 of the nitrogen acts, though that was made before the authority met with the statement of Mr. Phinney."

Dr. Dana furnishes another striking evidence of the favourable results from applying artificial manure. "Mr. George Robbins, of Watertown," he says, "is an extensive manufacturer of soap and candles, and of starch, and, still better, a man who employs the refuse of those trades in enriching and gladdening his land. For four years (and it is believed his crops will compare with any of the best cultivators around him) he has not used a spoonful of manure made by any animal, walking either on two legs or on four. He keeps 11 horses, 4 cows, 100 hogs; he uses not a shovelful of their manure, but, selling that, he uses peat and swamp-muck, mixed with his own barilla ashes. The proportions are, 1 part of spent ashes to 3 of peat, dug up in the fall, mixed in the spring. After shovelling two or three times, it is spread and ploughed in. The effect is
PEAT.

immediate, and, so far, lasting. The effects of this spent ashes alone on sandy loam, are excellent; it makes the whole quite "sally."

"In the preparation of manure," says Dr. Dana, "price is everything. Let the cost be estimated per cord, of artificial manure, prepared in the proportions stated. Peat or muck may be called worth 50 cents per cord, and the labour of digging, say $1.

92 lbs. potash, 6 cents - $5.32
or 61 " soda ash, or white
ash, 4 cents - 2.44
or 24 bush. ashes, 15½ cents

3.10 10¢

3.65

3.00

3.15

$15

$12.30

$5.15

Were they really good hard wood-ashes, about 16 bushels would be sufficient, but an excess here is allowed, to compensate for variation in quality. But this may appear a very high price; but it is to be remembered, that its value is to be compared with that of a cord of clear cow dung. What is the value of cow dung? It appears from the barn account of the Merrimack Manufacturing Company, that for 9½ years, ending October, 1838, a bushel of clear cow dung costs 21½ cents. During the same time dung of inferior quality was delivered at the printworks, by the neighbouring farmers, at 20 cents per bushel. Clear dung is delivered at the printworks in Dover at 12½ cents per bushel, and at several of the printworks in Rhode Island, at 16 cents per bushel, giving an average of 17-45 cents per bushel, and as a cord contains, in round numbers, 100 bushels, its price is $17.45. Deduct from this the price of an artificial cord, 5 15

$12.30

It is hence evident that an artificial cord is only about one-third of the price of a natural cord, and if the last may be mixed with two parts of loam or swamp-muck, so may the first, which will reduce the price of a cord of artificial manure to $5.71. Now this is equal, according to all experience, cord for cord, to stable manure; the value of that may be estimated at $5, so that an artificial cord costs only about one-half. The best plan for preparing the artificial manure, would be to dig the peat or swamp-muck in the fall; in the spring of the year let this be mixed in the proportion of 38 lbs. of potash, 20 lbs. of soda ash, or 8 bushels of common house-ashes, to every cord of fresh-dug peat, estimating this by the pit dug out, and allowing nothing in the spring for shrinking. If ashes are used, they may be mixed in at once with the muck, but if soda ash or potashes are used, they must be dissolved in water and the pile evenly wet with the solution. The pile is then to be well shovelled over, and used as is other manure. But it has been found by experience, that the peat may be dug in the spring, immediately mixed with the alkali, and used forthwith. If spent ashes are used to prepare this muck, add one cord of spent ashes to three cords of peat or swamp muck.

There are other sources of alkali, for converting peat into soluble manure. Of these the chief is animal matter. Here we have ammonia produced. It has been actually proved by experiment, that a dead horse can convert 20 tons of peat into a valuable manure, richer and more lasting than stable dung; a barrel of alewives is equal to a wagon load of peat. The next great and prolific source of ammonia is the urine. The urine of one cow for a winter, mixed up, as it is daily collected, with peat, is sufficient to manure half an acre of land with 20 loads of manure of the best quality, while her solid evacuations and litter, for the same period, afforded only 17 loads, whose value was only about one-half that of the former.

"It need only be added in confirmation of all that has been advanced, that those who have had the prudence to fill their yards and hogs, with meadow-mud which has thus become saturated with ammonia, have in no wise lost their reward. If they have been satisfied with their practice, perhaps they will be no less firm in their belief of success, when science offers them a reason for the faith that is in them." (Muck Manure.)

PEAT SOILS.

The improvement of peat soils is a subject of very considerable agricultural importance in England, where it involves not only the permanent improvement of large estates, but these peat soils include a very large proportion of several counties in the United Kingdom.

The deep peat mosses, or bogs, which are naturally the most difficult to bring into cultivation, often extend to a depth of many feet, contain but little earth, are usually tolerably level, and consist of a mass of light vegetable fibres. This peat, even in the midst of summer, is commonly saturated with water; at other periods semi-fluid, and very often a tumbling, dangerous quagmire. Its soil, if I may call it such, is usually of a dark brown, changing to a blackish colour when thoroughly dried by a gentle heat. In this state the peat is easily inflammable, is commonly used for fuel, and has been occasionally employed by the gas manufacturer, the lime-burner, the charcoal-maker, and even the iron-smelter.

The common masses of peat existing on the earth's surface in England are the products of the decay of the mosses, common heath-plants, coarse grasses, and the sedges which often accompany them. But the varieties of peat are numerous, according to their age and situation. There are some of the peats which are found beneath the soil, in the lower portions of the valley of the Thames, which are evidently the remains of considerable masses of underwood, and contain sulphate of iron. Many others, dispersed over the coast of Essex and in Ireland, abound with the remains of large forest trees, and were most probably produced by some great convulsion of the earth in a distant period. In the southern counties, except in those of the banks of the Kennet and the Thames, the depth of the peat has not often exceeded a few inches; but in the places mentioned, and in those in the northern counties, the depth generally extends to several feet.

The formation of bog-moss is first commenced in very many instances by the rapid-
Growing broad-leaved bog-moss (Sphagnum laticifolium), a plant of very curious habits, whose growth under favourable circumstances (and it is strictly an aquatic) extends from an inch in length to 2 or 3 feet. In dry situations, or in those only periodically flooded, its progress is not rapid; but when it vegetates always immersed in the water of low, stagnant situations, there it increases with great vigour. It is true that this plant is an annual; but it sheds an abundance of hardy seeds, producing seedlings, which vegetate and easily support themselves in the water, with a slight assistance from the mere remains of their preceding generation. Their thread-like stems remain on the surface of the water till the seed is ripened; they then fall to the bottom and form distinct layers, which, in some specimens of peat, may be distinctly traced. The bog-moss thus commenced, gradually gets mixed with a variety of lichens, mosses, and scirpi, which annually add to the depth of the accumulating peat; and as this firmness increases, the plants gradually establish themselves, such as several varieties of the rushes and sedges. It is only when the peat-moss is raised by the gradually-accumulated remains of these peats from beneath the surface of the stagnant waters, that the heaths, the cranberry, the bilberry, and the grass-weeds make their appearance. The few plants which commonly tenant peat moors and bogs are of the most worthless kind, such as all live-stock commonly refuse. Besides the common heath-plants there are various rushes (Juncus), sedges (Carex), rush-grasses (Schoenus), cyprines (Cyperus), cat's-tail rushes (Typha), bur-weeds (Sparganium), &c.

Amongst the few specimens of the common grasses which are found in such places, struggling, as it were, for existence, are the marsh-bent (Agrostis paludosa), the awnless brown-bent (Agrostis canina). This is a very common grass in bogs whose winter waters are deep. The awned creeping-bent (A. stolonifera var. arisata), the small-leaved creeping-bent (A. stoe. ang.), the black couch-bent (A. repens), the white bent (A. alba), the flote lesene (Glyceria fluitans), tall lesene (Poa macra), elater grass (Allocladium), ribbon grass (Allocladium), water meadow-grass (Poa aquatica), long-leaved cotton-grass (Eriophorum poly-stachion), and the sheathed cotton-grass (E. vagnatum).

It is of primary importance that the farmer should clearly understand the chemical composition of the peat with which he has to contend, and that of the watery solution with which it is usually saturated. The common varieties of peat, when dried by a moderate heat, lose a very considerable portion of their weight, and are materially reduced in bulk. The dry mass consists chiefly of woody fibrous remains of a dark-brown colour, of which a very considerable portion is soluble in water; and even by exposure to the unassisted action of the sun and air, under the most favourable circumstances, it decomposes with extreme slowness. When burnt to an ash, the solid product thus obtained, varies commonly in its composition with the nature of the stratum of earth on which the mass of peat rests. If this is of a gravelly or argillaceous nature, the ashes are generally composed chiefly of silex, and a small portion of alumina, oxide of iron, with some carbonate of lime and sulphate of iron: if, however, the substratum immediately under the peat is calcareous, then the ashes commonly yield a considerably larger proportion of carbonate of lime, of the sulphate of iron (green vitriol) is absent, and the sulphate of lime (gypsum) abounds in its place. The celebrated Dutch ashes, which are productive of such large crops of clover, are composed of—

The liquid with which peat is usually soaked is also equally varying in its composition. It almost always contains a very small portion of brown vegetable extract, a quantity of the red oxide of iron, and when pyrites (sulphur and iron) are contained in the gravelly or other substrata, these are gradually, by the action of the water and the oxygen of the atmosphere, converted to sulphate of iron, which dissolves, and is found in the water. When, however, this solution comes in contact with chalk or other calcareous matter, the lime decomposes the green vitriol, the iron is precipitated, and sulphate of lime, so enriching to some of the artificial grasses, is very commonly found with red oxide of iron, dissolved in the peat-water.

The chemical composition of peat soils of course varies in the proportion of their constituents. The following analysis of a specimen of an entirely barren peat moss, in a perfectly dry state, will give the farmer a tolerable idea of their general composition:

<table>

Such is the composition of a barren peat moss. The analysis of an active or fertile peat moss, with which it will be well to compare it, gave the following results, after being also dried in a gentle heat:

Such is the usual chemical composition of peat. This, however, is occasionally varied.
by the presence of other substances, but the above sketch will afford a tolerably correct view of its ordinary properties; and this kind of knowledge will very materially aid the farmer in proceeding to examine the mode in which the composition of such soils may be altered so as to be rendered tenantable by useful varieties of plants.

The most common delusion in which the possessors of peat soils are apt to indulge, is the belief in the possibility of rendering them permanently productive without either previous drainage or the application of earth. The melancholy attempts of this kind which I have witnessed in various parts of England, especially in timber planting, can only excite the pity of those who witness the effects of such misspent time and money. The young trees too, which are most commonly employed in these ill-judged attempts, are usually of the fir tribe, precisely the kind the least adapted to prosper in a bog of water and peat. Common reflection would suggest that, if any kind of trees could be expected to vegetate with even moderate vigour in soils such as these, composed as they are often merely of a mass of hard inert vegetable matters, saturated with a species of green vitriol—if any kind of plantations would progress, it would be the alder, the willow tribe, or the hardy birch tree, tenacious of life, which can endure more moisture and subsist on poorer soils than most other plants. After the slightest consideration we should hardly decide upon placing on such swamps trees which delight in dry upland slopes, as the Scotch fir and the larch; yet we can hardly traverse a single line of railway, driven as their constructors have too often been to take for their line of country the most trembling, dangerous bogs, the most worthless heaths, without being struck with the ludicrous appearance of bright yellow-topped larches and ragged, sickly-looking Scotch firs, soaking in bog-water—and that too not in mere patches, but over hundreds of acres. I do not confine these observations to the north of England—to Lancashire and Yorkshire—but the remark applies to many of the southern counties: for instance, by the road-side between Wareham and Poole, in Dorsetshire, may be seen similar wet, peaty, heath plantations of Scotch firs.

In effecting the underdraining of peats, the first error to be carefully avoided is placing the drains too near the surface of the peat. It has been in vain to try it in the different kind of various parts of England, and in consequence the roots of many cultivated crops are apt to penetrate, under the shallow-drain system, into the corrosive water of the peat, which they never do without material injury.

For let me again remind the farmer, it is not the mere presence of too much water which renders the peat moss sterile, but the noxious, astrangent, irky nature of that water. In the reclamation of peat soils, the necessary drainage being effected (see Draining), the next important object is to furnish the soil with a sufficient quantity of earthy matter to support vegetation, and this may be done in several ways: that by paring and burning, so common in various parts of Cambridgeshire and Lincolnshire, I consider the worst of all modes; for it merely furnishes the soil by an expensive rapid process with the freed earths, and which, its gradual decomposition would by other modes more profitably and steadily effect.

The first operation after the water has been drained off is to break up as deeply as possible, by the common and the subsoil-ploughs, the surface of the peat; and then, if good well-burnt lime can be procured, there is no earthy addition so rapid and so powerful in dissolving and rendering pliable the peat as this. A few ploughings, assisting the combined operations of the atmosphere and the lime, will, in a few weeks, bring the soil into such a state as to enable it to bear a first crop. The quantity of lime should be about 250 or 300 bushels per acre; but the quantity of necessity must vary with the readiness with which the lime is procurable; where it is very expensive, the cultivator is obliged either to reduce the quantity, or mix it thoroughly with a proportion of chaff or marl before he spreads it over the surface of the peat. Where limestone is to be obtained in the immediate neighbourhood, and other fuel is not to be readily procured, peat may be employed in many cases in the process of lime-burning without much difficulty, it chiefly requiring that the peat should be thoroughly dried previous to being used. For a first crop on thus so far reclaimed peat soils, I have found no other crop equal to potatoes. These are best planted in ridges; the horse hoe-plough can then be easily kept at work, which not only considerably promotes the decomposition of the peat, by facilitating the introduction of the moisture and gases of the atmosphere, but this very operation adds very materially to the vigour and produce of this valuable root, than which no other plant more delights in fresh soils, such as that produced by well-drained, new earth-dressed peaty lands.

It is not to avoid for a year or two all attempts to produce grain crops on land like that I am describing. The course of cropping which the farmer will almost always find the most profitable, is to follow the potatoes with...
PEAT SOILS.

peats, then turnips, oaks, grass-seeds, peas, wheat. In all cases, too, he must remember in what small proportion some of the essential ingredients of his crops are at first existing in this peaty soil, and how valuable even a slight dressing of clay or marl will be found in supplying such deficiencies. And, again, it is here that the services of the manure-drill are available to an invaluable extent in applying bone-dust, or any kind of organic or even earthy manure, especially to the young land's earliest crops. For the natural results of the progress of cultivation, the gradual decomposition of the soil and tough vegetable remains, the accumulation of more easily decomposable vegetable matters, the application of the ordinary farm-yard compost, finally sufficiently enrich the ground with those salts of lime and of potash which form the essential ingredients of all fertile land.

To expedite the accumulation of decomposing soluble matters in the soil, several expedients may be adopted. For instance, if the farmer has access to night-soil, an admirable compost may be made by mixing this seven or eight weeks previous to its employment with the peat itself. I know of no other compost so powerful on peat soils as a compost of well-petrefied peat and night-soil: 4 or 5 cubic yards of the night-soil is an ample dressing per acre with 12 or 15 cubic yards of peat. If the farmer has no access to night-soil, let him substitute farm-yard compost with the peat in a rather larger proportion, or even urine, or the drainage from his farm-yard. This plan, first, I believe, successfully adopted by the late Lord Meadowbank, is well described by Mr. Dixon, of Heathershow, in an essay for which a prize was awarded to him, in 1839, by the Royal Agricultural Society of England.

The farmer must, to derive the maximum benefit from this plan, avoid certain errors, which will else materially deteriorate the richness of the compost. He must be careful to have the peat he intends to use dug for some time in the farm-yard exposed to the drying influence of the sun and winds. The peat, in fact, can hardly be employed too dry; and the farmer will find that, if he makes the compost in the dry, warm weather of summer, he may then use more peat in proportion to his farm-yard dung or night-soil, than if he makes the mixture when the temperature of the air is less. In the warm weather of the spring and summer months, the cultivator will find 1 cubic yard of fresh, good farm-yard compost sufficient for 3 or 4 cubic yards of peat; but in colder weather the proportion of peat must be decreased. The farmer will find that the fresher and richer the animal manure, the larger will be the proportion of peat with which it may be successfully mixed. Thus, with the rich semi-fluid mixture from the slaughter-houses of London, with 1 cubic yard of this, 6 or 7 cubic yards of peat may be mixed; and I have found, on several occasions, every reason to agree with Lord Meadowbank and others who have employed peat in this way, that it is very desirable not to mix more than half the intended proportion of peat at first, but to wait until the fermentation of the mass is somewhat advanced, and the temperature of the peat increased, before the last half is added to the heap. Some persons recommend the addition of a portion of lime to this compost; but this is a plan I do not consider either judicious orpermanent for the lime combines with, and even partially decomposes, some of the richest portions of the animal matters of the manure; and I have on some occasions suspected, from certain appearances, that it retarded, when thus used, the dissolution of the peat. In 8 or 9 weeks the compost will be ready for use; the peat and dung will be thoroughly mingled together, and the whole heap will have the colour of a dark garden-mound. Of the nourishing quality of this mixture of peat with night-soil or yard-manure, or urine, the farmer will readily convince himself by the fertile effects which it produces; and, when drilled with turnip-seed, the roots of the young plants will be found to encircle the lumps of it, just as they do in the case of crushed bones.

If the possessor of a peat soil cannot well prepare a compost of either night-soil or farm-manure with the peat, he may still furnish his soil with a valuable dressing, by mixing hot lime and peat together, at the rate of 1 cubic yard of the former with 3 or 4 cubic yards of the latter. In this case it is not necessary to dry the peat previously, for the lime readily absorbs the water contained in it; and in the course of 7 or 8 weeks the entire mass is reduced to the state of mould. From some experiments which I have made on a small scale, I have found that the addition of a portion of common salt to the lime, not exceeding 1 part of salt to 3 parts of lime, will still more increase the fertilizing powers of this peat compost; but my experiments on this head require repetition before I can confidently recommend this plan for the farmer's adoption.

When once the peat is well drained, a very thin covering of earth will produce much a better effect in forming a solid soil than the farmer may imagine possible: the facility with which roads are made across the extensive deep Scotch peat-mosses and the great Irish bogs, in some degree illustrates the same fact: the bog, when once dried, is found to require only a thin layer of gravel to make an excellent road. It is true that these are apt to tremble pretty considerably under the feet of the plough-horses, but they bear the heaviest carriages with perfect safety, even in places where the bog of peat is of a depth of from 20 to 40 feet.

PEAT-moss lands are commonly divided by the deep ditches or channels by which they are drained.

PECK. A measure of capacity containing 2 gallons, or the fourth of a bushel. The imperial peck contains 554-55 cubic inches. Besides the standard peck, there are in England
local pecks, which are extremely various: thus the Lancashire peck contains six gallons; but in other counties it is much less.

PEE-TSEE. A species of water chestnut, which grows in the southern provinces of China, in shallow rivers and ponds, with leaves like a bulrush, and hollow like the stalk of an onion. Its fruit is in the capsule of the root, like the husk of a chestnut.

PENNYROYAL (Mentha pulegium). English pennyroyal. This well known perennial plant is found growing wild in England on wet commons, and about the margins of small brooks. It has a strong acid, and very peculiar smell, and is, consequently, of no use as an ingredient of Pennyroyal. The stems are somewhat procumbent, or quite prostrate. Leaves ovate, scarcely half an inch long, full of pellucid dots. Flowers whorled. Flower-stalks purplish, clothed entirely with very short, dense, hoary pubescence.

Pennroyal is cultivated in Europe for its use in culinary and pharmaceutical preparations. There are two varieties—the trailing, which is usually cultivated, and the upright. These plants are best grown on a tenacious soil: even a clay is more suitable to them than a light silicious one. It should be moderately fertile, entirely free of stagnant moisture, and consequently on a dry subsoil, or well drained. A wet soil makes them luxuriant in summer, but insures decay in winter.

They are propagated by parting the roots in February or March, September or October, and by slips or offsets at the same season. The mints likewise may be increased, by cuttings of the annual shoots in May or June, as well as by cuttings of the roots either in spring or autumn. For production of green tops throughout the winter and early spring, the spear-mint is often planted in a hot-bed; and more rarely pennyroyal, every three weeks during October and three following months.

The pennyroyal indigenous to North America is the Helicoula pulegoides, an aromatic annual plant, very different in its habits from the European pennyroyal. It grows in all parts of the country, preferring dry grounds and pastures, where it often scents the air to a considerable distance. (Flora Cestrica.)

PEPPER-BRAND. A disease in grain.

See Mildew.

PEPPER-GRASS (Lepidium sativum). Tongue-grass. A kind of cress, possessing very pleasant and refreshing qualities, and generally cultivated in the United States for the table. The Virginia lepidium, or wild pepper-grass, is an annual commonly found in fields and along road-sides. One or two other species are known in the United States. (Flora Cestrica.)

PEPPERIDGE. An appellation improperly applied by the descendants of the Dutch in New York, to the tupelo or black-gum. The name more appropriately belongs to the common barberry.

PEPPERMINT (Mentha piperita). This species differs from the common spearmint chiefly in the intensity of its taste and dark colour of its foliage. It is only cultivated for distillation; the essential oil or distilled water enters into various cordial and medical preparations.

PEPPERS. See Capsicum.

PEPPER-SAXIFRAGE (Cnidium, the ancient name of orach). These are worthless herbaceous plants.

The meadow pepper-saxifrage (C. silans) is an indigenous perennial species, with smooth dark-green herbage. The root is spindle-shaped; stem erect, furrowed, solid, tough, from 1 to 2 feet high. Flowers yellowish or greenish-white, blooming in August and September. The whole plant being fetid when bruised, is supposed, in some parts of Norfolk, to give a bad flavour to milk and butter; but cattle certainly do not eat it, except accidentally or in small quantities. When this herb abounds in pastures, it may be found partially cropped, though generally left almost entire.

PEPPERWORT (Lepidium, from lepis, a scale, in allusion to the shape of the pods, which appear like little scales). Most of these plants are uninteresting; and none of them are pretty. L. sativum is the well-known garden cress. There are, in England, four indigenous species.

PERCH. In land measure, is the fourth part of a rood, or equal to 30½ square yards. Perch is also sometimes used as a denomination of long measure, when it signifies the same thing as a rod or pole, being 5½ yards or 16½ feet.

PERENNIALS (Lat. perennius, lasting throughout the year). In botany, those herbaceous plants, the roots of which remain alive more years than two, but whose stems flower and perish annually. Gardeners generally call them herbaceous plants.

*PERIWINKLE (ViOCEA, probably from vi-
culem, a band; in allusion to the suitableness of the shoots for making bands). These plants are well adapted for covering naked ground in shady situations. Any common soil suits them, and they are readily increased by separating the rooted trailing shoots. The two species indigenous to England are called the greater and the lesser periwinkles.

PERRY. A pleasant and wholesome liquor made from the juice of pears, by means of fermentation somewhat in the same manner as cider from apples.

The best pears for perry, or at least the kinds which have been hitherto deemed the fittest for making this liquor, are so excessively tart and harsh, that no one can think of eating them as fruit; for even hungry swine will not eat them.

It is observed by Mr. Knight, that in making this liquor, the pears are ground and pressed in exactly the same manner as apples in the manufacturing of cider; but that it is not usual for the reduced pulp to be suffered to remain any length of time without being pressed.

The after-management is in all respects so nearly similar to that of cider, that no further description is necessary here.

On the whole, the pear furnishes a less popular but far superior liquor to that afforded by the apple. The tree is capable of being grown on a greater variety of soil, and is more
PERSIMMON.

productive, furnishing in the proportion of 600 gallons of liquor to the acre, where the trees are full grown. See CIDER and PEAR.

PERSIMMON ( Diospyros Virginiana). The banks of the Connecticut, below lat. 45°, has been considered by Michaux as the northern limit of this American tree. But it is rendered rare in those parts by the severity of the winter, whilst in New Jersey, southern Pennsylvania, and others of the Middle, Southern and Western States, it is abundant. The French call it Plagueninier, and its fruit plaguenines. The tree varies surprisingly in size in different soils and climates, being in the vicinity of New York not more than half as large as in the more Southern States, where, in favourable situations, it is sometimes 60 feet in height and 18 to 24 inches in diameter. The tree belongs to the class of plants of which the male and female flowers are on different stocks. It is remarkable for producing a great abundance of fruit of a roundish-oval shape, about an inch in diameter, of a reddish orange colour when mature, which is generally just after the first autumnal frosts. Whilst green, the fruit is proverbial for its harshness and astrigency, but when ripe, it abounds in saccharine and other properties which render it luscious, wholesome, and highly nutritious.

PHLEUM. See CAX'S TAIL.

PIGEON (Columba). This bird, with all its numerous varieties of tumbler, carriers, pows, &c., is derived from one common species, denominated the stock-dove. Mr. Yarrell, in his History of British Birds, describes five species of doves or pigeons, viz.—

1. The ring-dove, or wood pigeon (C. palumbus), so called from the white feathers which form a portion of a ring round its neck, a well-known bird, which is also called a wood pigeon in many parts of England, is the largest wild pigeon known in Europe. In England, the ring-dove is also called the cushat, and the quest: the last names having reference to a tone of sadness which pervades their notes.

The whole length of this bird is 17 inches. The plumage of the upper parts of the body is bluish-gray, the neck and breast are vinous purple-red; the belly, &c., ash-gray; legs and toes red.

2. The stock-dove (C. annus). This species derives its name from building in the stocks of trees, particularly such as have been headed down, and have become in consequence rugged and bushy at the top. The plumage is for the most part bluish-gray, the sides of the neck glossy, with green reflections; breast purple-red. The whole length of the female is 13 inches.

3. The rock-dove (C. livia), as its name implies, is a species which, in its natural and wild state, inhabits high rocks near the sea-coast, in the cavities of which it lives the greater part of the year. The whole length of the bird is 11½ inches.

4. The turtle-dove (C. turtur) is only a summer visitor. These birds arrive in England from the African coast about the end of April or the beginning of May, and are rather more numerous in the south-eastern, southern, and midland counties, than in those which are farther north. The plumage is in general brown, of various shades; legs and toes yellow-brown. The whole length of the bird is 11½ inches.

5. The passenger pigeon (C. Ectopistes migratorius). This beautiful bird is a native of North America. Its appearance on the English coasts is very rare. The whole length of an adult male bird is 17 inches. See Dove-cote and Guinea.

PIGEON'S DUNG. See Dové-cote and Guinea.

PIGGERY. A collection of small sties where hogs or swine are lodged. See SWINE.

PIKE. A word of various signification in different districts. In some counties it is applied to a prong, or what is generally called a fork, used for carrying straw, &c., from the barn, cocking of hay, &c. In others it signifies a sort of stakelet or load, cock of hay, &c. In the midland districts it means to glean.

PILE. A sharpened beam of wood driven down into the ground to protect the banks of rivers or for other similar purposes. Pile is also provincially applied to the breaking off the awns of thrashed barley, and to a blade of grass.

PILING-IRON. A tool used in breaking off the awns of barley, and sometimes the tails of oats, an operation which with the farmers is called piling barley. See Hummeller.

PILEWORT CROWFOOT. See CROWFOOT.

PIE. A provincial term for a raised mound, or pit for preserving potatoes and other roots; and it is also applied to the compost heaps formed when the farm-yard dung is carried into the fields.

PIECE-WORK. That which is done by the job or piece. It is sometimes called task-work. See Labour.

PIG. See SWINE.

PIGEON (Columbus). This bird, with all its numerous varieties of tumblers, carriers, pows, &c., is derived from one common species, denominated the stock-dove. Mr. Yarrell, in his History of British Birds, describes five species of doves or pigeons, viz.—

1. The ring-dove, or wood pigeon (C. palumbus), so called from the white feathers which form a portion of a ring round its neck, a well-known bird, which is also called a wood pigeon in many parts of England, is the largest wild pigeon known in Europe. In England, the ring-dove is also called the cushat, and the quest: the last names having reference to a tone of sadness which pervades their notes.

The whole length of this bird is 17 inches. The plumage of the upper parts of the body is bluish-gray, the neck and breast are vinous purple-red; the belly, &c., ash-gray; legs and toes red.

2. The stock-dove (C. annus). This species...
of commerce, both in Europe and America. The genus *Pinus* is distinguished from the firs, by the leaves being needle-shaped and grouped in pairs, or in three, four, or five together; held, as it were, together by a sheath at their base. Most, if not all of the species, are highly deserving of culture, being very ornamental and beautiful in every stage of their growth. They will succeed on almost any kind of soil, but to bring the timber to its greatest state of perfection, a somewhat loamy surface soil and a cool subsoil are requisite. Young plants may be obtained by a variety of methods. All the species may be propagated by layers, by inarching on nearly allied kinds, and by herbaceous grafting; many may also be increased by cuttings, but the speediest way is by seed, and which process I shall briefly notice. In some of the species the cones attain their full size the first year, but in most not till the end of the second autumn. The cones of the Scotch pine (*P. sylvestris*), and those allied to it, open of themselves shortly after being gathered from the tree, and spread out in the sun; but the cones of *P. pinea*, *P. pinaster*, *P. sabina*, and some similar species, do not, though treated in the same manner; and open their scales only after several months. The seed should be sown on a finely-prepared rather sandy soil, in March or April. The seeds of the most common kinds are always sown on beds, and after being gently beaten down are slightly covered with light soil.

There are upwards of fifty species of pines and the appearance of the tree, as well as the quality of the timber, varies with the species and with the situation in which each grows. Generally speaking, the timber is hardest and best in exposed cold situations, and where its growth is slow. See Fir Tree.

**PINE, THE GROUND.** See Bough.

**PINK** (*Dianthus;* from *diön*, divine; and *austos*, a flower, in reference to the fragrance of the blossoms and the unrivaled neatness of the flowers). A truly beautiful and ornamental genus, containing some of the most prized flowers we possess, on account of the beauty and fragrance of their blossoms, and their foliage, which is as green and vivid in winter as it is in summer. The genus is divided into those with *solitary* and those with *aggregate* flowers.

**PIP.** A disease among poultry, consisting in a white thin skin, or film, growing upon or under the tip of the tongue, which hinders the feeding. It is supposed to arise from the drinking of foul water, or eating filthy meat; it is usually cured by pulling off the film with the fingers, and washing the part with a solution of common salt.

**PIPE-CLAY.** A species of clay abounding in Devonshire and other parts of England, employed in the manufacture of earthenware. See Mixture of Soils.

**PISTIL.** In botany, the columnar body in the centre of a flower, consisting commonly of three parts; viz., the ovary, styles, and stigmas. It is one of the essential parts of the flower; and when it is absent the flower is sterile. It receives the pollen, and communicates its stimulus to the ovules; without which the seeds are imperfect, and do not germinate.

**PITCH** (Ger. *pech*). In commerce, the residue which remains on insipissating tar, or boiling it down to dryness. It is a black solid substance, with a shining fracture, softens at 90°, and becomes liquid in boiling water. It is extensively used in ship-building, and for other purposes. Large quantities are manufactured in Great Britain, but not sufficient to supply the great demand. The duty on importation is 16d. per cwt. In husbandry, pitch signifies a fork-full of hay, corn, or straw, or as much as is raised to the load, stack, or mow, at one time.

**PLANE-TREE (Placenta ulmifolia).** "Kentucky, Tennessee, the banks of the Mississippi, and the Southern States, are, says Michaux, the only parts of the American republic where my father and myself have found the planter tree. "I have more particularly observed the planter tree in the large swamps on the borders of the river Savannah in Georgia. It is a tree of the second order, and is rarely more than 35 or 40 feet high, and 12 or 15 inches in diameter. Its bloom is early and not conspicuous. Its minute seeds are contained in small, oval, inflated, unswelled capsules. The leaves are about 1½ inch long, oval-acuminate, dentilolated, of a lively green, and a little like those of the European elm, to which this species bears the greatest analogy.

"The wood of the planter tree is hard, strong, and seemingly proper for various uses; it is probably similar in its characters to the analogous species in the north of Asia, the *Siberian elm*; but the tree is rare and the wood is neglected." (J. A. Sylvis.)

**PLANKS** (Ger. *planke*; *Dan.* *planke*; *Fr.* *planche*). Thick strong boards cut from various kinds of wood, especially oak and pine. Planks are usually of the thickness of from one inch to four. They are imported in large quantities from the northern ports of Europe, and from several ports of North America. Those employed for making sheds or farm out-houses should be tarred, or steeped in corrosive sublimate.

**PLANT.** In natural history. See Acclimatisation, Botany, Earth, Glasses, Organic Chemistry, Temperature, Water, &c.

**PLANTS IN CLOSELY GASED CASES.** By the recent discovery of Mr. Ward, of London, that certain plants will grow when enclosed in glazed cases, the most forbidding local circumstances may be overcome, and any person, whether inhabiting the most humble or the most splendid dwelling, provided they are exposed for a few hours every day to the sun's light, has it in his power to rear and cultivate a miscellaneous collection of plants, to enjoy the beauty of their appearance, and to watch their progress through all the stages of their growth, at an expense so insignificant as to be within the means of every one, even in very moderate circumstances; in short, to enjoy, even in rooms heated with anthracite coal, a parlour green-house.

To do this an apparatus must be provided, consisting of a box and a glass roof, such as are used for raising cucumbers, for instance, or more ornamental, as may be desired. The box should be lined in the bottom with zinc to prevent leakage. The whole should be close, as
prevent evaporation, and may be painted to represent any description of wood; a hole or holes should be left in the bottom, through the zinc and board, to carry off any extra water, if you find there is too much for the health of the plants enclosed. At the upper edge of the box a groove is sunk to receive the lower edge of the glass roof, which rests tightly upon it.

The framework cover should be glazed with good glass, with a door on one side made to fit close, and which may be opened to remove dead branches, for trimming, and the addition or subtraction of plants. Along the top of the roof, hooks or brass rods may be placed, from which small pots may be suspended with brass wires; twine will soon decay in the continued dampness. The whole of the framework should be well fatted, so as to preclude, as far as possible, all interchange between the air in the case, and that in the room.

Lay the bottom of the box with pieces of broken earthenware, as an open subsoil. Next lay a stratum of turfy loam, one inch deep, and fill in the remainder of the space with soil, composed of equal portions of peat and loam, mixed with about one-twentieth part of rough white sand, free from iron. The artificial garden plot is now ready to receive the plants. Plant these in the usual manner, and then shower over them, with a fine rose watering plant, sufficient to saturate the soil, till the liquid begins to run off by the opening in the bottom. After draining thus for 24 hours, cork up the hole or holes, place the glass case on the box, and the operation will be finished.

The most remarkable part in the economy of the case, thus closed up, is the preservation of atmospheric purity. To all who reflect, for the first time, on this subject, it will seem incomprehensible how the plants can possibly thrive and blossom, without the occasional interchange of fresh air with the atmosphere. This certainly does appear extraordinary, yet it is ascertained by experiment, that no such reinvigoration is requisite: to account for the phenomenon it will be necessary to explain the constitution of atmospheric air, and the means adopted by nature for its purification.

Air consists of three gases in close mechanical union, nitrogen, oxygen, and carbonic acid, in the proportions of about 79 of nitrogen, 20 oxygen, and 1 of carbonic acid, in 100 parts of pure air. In this mixed composition, the essential element for the support of respiration in both animals and plants, and also for combustion, is the oxygen being little else than a diluent to modify the strength of the oxygen. It was long believed by men of science, that plants possessed the power of exuding oxygen, and so formed a prime agent for restoring vitiated air to purity. Later investigations, however, by French chemists, have made it evident that plants have no such power, unless when placed under the influence of the sun's rays, or, in other words, that solar light is the grand cleanser of the atmosphere, and without which, both plants and animals languish and die.

With respect to plants in particular, it is ascertained, that while inhaling oxygen, and expiring carbonic acid, their leaves possess the remarkable property, in conjunction with the sun's light, of retransforming the carbonic acid into oxygen. At night, when the light of day has departed, the expired carbonic acid may be detected in the neighbourhood of plants, and hence, one cause of injury to health by breathing night-air; but when the morning sun again bursts upon the scene, a great chemical process commences in the atmosphere: the carbonic acid is decomposed, oxygen is evolved, and all nature rejoices in re-creation of its appropriate nourishment.

A question will here readily occur—What species of plants are best adapted for these domestic green-houses? This has been answered ably by Mr. Ellis, in a paper read before the Edinburgh Botanical Society in 1839. According to this gentleman's statement, the plants most suitable are those which partake largely of a cellular structure, and possess a succulent character, and especially those which have fleshy leaves; whilst on the contrary, the continued humidity is unfavourable to the development of flowers of most exogenous plants, except such as naturally grow in moist and shady situations." Plants, therefore, which grow naturally, and bloom in cavernous and moist situations, or in moist and warm climates, are best adapted for these cases; within this class of vegetables there are many beautiful and luxurious plants, which it would be no small pleasure to enumerate. We name but a few which have eminently succeeded. A specimen of this mode of culture may be seen in the possession of Mr. J. J. Smith, Jr., Librarian of the Philadelphia Library, which is eminently successful.

Crocuses, and winter aconite; joy; lycopodium; the various cactuses; aloes; primroses; the fairy roses; begonias; all the ferns; anemone; musk plants; myrtles; jasmines, &c.

All the vacant spaces in the case may be employed in raising salads, radishes, &c.; and one may, says Mr. W., "that a man engaged in gardening who could not, in the course of a twelvemonth, pay for his case out of its proceeds."

Sir W. J. Hooker, in a letter to Mr. Ward, says, "Splendid as is the hot-house and green-house collection at Woburn Abbey, I doubt whether that gives more pleasure to the noble proprietors and their numerous visitors than the beautiful little collection in Mr. Ward's case, that occupies a table in the library, and flourishes without requiring the skill of the gardener in its cultivation. Once properly watered, these cases have remained for seven years without any additional moisture.

The uses to which this discovery of Mr. Ward's has led, are important to man; especially so in the transmission of plants from one country to another by sea. So admirably does it answer to thus enclose plants for sea-voyages, that few instances of failure have occurred in their transmission, where care has been taken to renew the glasses, if broken, and to expose the cases to the action of the sun's rays on deck in fine weather. But, even more important than this, it will enable the chemist to make observations comparative on the effects of different soils, manures, &c.; to determine the powers possessed by plants of
PLANTAIN.

absorbing, and selecting various substances by their roots; to ascertain the existence and nature of the deleterious excretions from the roots; the poisonous character of these excretions, if they exist, being rendered very problematical by the circumstance of plants, in a state of nature, occupying the same situation for ages; to prove the effects of poisons on plants; to test the influence of light in protecting plants from the effects of low temperatures; and, lastly, by means of these cases the scientific naturalist will be assisted in exploring that debatable ground on the confines of the animal and vegetable kingdoms, where it is often impossible to determine the point at which one ends and the other begins.

PLANTAIN (Piantago; derived from planta, the sole of the foot; resemblance in the leaves). A genus of plants, the greater number of the species of which are mere weeds: they are generally almost stemless, and for the most part perennial. There are in England five native species:—

1. Greater plantain, or way-bread (P. major), which is very common in meadows, pastures, and waste and cultivated ground, perennial, and in flower all summer. The root consists of many long, stout fibres. The leaves are radical, numerous, broad, with seven or nine ribs, on channelled, ribbed stalks longer than themselves; margins wavy or toothed. Flowers on long spikes, small, whitish, with reddish anthers, very numerous: the spikes, each on a simple, naked, radical stalk. The seeds, which are angular, in a membranous capsule, are the food of small birds. The rose-shaped variety and the paniced one are often cultivated in gardens for the sake of curiosity, and afford remarkable instances of vegetable transformation. This species, like the whole genus, in general, is mucilaginous, and somewhat astringent, qualities which render it not altogether a useless rustick medicine. Cows, horses, and horses do not relish this plant, but it is eaten by sheep, goats, and swine. This perennial-rooted plant is extensively naturalized in the United States, and is remarkable, says Dr. Darlington, for accompanying civilized man, growing along his foot-paths, and flourishing around his settlements. From this circumstance, the American Indians call it by a name which signifies "the white man's foot."

2. Hoary plantain (P. media). This species grows abundantly in chalky or gravelly hills. The root is rather woody. The leaves are numerous, erect, deep-green, acute, each tapering at the base into a broad, flat, ribbed foot-stalk, accompanied at its insertion with large tufts of soil, white, woolly fibres. Flower-stalks round, longer than the leaves, erect, smooth. Spikes cylindrical, slender, many-flowered, dense, with fleshy keeled bractes, not longer than the calyx. Sheep appear to be very fond of this species.

3. Ribwort plantain, or rib-grass (P. lanceolata), is also a very common species in meadows and pastures. Pl. 9, i. The leaves are numerous, erect, deep-green, acute, each tapering at the base into a broad, flat, ribbed foot-stalk, accompanied at its insertion with large tufts of soil, white, woolly fibres. Flower-stalks taller than the leaves, likewise woolly at the base, five-angled, with intermediate furrows, nearly smooth, twisted. Spike ovate, an inch long, with black imbricated bractes, occasionally leafy at the base. This species makes a part of most meadow hay, and has been cultivated as a crop, but seems to be now disused. Cattle are said not to eat it willingly, at least by itself. The total absence of rib-grass in marshy lands is a certain criterion of their indifferent quality; and in proportion as such soils are improved by draining, this plant will flourish and abound.

4. Sea plantain (P. maritima). This grows in muddy salt-marshes, and about the mouths of large rivers. It is perennial, and flowers in August and September. The root is long and cylindrical; herb various in luxuriance, leaves are all radical, numerous, from four to twelve inches long, dull-green, linear, channelled, hairy, nearly entire. Flower-stalks round, longer than the leaves, erect, smooth. Spikes cylindrical, slender, many-flowered, dense, with fleshy keeled bractes, not longer than the calyx. Sheep appear to be very fond of this species.

5. Buck's-horn plantain, or star of the earth (P. Coronopus). This is an annual species, which flourishes on dry, sandy, or gravelly ground, flowering from June to August. The root is tapering; leaves pale, hairy, in panicles, many-flowered, farious, numerous, lanceolate-cylindrical, varying greatly in length, on spreading hairy stalks.

The White, or Virginia Plantain, is a native of the United States, where it is commonly found in barren old fields and stony hills. It has a biennial root, leaves 2 or 3 inches long, and from 1 to 2 wide, the whole plant being covered with a gray pubescence or down. Nine or ten additional species of plantain are enumerated in the United States.

PLANTAIN. WHITE, see CUNWORT.

PLANTATION. In England this term is applied to a piece of ground planted with trees for the purpose of producing timber or cop- pine wood; and the term is also applied to a collection of trees or shrubs placed in the ground for their beauty or usefulness.

For the correct consideration of the best mode of forming plantations of timber trees, several circumstances must, of necessity, be taken into the planter's account, of which the principal are—1st, The composition of the soil; 2dly, The trees to which that soil is best adapted; 3dly, The elevation, or inclination of the land: an attention to these three principal points has been the source of much waste of time, of labour, and of capital.

In this, as in all researches where vegetation is concerned, nature is ever our best guide and instructor. We find indigenous on the chalks, the beech, the birch, and the ash; the oak tenants the clay formation, the elm delights in rich alluvial bottoms, and in warm, sheltered situations. To the sand is left the fir tribe, the ash, and the birch; which last most picturesque tree will endure a climate, and vegetate on soils, far too cold and too barren for any other to exist on. On the warm gravels, and on deep, dark soil, we find the Spanish chestnut located; and if, on even the peat, we only occasionally meet with a few straggling
mountain ash and Scotch firs, it is not because the composition of the soil is too poor to sustain a better description of timber tree, but that the soil is usually saturated with water, too much impregnated with the salts of iron for any plants to be successfully planted till that corrosive moisture is removed.

Then, again, as regards the temperature best adapted to the tree, much too little attention is commonly paid. The fir tribe are found to delight in dry, cool elevations, whilst attempts to make the larch grow in warm, rich bottoms, generally fail. These facts should be more carefully attended to by the planter: he should consider the inequalities of his land and the habits of his trees, and distribute them accordingly. Leaving the natives of a temperate climate to the southern and western slopes, he should devote to the northern declinations the natives of a colder clime; to them consign the larch and the Scotch fir, the ash and the birch.

This last-mentioned tree will, in fact, grow at a greater elevation above the sea, and in a more northern latitude, than any other. As we approach the Arctic regions, it is the last tree that remains. Long after all others have departed it still flourishes: in Greenland there is no other tree.

Then, again, as in all other questions where plants of any kind are to be made to vegetate, the chemical composition of the soil is a tolerably certain criterion, when compared with that of the wood of trees, to guide us in our selection of the species to which that land is the best adapted: the earths found in them by the chemist are sure to indicate the soils on which they will flourish. Thus, the ashes of the perfect wood of the oak contain more than 38 per cent. of soluble salts, and only 2 per cent. of silica (tint); that of the fir (bérie), grown on granite, only 16 per cent. of soluble salts, and 19 per cent. of silica. Now the fir flourishes very well on the poorest silicious sands, but the oak will not grow on such soils without a dressing of other earths. Carbonate of lime (chalk), when in excess in soils, is less prejudicial to the growth of trees than an excess of any other earth. Now the carbonate of lime is precisely that earth which is most commonly found in timber trees, and in the largest proportions. The ashes of the wood of the oak, for instance, contain about 22 per cent. of the earth carbonate; the birch 29, the hazel 22, the hornbeam 26 per cent.; and that of the beech a still larger proportion. And so almost universally does carbonate of lime and silica exist in wood, that M. Einhof, an able Prussian chemist, came to the conclusion that the plant had the power of forming these earths when growing on soils that did not contain them: they certainly, however, are found to absorb the largest proportion of carbonate of lime and silica on soils in which those earths abound. Thus M. Saussure found in the ashes of the fir, growing on a soil which contained 1.74 per cent. of carbonate of lime, 46.34 per cent. of this earth; but in the ashes of the same wood, produced from a soil containing 93 per cent. of carbonate of lime, he found 63 per cent. of that earth. And when the soil contained 75-25 per cent. of silica, the timber growing on it contained 13.49 per cent.; but when the soil was entirely free from the earth, it was equally absent from the wood.

The observations of the planter confirm entirely those of the chemist. Thus, on the poor, hungry, heath lands, such as those of Norfolk, Sury, and the north, which contain hardly a trace of carbonate of lime, they find that by dressing land intended for planting with chalk or marl, the growth of the trees is very materially increased; and more recently, as in the forest of Darnaway, in Scotland, the planters have reaped the greatest advantage from placing only a handful of lime (about four bushels per acre is sufficient) in the soil under the plants: by this means the young trees, they say, are forced forward, that is, they are supplied with the carbonate of lime at the very period of their growth when their roots, from want of extent and vigour, are least able to absorb from the soil the portion of this earth so essential for their healthy growth. And it is precisely such heath soils as those to which I have alluded as being so materially benefited by the application of lime, chalk, or marl (which also contains chalk), that are found when examined, in the best state, to be nearly destitute of carbonate of lime.

It is for the same reasons that, in the early state of their growth, timber plantations are benefited so materially by being manured with organic matters, a fact well known to those who plant for merely ornamental purposes; and it is because all timber trees contain phosphate of lime in very considerable proportions, that crushed bones are found to be so excellent a fertilizer for them; and hence one reason why it has been long a well-known fact, that by burying dead animals under trees nearly exhausted for want of nourishment, those trees will almost invariably be considerably revived, and send out their shoots with unusual vigour; and how essential the presence of phosphate of lime is to their growth, may be judged of from the fact, that this salt constitutes 4.5 per cent. of the ashes of the oak, 35 in those of the hazel, 16-75 of the poplar, 23 in the hornbeam, 12 per cent. in those of the fir.

These chemical examinations naturally support the conclusions to which I have long come in my own experiments, that in all plantations of timber trees, both on the score of profit and their natural growth, it is in almost all situations desirable to assist the growth of the young trees by a small addition of manure. On a large scale, this must be chiefly confined to the use of the earths, either lime, chalk, or marl, according to their respective local value; and for this purpose a smaller proportion per acre of any kind of manure is of much greater value than is commonly supposed. In Scotland they have found about 4 bushels of lime an abundant addition, since they merely mix a handful of this earth in the soil under each plant; and in the fine woods produced by Mr. Withers, of Holt, by spreading a poor marl over his hungry, black, heath soil, and then ploughing them in very deeply, he merely added about 20 cubic yards per acre.

In preparing the land for plantations, the
The same chemical examination of its composition well illustrates the advantage derived by the plant from merely previously stirring the soil, since it is evident that when the constituents of the young trees are contained in it in only very limited proportions, in such case the more easily their roots are enabled to penetrate a search of that necessary nourishment, the more rapid will be their growth. Previous trenching of the soil also conduces to the healthy growth of trees in more ways than one. It renders them less subject to injury from want of moisture in the heats of summer; the atmosphere more freely finds access to their roots, and not only yields its watery vapour in the warmest weather for their service, but its gases, so essential to their very existence, are also in a similar manner more readily absorbed.

I have had many occasions to notice the advantages of deeply stirring the land for timber trees. In my early plantings, my larch and other timber trees made but little progress, for I merely placed them in holes dug in the soil; I neither manured, nor in any way prepared the soil. An experiment, however, which I made some years since—in which, by merely trenching the soil with the fork in a clump of larch, Scotch firs, and birch, to the depth of about 30 inches, the growth of the trees, which had for several years been extremely slow, was in the succeeding years exceedingly vigorous—convinced me of the truth of the observations made by Sir Henry Steuart, Mr. Withers, and others, of the great advantages of trenching the soil, either by the spade or by the common or the subsoil plough.

The opinions and explanations given by the labouring woodmen of the cause of the occasional very luxuriant patches in extensive young plantations accord with these conclusions. They tell you that those favoured trees are on a deep, tender piece of land.

The last branch of the investigation—that of the best mode of planting and of expense—is now to be considered. Too little attention is usually paid by planters in the choice of their plantations, in the mode in which they have reared, and in the care of their removal: instead of attending to the acquired habits of the tree, it is a very common practice for the plants to be bought of some nurseryman; who has reared them in a warm, rich bottom, and then, as a natural consequence, when the trees are transplanted to a cold, poor, hungry, exposed soil, a large portion of them are sure to perish, or, if they live, many become stunted or stagheaded. That all these evils may be avoided with only ordinary care, is proved by the experience of the best planters, who are careful to procure their seedlings from land at least not better than that on which they are intended to be placed; and is further evidenced by the fact that, when the soil is prepared by either deep digging or manuring, or both, then the mortality amongst the plants is very small indeed,—they need no further attention, they equally set at defiance the extremes of heat and cold, are very rarely diseased, and shoot with uncommon vigour. This attention to the early acquired habits of the plant is not entirely a modern observation—the early Italian planters were careful in replacing the tree in the same position as regards the cardinal points that it occupied in its early growth. (Virgil, Geo. ii. 269.)

There are other very common errors, of which I have long noticed the ill effects; for instance, I have seen planters with the young trees so deeply planted in the earth, and the unnecessary length of time which is suffered to elapse between the period when the plant is taken from the nursery and replanted. I have always found the after good effect of causing the roots of the young plant to be carefully arranged, and spread out before the earth is thrown in upon it; the usually heedless way in which the roots are thrust into the hole, and perhaps broken or materially bruised in the act of treading in the earth upon them, is of necessity very prejudicial to the young plant; and, then, again, a still more negligent practice, that of ploughing in the young trees, is too often adopted on a large scale, by which the plants are still more hastily deposited in the soil, and are neither fixed with sufficient firmness in the ground, nor even placed in an upright position. From these causes I have witnessed some very decided failures; and there is certainly no economy in this hasty mode of planting; the trees perish in great numbers; they linger for years without vigour; have to be replaced at a considerable expense; and in the mean time the owners lose all the advantages which might have been insured from a more skilfully obtained rapidity of growth.

The grouping or mixture of trees is a question which rarely engages the attention of the planter, although it is certain that, like the commonly cultivated crops of the farmer, some trees grow better when mixed with other kinds than when vegetating in plantations of the same species: that they have certain secretions, and excrete matters, both by their roots and leaves, which are noxious to other trees, is certain. Thus the ash, and more particularly the locust, are very obnoxious to most trees. Then, again, the grouping together of certain trees is particularly grateful to them all. Thus, the larch is a very good neighbour; the Scotch fir, the birch, and the Spanish chestnut grow very luxuriantly with it; the oak, the elm, the hazel, and the hornbeam are evidently good neighbours. The Roman planters had remarked this habit of trees. Thus, they believed that the elm was particularly grateful to the vine; and they were so convinced of the existence of what they called the sympathy between them, that they called the elm the husband of the vine. It was invariably their custom to plant them near each other; and as we are indebted to them for the introduction of the vine into England, so hence, in all probability, came with them our first elm trees.

The expense of these different modes of planting is next to be ascertained; it is an inquiry which will well repay the planter. The favourite mode, that of digging a small hole and inserting the tree, is, apparently, attended with the least outlay of money; in some instances it has been done for 4l. or 5l. per acre, or even less; but such plantations are very rarely profitable,—the trees die, or barely
PLANTATION.

vegetate for years, have to be renewed again and again, and the general appearance of the plantation, overrun with weeds, or heath-moss, or furze, is very melancholy. About 40s. per acre more, bestowed in deep ploughing or subsoiling, will make a strange difference in the rapid growth and consequent early profit of the plantation, and, moreover, save materially the expense of the trees; for the number of them which perish in land thus prepared for their reception is very small.

In a still greater degree are these good results obtained by the addition of say 20 cubic yards per acre of marl, or clay, or a still less quantity of chalk, according to the nature of the soil, or lime, which may usually be procured for an outlay of less than 30s. per acre; or of 2 or 3 tons of well putrefied farm-yard manure, a shovelful under each tree, in the manner I have before described. Now, supposing that even all these preparations of the soil are made, the expense per acre will then, in many situations, stand as follows,—

$$
\begin{array}{l}
\text{Ploughing deeply} \\
\text{20 cubic yards of marl or clay, or 10 of chalk} \\
\text{3 cubic yards of dung, at 6s.} \\
\text{Trees, ploughing, &c.} \\

\end{array}
$$

Subsoil ploughing will cost from 24s. to 30s. per statute acre.

If the manure is omitted, as well as the earth and the ploughing, the outlay of 5s. per acre in lime, in the way I have noticed, will not be without decided advantage. I am quite convinced, therefore, that if all planters were to confine their operations to a less extent of the land, and prepare and plant that ground well, they would reap a much earlier and richer harvest from the money expended than they now do from a much greater extent of unplanted, exhausted soil. Such are the facts which I have noticed, in my own practice and that of others, as most necessary to be attended to in rearing profitable, luxuriant plantations of timber trees, on the poorest lands of England; hardly any of whose soils, however, are so barren or so elevated as not to be able to produce, with only reasonable care and expense, an ample return for the capital expended. It is a pursuit which is, in more respects than one, worthy of the attention of the landed proprietor, since he not only by his plantations adds to the beauty and income of his own estates, but at the same time yields to the community at large great and important services; its barren wastes are made to produce timber and underwood, the soil is gradually rendered fertile, profitable supplies of labour are afforded, its health is promoted, the very climate by a general system of plantations is ameliorated, for its bleak hills are clothed, its stagnant swamps are drained.

There is an excellent paper "On collecting and preparing the seeds of Forest Trees, the mode of sowing them," &c., by Mr. Adam, and other planters. (Trans. High. Soc. vol. iii. p. 329.) He advises Scotch planters to collect the seed of the white larch (Pinus larix) in November, from trees of 20 to 40 years of age, at an elevation not exceeding 400 feet; that the seed-

bed should be manured with cow dung, well mixed with the soil for some time previously to sowing the seed, which should be in April and May; the beds to be 42 inches in breadth, with intervals of 18 inches. The seed should be sown so that each square yard of ground may produce 2000 plants, which in the first year should reach to a height of 5 or 6 inches. One-third of the plants may be drawn and pricked out in rows at a distance of 10 inches, and the remainder left for another year. The autumn, Mr. Adams thinks, is the best time for forming plantations.

The seed of the Scotch fir (Pinus sylvestris) is gathered in the same way, and, to separate the seeds from the cones, it is necessary to kill-dry them; about 114 quarters of cones produce about 112 lbs. of seed. The Scotch fir must stand 2 years in the seed-bed. Oakes are to be sown early in February; the best acorns are to be had in Kent, the brightest and heaviest being the most valuable; they keep very well spread on a deal floor; and may be planted in drills a foot apart, 2 inches deep, to be planted out when 3 or 3 years old. Ask keys are gathered in December or January, and laid in heaps mixed with one-third of their bulk of sand under cover; they should be turned over once or twice in the following year, and thus, after resting for 12 or 14 months, are ready for sowing in March, in drills a foot from each other, and 1½ inches deep. The seed of the Scotch elm is ripe in June, and should be sown soon after; that of the beech is gathered in September, and sown in the following March or April, in drills ½ inches deep. The seeds of the Spanish chestnut are best procured from Spain; they may be sown in February, in drills 4 inches deep. The horse-chestnut seeds are to be sown in October: those of the weeping birch should be sown as soon as gathered, and covered with earth half an inch deep. Those of the lime should be gathered and sown in October. Poplars are propagated by cuttings.

For a description of the advantages of preparing the land for plantations, I would advise the young planter to consult the works of Mr. Withers, the excellent Planter's Guide of Sir Henry Stewart, and the Journal of the Royal Agricultural Society of England. And for those who wish to plant in the most simple way at an expense of only 10s. per acre, see a paper by Mr. Grigor. (Trans. High. Soc. vol. iii. p. 363.)

By this mode, which consists of merely making a hole, or raising the turf of the ground sufficiently to put in the plants, the estimate is for a Scotch acre (which is equal to 6150 square yards)—

$$
\begin{array}{l}
500 \text{one-year transplanted larches} \\
1500 \text{two-year seedling, do.} \\
500 \text{one-year transplanted Scotch firs} \\
1000 \text{two-year seedling, do.} \\

But the gypsum of commerce is usually united with a portion of silica and carbonate of lime. It is thus combined in its native state. According to Chapital and Buchholz, gypsum consists of—

There is, perhaps, no artificial manure so decided in its effects upon some soils, so readily obtainable by the farmer, and so plentiful, as gypsum. Its mode of action, too, is now easily understood. It acts as a direct food for some plants. There are five commonly cultivated crops which contain gypsum in sensible proportions, and to which, in consequence, it is a direct food, viz., maize, unoin, red clover, ryegrass, and turnips. Now, these are precisely the crops to which the farmer finds, on most soils, gypsum to be a fertilizing topdressing. Wheat, barley, oats, beans, and peas, do not contain a trace of this salt; and the farmer tells you that gypsum is of little or no service to these crops, however the application may be varied. That it does not operate by its attraction for atmospheric moisture, I some time since determined by my own experiments; for 1000 parts, previously dried, when exposed to air saturated with moisture for 3 hours, have gained 9 parts, while under the same circumstances a good arable soil, worth 2 guineas per acre, gained 14 parts; and when compared with other manures, the disproportion is still greater: thus soot gained 36 parts, and horse-dung 145 parts. That it is not a promoter of putrefaction, I have ascertained by mixing this salt with various animal and vegetable substances; it seemed, in every case, rather to retard than promote the spontaneous decomposition of them all. The housewives consider hard water, which commonly owes its properties to the presence of this salt, to be a greater sweeter of tainted food than soft water. Davy, also, in a good experiment with minced veal, thought that the addition of the gypsum rather retarded putrefaction.

There is no reason to believe that the proportion of sulphate of lime found in certain plants is as essential to their growth as the presence of the other earthy salts and pure earths. Thus, those plants which yield this salt never grow well on lands which do not contain it; those in which carbonate of lime is found never flourish in soils from which this salt is absent. Plants which abound with nitrate of potash (saltpetre), such as the sunflower and the nettle, always languish in soils free from that salt; but when watered with a weak solution of it, their growth is very materially promoted, and the saltpetre is then found in them, as shown, upon analysis, in very sensible proportions. The same remarks apply to the growth of those plants which contain common salt, or phosphate of lime; the effect is the same, the result invariable.
Liebig contends that the nature of gypsum consists in its giving a fixed constitution to the nitrogen, or ammonia, which is brought into the soil, and indispensable for the nutrition of plants. He says, that 100 lbs. of gypsum give as much ammonia as 6250 lbs. of horses' urine would yield it: 4 lbs. of gypsum, he affirms, increase the produce of the meadow 100 lbs. The decomposition of gypsum is slow, which, he says, explains the reason why the action of gypsum lasts for several years. See Ammonia.

I have noticed, in applying gypsum to grasses, that the weather, at the time of spreading it, has a very material influence upon the result of the experiment. Its effects are never soon apparent when it is sown in dry weather; but if the season is damp, so that the white powdered gypsum adheres to the leaves and stalks of the young grass, the good effect is then immediate. This observation was made many years since by Arthur Young, by Mr. Smith, and by the American farmers: it is a well-known fact with the sainfoin growers, of the Berkshire and Hampshire chalk formation; the clover cultivators of the gravels and loams of Surrey and Kent; and on the lucern grounds of the alluvial soils of Essex and Middlesex. The farmers of the United States, when sowing the clover or turnips with gypsum, always found it answer best when spread in rainy weather.

The result of the analysis of the clover and sainfoin grasses shows that an ordinary crop of these usually contains from \( \frac{1}{4} \) to 2 cwt. per acre of sulphate of lime. Now, this is precisely the proportion of gypsum which the best cultivators find to be attended with the maximum benefit; those of Kent and Hampshire find it useless to apply more; but then they all agree that the annual repetition of the dressing, as long as the grass is suffered to remain on the ground, is attended with the well-marked beneficial effects. It is here again that the experiments of the chemist and the farmer mutually confirm and illustrate each other; the very quantity of sulphate of lime which the first shows to be carried off the land in the clover, is precisely that which the latter returns to it in his dressings with gypsum.

One of the chief reasons why gypsum has not been universally employed by all cultivators of the artificial grasses, arises perhaps from the fact that many good soils naturally contain sulphate of lime in sufficient abundance for the service of the plants, and, in consequence, they have considered the application of gypsum is useless—it is an attempt to supply a deficiency which does not exist. I have invariably found in those soils to which gypsum is not a manure an abundance of this salt. It is not, however, necessary for the farmer to have his soil analyzed to determine the probable advantages of applying gypsum to his clover and other grasses; there are several easy observations which will readily indicate to him the nature of the case. Thus, when he finds that those fields which once produced luxuriant crops of red clover or sainfoin will no longer yield so well, he will know in abundance; if he notices that the young plants spring up very numerously, but die away as the summer advances; if he finds that his fields will only grow clover successfully once in 8 or 12 years, and that his neighbours tell him his land is tired, or clover-sick; if he notices that even the application of farm-yard compost hardly adds to the luxuriance of his grasses; he may then safely conclude that his crops have gradually exhausted his land of sulphate of lime; and he may, with every confidence of success, apply a dressing of gypsum, at the rate of 2 cwt. per acre, taking care to choose a wet morning for the application; and this may be done at any season of the year, but it is best either in April or the first days of May. These facts I can attest from the results of my own observations and experience. In an old grass paddock, of about 70 acres, in the vale of Kennett, in Berkshire, the grass had for many years gradually become less and less productive, and this in spite of all kinds of applications; the earths (such as clay and chalk), farm-yard compost, &c., had been liberally and repeatedly spread, without producing any thing like a luxuriant crop; but it was found at last that the peat ashes of the banks of the Kennett, when spread at the rate of about 40 bushels per acre, produced the very best results, an excellent crop, both in weight and in colour; certainly more than a ton of hay per acre beyond what the soil yielded before. The fact was now evident that it was gypsum that the soil needed; for as these peat ashes contain about 12½ per cent. of sulphate of lime, more than 2 cwt. of gypsum was conveyed into the land in them; it constitutes, in fact, by far the chief fertilizing ingredient in these peat ashes, the remainder being about 40 per cent. of sand, and the rest chalk, red oxide of iron, and a small quantity of common salt.

If this conclusion, therefore, was correct, as to the gypsum being the only valuable portion of the peat ashes, it was then certain that an application of 2 cwt. per acre of gypsum to the same land would produce similar beneficial results; and, upon a trial, it was found that benefits fully equal to any yielded by the application of the peat ashes resulted. 2 cwt. per acre of gypsum, in fine powder, was spread on a portion of the grass with the most excellent effect: the grass not only grew with greatly increased vigour, but a quantity of white clover and other grasses made their appearance on the portion dressed, in so marked a manner as to attract the attention of the tenant to the fact. The soil on which these experiments were tried consisted of:

| Organic matter, chiefly vegetable | - | 3·5 |
| Soluble matters | - | 3·5 |
| Carbonate of lime and magnesia | - | 1·9 |
| Oxide of iron | - | 2·75 |
| Alumina | - | 8·5 |
| Sand and gravel | - | 62·9 |

(96·75)

This is about 10 inches deep, and it rests on a thin stratum of gravel and thin chalk.

There is another fact which clearly supports these conclusions, viz., the great use of common coal-ashes as a top-dressing to clover, sainfoin, and lucern; there is no manure uni-
versally in the possession of the farmer, in fact, equal to them for immediate effect upon those grasses. Now, coal-ashes usually contain about 10 per cent. of sulphate of lime; and, therefore, a dressing with 50 bushels of coal-ashes per acre is equal to an application of about 5 bushels of gypsum; the remaining portion of the ashes consists principally of about 10 per cent. of lime and sand, and a small portion of red oxide of iron and alumina: so that the gypsum is here again evidently the active ingredient—the other constituent parts being nearly inert substances. My own experiments and observations have been confirmed by many others within the last two years, for gypsum is evidently creeping gradually into use as a manure for the grasses.

In England, the expense of the application of the gypsum is about 7s. per acre; this substance being usually sold in London for about 2l. 10s. per ton—at Reading and Southampton at 1s. 9d. per bushel. In the midland counties it may be had at a still more reasonable rate; thus, in 1840 it was reported that so high prices of farmers' cheese-room floors are commonly formed with it; it abounds, too, in the north of England. The comparative produce of the gypsumed over not-gypsumed land is very great; it of course varies in amount. I have seen it double the produce of clover hay, and give an equally copious crop of lucerne; but this last I invariably cut green for soiling.

Mr. Smith, of Highstead, found still greater benefit from the use of gypsum to his clover leys; for where the simple soil produced 1 ton only per acre of hay, the portion of the same soil to which 8 bushels per acre of gypsum had been applied yielded 3 tons; the first yielding only 20 lbs. of seed, while the latter produced 106 lbs. Mr. Smith, too, first noticed what my own observations have confirmed—that cattle, horses, &c., always prefer the grass growing on the gypsumed portion of the field to any other. The same remark is made by those who spread coal-ashes on their grass leys; the peat-ashes of Berkshire produce the same effect.

The general introduction, then, of gypsum, as a top-dressing for the artificial grasses which I have mentioned, is certainly an object of no mean interest to the farmer, especially if he cultivates the poor inland soils of England, where artificial manures are scarce, and the carriage of even the most portable is expensive; for gypsum possesses, in this respect, two advantages combined, which do not belong to any other, even of the saline manures: its first cost is trifling, and its carriage light, since a wagon will convey sufficient gypsum to dress 30 acres of grass.

PLASTER FOR TREES. See CANKER.

PLASTIC CLAY. Clay used in the manufacture of pottery.

PLATYPHYLLUM CONCAVUM, or KATY-DID. A kind of grasshopper found in the United States. Dr. Harris, who was the first to give a scientific description, has called it Platypylhum concavum. The front of its head is obtuse, body of a pale-green colour, the wing-covers and wings being somewhat darker. Its thorax is rough like shagreen. The musical organs of the male consist of a pair of taboret, formed by a thin, transparent membrane, stretched in a strong half-oval frame in the triangular overlapping portion of each wing-cover. During the daytime these insects are silent, and conceal themselves among the leaves of trees; but at night, they quit their lurking-places, and the joyous males begin the tell-tale call with which they enliven their silent mates. This proceeds with the period of the taboret frames against each other when the wing-covers are opened and shut; and the notes are repeated, at intervals of a few minutes, for hours together. The mechanism of the taborets, and the concavity of the wing-covers, reverberate and increase the sound to such a degree, that it may be heard, in the stillness of the night, at the distance of a quarter of a mile. At the approach of light the Katy-did mutes; and such is the mode of life of the insect in which he lives, and, as soon as the shades of evening prevail, begins his noisy babble, while rival notes issue from the neighbouring trees, and the groves resound with the call of "katy did, she did," the live-long night. From the head to the end of the wing-covers, this insect measures rather more than 1 inch, the body alone being 1 inch in length. The piercer is broad, laterally compressed, and curled like a cimeter; and there are, in both sexes, two little thorn-like projections from the middle of the breast between the fore-legs. It is found in the northern counties in the months of September and October. (Harris.)

PLEASURE-GROUND. That portion of ground adjoining a dwelling-house in the country; and which is exclusively devoted to ornamental and recreative purposes. In the ancient style of gardening, the pleasure-ground was laid out in straight walks, and regular or symmetrical forms, commonly borrowed from architecture; but in the modern style, it is laid out in winding walks, and in forms borrowed direct from nature. A portion of lawn or smooth grassy surface may be considered as essential to the pleasure-ground of both styles. See Gardening, Lawn, and Partets.

PLUGH. (Sax. Plow; Dan. Ploegh.) A well-known, perhaps the most ancient, certainly the most valuable of all agricultural implements. There are traces of it in even the earliest of all written authorities, and, judging of its importance in agriculture, we can hardly imagine it possible to carry on extensive systems of cultivation in any period or country without its assistance. By consulting the sacred records, we find, that in very early times they ploughed with two oxen (Deut. xxii. 10), that their plough had a coulter and plough-share (1 Sam. xii. 20), and that they were early aware of the advantages of a winter's fallow (Prov. xx. 4). It is certain that their ploughs were long since furnished with wheels; a fact which is proved by the drawings of the early Greek ploughs which have escaped to us. Hesiod (Works and Days, p. 50—441 advised the Greek farmers to have a spare plough, that
an accident might not interrupt the work; and he also enforces the advantages of careful and skillful ploughing.

The ploughs of Rome were of the most simple form, as may be inferred from ancient drawings. See Agriculture.

Rivalling these in simplicity and rudeness of form, are the never altered or improved ploughs of the Hindoos and the Chinese, from whose implements it is probable the shape of those of Rome was borrowed.

The object sought to be effected by means of the plough, is exactly the same as that accomplished in the primitive ages by the spade. The addition of cattle to pull the operation of breaking up the ground, leads to complexity. But although the spade is an implement of such great simplicity, the act of digging with it exacts a great deal of individual exertion, almost every muscle of the body being called into play in alternately pushing and lifting. In this respect the modern improved plough possesses great advantages in being propelled by animals and directed with very little individual muscular exertion.

It is curious to trace the progress of plough-making in England. Those of the early cultivators were of necessity rude and imperfect, for the early ploughman made his own plough. A law of the early Britons in fact directed that no one should guide a plough until he was able to make one. The driver was, by the same law, to make the traces by which it was drawn, and these were to be formed of withes of twisted willow; a long-explosed custom; many of the olden terms of which, however, are still retained by the rustic ploughmen. Thus the word withy is yet called the weambye or wyanty. Withen trees are denominated weaten trees, or whipple trees, &c.

It is uncertain whether the early British ploughs had wheels; some of those of the Saxons have, and it is supposed that with them did. Yet it is pretty certain that they used ploughs of a form rivaling those of modern India in simplicity; a rude sketch of one of these is given in a Saxon MS. (Hart. MS. 603), from which it would seem that our Saxon forefathers were wont to fasten their horses to the plough by their tails; a barbarous custom, which certainly was formerly practised in Ireland to such an extent that the legislature interfered in 1634, and declared by the 11 & 12 Car. II. c. 15 (Irish Parl.), entitled "An act against ploughing by the Tayle, and pulling the Wold off living Steeds", that "any person or persons" who used this custom were to be punished.

Yet, it is certain, that the ox was at first, and for a longened period, the only animal employed to draw the plough. Thus, although the plough and oxen are so frequently mentioned in conjunction in the Bible, the horse is never alluded to for such an occupation: an old British law forbade the use of any animal except the ox for this purpose. The first representation, of which I am aware, observes Mr. J. A. Ransome, of a horse employed in the plough, is that given (A. D. 1066) in the tapestry of Bayeux.

The earliest plough in the British Museum, which is shown in a rude sketch at page 41 is engraved.

they began to be improved by the Dutch and Flemish. In the seventeenth century the plough underwent further improvement in England; and it was greatly improved in that following, in Scotland. There are now a great variety of excellent forms, the best of which, for general purposes, is, in Britain, universally allowed to be what is called the Scotch plough, and in Scotland the improved Scotch plough. In speaking of the implement we shall adopt the latter term, because the unimproved Scotch plough differs little from some old forms of the implement common to Europe from the time of the Romans. As the operation of ploughing, like many other operations in practical husbandry, must often vary in the manner of its being performed, it is evident that no one particular sort of plough can be superior to all others, in every season, and under every variety of soil or inclination of surface. The Scotch plough, however, and the variations of which it is susceptible, render it perhaps the most universal tillage implement hitherto invented or used.

In Britain ploughs are classed into two kinds: those fitted up with wheels, and called wheel-ploughs; and those without wheels, called swing ploughs. The latter are the lightest of draught, and require an experienced and attentive ploughman to use them; the former, with greater steadiness, and require much less skill in the manager; some sorts, indeed, do not require holding at all, excepting at entering in, and turning on and off the work at the ends of the ridges. On the whole, taking ploughmen as they are, and ploughs as they are generally constructed, it will be found, that a district ploughed with wheel-ploughs will show greater neatness of work than one ploughed with swing ploughs: but, on the other hand, taking a district where the improved form of swing ploughs is generally adopted, the ploughmen will be found to have gained not only the former work performed in a better manner, and with less expense of labour, than in the case of wheel-ploughs.

In the construction of ploughs, whatever be the sort used, there are a few general principles that ought invariably to be attended to; such as the giving the throat and breast, or that part which enters, perforates, and breaks up the ground, that sort of long, narrow, clean, tapering, sharpened form that affords the least resistance in passing through the land; and to the mould-board, that kind of hollowed-out and twisted form which not only tends to lessen the friction, but also to contribute greatly to the perfect turning over of the furrow-slice. The beam and muzzle should likewise be so contrived, as that the moving power, or team, may be attached in the most advantageous line of draught. This is particularly necessary where a number of animals are employed together, in order that the draught of the whole may coincide.

Land, when properly ploughed, must be removed from a horizontal position, and twisted over to a certain angle, so that it may be left in that inclining state, one furrow leaning upon another, till the whole field be completely ploughed. The depth and width of the furrows which is most approved of by farmers, and commonly to be met with in the best-ploughed fields, is on the proportion of 2 to 3; or, if the furrow be 2 deep, it must be 3 wide, and left at an angle of 45 to 46 degrees.

Various forms have been given to the different parts of the plough, by ingenious persons, according to their different fancies, in order to diminish the weight of the draught, and to turn over the furrow, and leave it in its proper position, without tearing or breaking it.

To have the line of draught at right angles to the horses' shoulders is of great importance in the formation of a plough; a circumstance of which the greatest part of the plough-makers are totally ignorant, although it is well known to every one that has the least knowledge of mechanics. If we take the angle that the horses' shoulders make with a perpendicular from the horizon, and continue another line at right angles to it, or parallel to the draught chain; the length of this line from the horses' shoulders to where it meets or crosses the coulter, at half the depth of the furrow, will be 13 feet 2 inches for ordinary sized horses.

Length of beam.—If the plough be properly made, the line of draught should pass through the middle hole of the plough bridge at the point of the beam. This requires the beam to be 7 feet long, to give it a proper height at the bridge.

Left side plane.—That part of the plough next the solid land should be made a perfect plane, and run parallel to the line of draught; whereas some of the common ploughs are completely twisted in that part, and deviate more than 2 inches from the line of draught; this throws the plough to the left, and causes the hinder part of the mould-board to press hard against the furrow, and crush and break it, besides increasing the labour of the cattle.

The position of the coulter must not deviate much from an angle of 15 degrees: for if we make it more oblique, it causes the plough to choke up with stubble and grass roots, by throwing them up against the beam; and, if less oblique, it is apt to drive the stones or other obstacles before it, and make it heavier to draw.

The mould-board, for all free soils, and for working fallows, is generally most effective when it has a considerable concavity; but for breaking up clover leys, pasture, or any firm surface, and also for clayey soils, it is found to clean itself better and make nearer work when it approaches an angle of 45 degrees: for if we make it more oblique, it causes the plough to choke up with stubble and grass roots, by throwing them up against the beam; and, if less oblique, it is apt to drive the stones or other obstacles before it, and make it heavier to draw.

strength and durability, and some also in point of convenience. Among the conveniences most particularly mentioned, the facility which they afford of bending the left handle to the right of the straight line first introduced by Mr. Willie of Uddingston (who, if not the inventor, may certainly be considered the greatest improver of iron ploughs,) by which means the ploughman is permitted to walk with ease in the bottom of the furrow. The stilts or handles may also be joined to the body of the plough, in such a way as to admit of taking off and packing for a foreign country, or raising or lowering the points of the handles according to the size of the ploughman, as in Weatherley's plough.

A wooden Scotch plough with iron mountings, says Mr. Stephens, usually weighs 13 stones imperial, and an iron one for the same work 15 stones. The cost of a wooden one is 3l. 16s., capable of being serviceable, with repairs, for the currency of a lease of 19 years; that of an iron one 4l. 4s., which will last a lifetime, or at least many years. Some farmers, however, still prefer the wooden one, alleging that it goes more steadily than the iron. What is this prejudice there may be in this predilection of the Scotch ploughwright, who must be aware that the iron one executes its work in a satisfactory manner. There is, I believe, no great difference of economy in the use of the two kinds of ploughs. (Stephens.)

Of swing ploughs, says Loudon, by far the best is the implement known in England as the Scotch plough. It is almost the only plough used in Scotland, and throughout a considerable part of England; it is drawn with less power than wheel-ploughs, at least, those of the old construction, the friction not being so great; and it probably admits of greater variations in regard to the breadth and depth of the furrow-slice. It is usually drawn by two horses abreast in common tillage; but for ploughing between the rows of the drill culture, a smaller one drawn by one horse is commonly employed. A plough of the swing kind, having a mould-board on each side, is also used both in forming narrow ridges for turnips and potatoes, and in laying up the earth to the roots of the plants, after the intervals have been cleaned and pulverized by the horse and hand-hoe. This plough is sometimes made in such a manner that the mould-board may be shifted from one side to the other when working on hilly grounds; by which means the furrows are all laid in the same direction.

Swing ploughs, similar to the Scotch plough, have been long known in England. In Blythe's Improver Improved we have engravings of several ploughs; and what he calls the "plain plough" does not seem to differ much in its principal parts from the one now in use. Amos, in an Essay on Agricultural Machines, says, that a person named Ummis (whom he is mistaken in calling a Scotchman) "first attempted its construction upon mathematical principles, which he learned in Holland, but having obtained a patent for its making and vending of this plough, he witheld the knowledge of these principles from the public. However, one Pashley, plough-wright to Sir Charles Turner of Kirkleathem, having a knowledge of those principles, constructed upon them a vast number of ploughs. Afterwards his son established a manufactory for the making of them at Rotherham. Hence they obtained the name of the Rotherham plough; but in Scotland they were called the Dutch or patent plough." Plate 17, 2, represents a Rotherham plough constructed chiefly of wood. The Americans have claimed the priority of the invention; and President Jefferson, of the United States, presented the principles for the construction of a mould-board, first to the Institute of France, and next to the Board of Agriculture in England.

The Scotch plough was little known in Scotland till about the year 1764, when Small's method of constructing it began to excite attention (Small's Treatise on Ploughs and Wheel Carriages, 1784; and Lord Kaimies's Gentleman Farmer.) This ingenious mechanic formed the mould-board upon distinct and intelligible principles, and afterwards made it of cast iron. His appendage of a chain has been since laid aside. It has been disputed, whether he took the Rotherham, or the old Scotch plough, for the basis of his improvements. The swing plough has been since varied a little in various parts of Scotland, from Small's form, for the purpose of adapting it more completely to particular situations and circumstances. Since 1810, this plough has been very generally made entirely of iron. In Northumberland, the mould-board is made less concave than in Berwickshire, and in Berwickshire it is even less concave than in Small's plough. Different degrees of concavity in the mould-board suit different soils: soft and sandy soil requires most, and a loamy or clayey soil least concavity. The following are the principal varieties of the improved Scotch plough at present in use in the most improved districts of the north, and among scientific farmers in all countries.

Small's plough.—The mould-board is more concave than in most other varieties, and this may be considered its characteristic as compared with these varieties. It is sometimes drawn by a chain proceeding from the muzzle to the head, in order to lessen the strain on the draught-beam, and in that case it is called Small's chain-plough. It is commonly made of wood and iron. Pl. 17, b. For a design of the East Lothian plough, or Small's improved, see Pl. 17, e, g, the figures representing two views. In this plough the proper lines of the body on the land-side lie all in one plane, which, in working, should be held in the vertical position, or very slightly inclining to the left. The cutting edge of the body being nearly as low as the plane of the sole. The neck of the share is prolonged backward, joining and coinciding with the curve of the mould-board, which curvature is also carried forward on the
back of the feather. The character of this plough is to take a furrow of 10 inches in breadth by 7 inches in depth, cut rectangular, leaving the sole of the open furrow, level and clean. The resistance to the draught is generally below the average of ploughs, and this plough is employed for every kind of soil. The improved English swing plough, as made by Ransom, is represented in Pl. 17, c.

The Northumberland plough, and the Berwickshire plough, are very nearly the same implement; differing from Small's plough in having the mould-board less concave.

Wilkie’s swing plough, which Loudon says is the best iron swing plough in Scotland, is formed entirely of iron, except the points of the handles. Its characteristic, in point of form, is a longer mould-board with a greater twist in it, the object of which is to reverse the furrow more completely in light or highly pulverized soils.

Finlayson’s iron ploughs are, as he informs us (British Farmer, p. 9), constructed in imitation of those of Wilkie, but with improvements and modifications adapted for particular circumstances.

The heath or self-cleaning plough, or rid plough, is formed with the beam so curved vertically, or divided and curved horizontally, as to leave no resting-place for stubble, heath, or other vegetable matter, at the top of the coulter, where in rough grounds, with ploughs of the ordinary construction, it gets entangled and stops the work.

Finlayson’s Kentish skeleton self-cleaning plough (Pl. 17, f) is intended as a substitute for the common Kentish turn-wrest plough. “The soil, in great part of Kent, is of a peculiarly adhesive clay. When this soil is between the wet and dry, it adheres to the body of the plough like glue, by which the draught is increased probably double or treble.” By substituting 5 or 4 iron rods for the mould-board, the soil is prevented from adhering, while the operation of ploughing is at the same time performed in an equally perfect manner with two horses as with four. This is accounted for “by the whole surface of this plough not being more than one-third or one-fourth the surface of other ploughs.” In like manner, when it is necessary to dig or trench very strong clayey soil between the wet and the dry, the operation is performed with much greater ease by a two-pronged fork. It is important to agriculturists to know the opinion and experience of a man of so much science and extensive practice as the late Mr. Finlayson, who says, “from my own experience I have no hesitation in saying that the most adhesive land may, with ease, be ploughed by the skeleton plough and one pair of good horses.”

Finlayson’s line plough is characterized by a rod which proceeds from the sheath of the plough to the muzzle, which is put on when the plough is drawn by horses in a line—a very disadvantageous manner, but yet common in many parts of England.

The Somerville swing plough is known by its mould-board, a part of which is rendered movable by hinges; the advantage of this is, that the furrow can be laid more or less flat at pleasure. This plough, however, has been but little used, and does not seem to meet the approval of the best cultivators.

Turn-wrest swing ploughs are as much ad in removing the mould-board from one side to another at the end of each furrow, for the purpose of easting of uncultiy soils always to one side. Their principal use is in ploughing across steep declivities, in order that the furrow-slice may always be thrown down. Wherever it is practicable, however, it is best to plough obliquely up and down such declivities; because the other practice soon renders the soil too rich and deep at bottom, and too thin and poor at top.

Gray’s turn-wrest swing plough is one of the most scientific implements of the kind. The beam, head, and sheath, must always be placed in the direction of a line passing along their middle; and the two handles must be placed equidistant on each side of that line. There are two mould-boards and two coulters, and a mould-board is produced on either side, at pleasure, by moving a lever between the plough handles from the one side to the other. The line of draught can be shifted with equal ease and expedition, and at the same time one of the coulters raised up clear of the land, and placed along the side of the beam, whilst the other is put down, and placed in a proper position for cutting off the furrow-slice from the furrow-ground. All this is performed at once, without the ploughman changing his position, by means of two levers.

A stem-coulters (Pl. 17, m, m) may be added to any plough, and may be useful in turning down green crops and long dung, as well as in trench ploughing. But in most instances it is thought a preferable plan, where the soil is to be turned to an unusual depth, to make two common swing ploughs follow each other in the same track; the one before taking a shallow furrow, and the other going deeper, and throwing up a new furrow upon the former.

The double share plough is distinguished by having one share fixed directly over the other. It is made to suit some of the southern districts of England with advantage, in putting in one crop immediately after ploughing down another; as by it a narrow, shallow furrow is removed from the surface, and another from below placed upon it, to such depth as may be thought most proper,—it being capable of acting to 10 inches or more. In this manner many sorts of crops, such as rye and other green crops that have much height of stem, may be turned down without the inconvenience of any of the parts sticking out through the seams of the furrow-slices, by which the farmer has a clean surface of mould for the reception of the grain.

The mixing plough, or trenching plough, is sometimes employed for the purpose of loosening the soil to a great depth, without bringing it up to the surface; a mode of operation which is particularly useful for various sorts of tap rooted plants, as well as for extirpating the roots of such weeds as strike deep into the ground. For these purposes it may be employed in the bottom of the furrow after the common plough. It is constructed in a very

903
strong manner, having a share, but no mould-board. The share raises the earth in the bottom of the furrow, and, passing on under what it has raised, leaves the soil where it was found, but in a loosened state. See Subsoil Plough.

Somerville's double-furrow plough is obviously advantageous in performing more labour in a given time, with a certain strength of team, than other sorts of ploughs, as producing two furrows at a time. It has been found useful on the lighter sorts of land, where the ridges are straight and wide, though some think it more confined in its work than those of the single kind. The saving of the labour of one person, and doing nearly double the work with but little more strength in the team, in the same time, recommend it for those districts where four-horse teams are in use. This plough has been brought to its present degree of perfection by Lord Somerville, especially by the introduction of movable plates at the extremities of the mould-board, as in his lordship's single plough. But, as observed by an excellent authority, "with all the improvements made by Lord Somerville, it can never come into competition, for general purposes, with the present single-furrow ploughs." Lord Somerville admits, that it would be no object to invade the system already established in well-cultivated counties; though, where large teams are employed, with a driver besides the ploughman, it would certainly be a matter of importance to use this plough, at least on light, friable soils.

"Their horses," he says, "will not feel the difference between their own single furrow, working one acre, and the well-constructed two-furrow plough, with two acres per day; here is no system deranged, and double work done." This plough is also of particular value for ploughing up and down steeps.

The Yorkshire plough differs from Small's, or any single swing plough, in having no counter fixed in the beam, but, in lieu of this, a fin or knife rising from the seat side of the share, which serves the purpose of slicing off the furrow as well as a coulter. This fin or knife must be placed at the same angle as the coulter, and should terminate in a lance-like shape, in order to furnish the least obstruction to stubble, weeds, or stones. This plough is not liable to be choked by stubble, or thrown out by catching small stones between the points of the coulter and sock. In point of draught it is precisely the same as the common plough.

The double mould-board plough is a kind of plough often used with advantage in clearing out furrows, in setting potatoes, cabbages, and other similar crops, and in earthing up such as are planted in wide rows. Those whose mould-boards move on hinges, and may be set wide or narrow at pleasure, are the most convenient. A variety of this plough, made by Weir of London, admits of removing the mould-boards, and fixing in curved coulters and hoes, for cleaning between drilled turnips and similar crops.

The binot is almost the same thing as the double mould-board plough, and the one is commonly sold for the other, with no loss to the purchaser. It has two mould-boards, one on each side of the beam. It is used in some soils in forming a ribbed or ridged bed for wheat or other grains; by which means, when the grain is sown over the ribs or ridges, in the broadcast manner, as it falls for the most part into the furrows, or is harrowed into them, it comes up in rows. It is also used in earthing up crops; and sometimes in Flanders, but never by the best cultivators in England, in giving the first furrow to stubbles.

The marking plough is used in straightening and regulating the distance of ridges where the drill system is practised. Any plough with a rod fixed at right angles to the beam, and a short piece depending from this rod, will trace a line parallel to the furrow drawn by the plough, which line will serve for a guide as to the width of ridges, &c.

Cluny's plough is a recent modification of the implement, formed entirely of iron, and chiefly remarkable for the absence of the coulter, or rather its attachment to the breast, and for the share, mould-board, and other parts, which move under gravity, being composed of distinct pieces of cast-iron. This is considered as cheaper to commence with and easier to repair, because any one part may be renewed of the same material without deranging the rest; whereas renewing or repairing wrought-iron shares, mould-boards, or coulters, is found in many districts both difficult and expensive. It has never come into use in England.

Stothard's plough is characterized by a perforated mould-board. The holes may be in any form or dimensions; and their object is to allow the air to pass through, and thereby prevent the adhesion of wet earth, which it is contended adheres in ordinary ploughs with such a degree of tenacity as greatly to increase the friction, and diminish the speed of the horses.

Morton's trenching plough has two bodies, the one working 4 or 6 inches deeper than the other. The first cuts or pares off the surface to the required depth, say 5 inches, and turns it over into the furrow, 10 or 12 inches deep, made by the main body. The second body generally works from 10 to 12 inches deep, but might be made to work to the depth of 13 or 15 inches; upon its mould-board is formed an inclined plane, extending from the back part of the feather of the sock or share to the back part of the mould-board, where it terminates about 6 inches above the level of the sole. This inclined plane raises the soil from the bottom of the furrow, and turns it over on the top of that which has been laid in the bottom of the previous furrow, by the body going before.

Draining ploughs are of various kinds, but none of them are of much use; the work can always be done better, and generally cheaper, by manual labour.

Wheel ploughs are of two kinds: by far the most common, are those where the wheel or wheels are introduced for the purpose of regulating the depth of the furrow, and rendering the implement more steady to hold; those less common are where a wheel is introduced for the purpose of lessening the friction of the sole or share. This last description of wheel plough
is scarcely known, but it promises great advantages. The former is of high antiquity, having been used by the Romans.

Ploughs with wheels for regulation and steadiness vary considerably in their construction in different places, according to the nature of soils and other circumstances; but in every form, and in all situations, they probably require less skill in the ploughman. Wheels seem, indeed, to have formed an addition to ploughs, in consequence of the want of experience in ploughmen; and in all sorts of soil, but more particularly in those which are of a stony and stubborn quality, they afford great assistance to such ploughmen, enabling them to perform their work with greater regularity in respect to depth, and with much more neatness in regard to equality of surface. From the friction caused by the wheels, they are generally considered as giving much greater resistance, and consequently demand more strength in the team that is employed; and, besides, are more expensive in their construction, and more liable to be put out of order, as well as more apt to be disturbed in their progress by clods, stones, and other inequalities that may be on the surface of the ground, than those of the swing kind.

With regard to wheel ploughs, those more especially in which the wheel is placed in the heel of the plough, the following extract from Mr. Stephens's Book of Ploughing, will explain both the philosophy and practical effect:

The application of a wheel in the heel of a plough, does not come under the same mode of reasoning as that under the beam, the former becoming a part of the body, from which all the natural resistance flows; but in viewing it as a part of that body only, we can arrive at certain conclusions which are quite compatible with careful experiments.

The breadth of the whole rubbing surface in the body of a plough, when turning a furrow, is on an average about 1½ inches; and supporting that surface in all parts, we shall have the sole-shoe, which is about 2½ inches broad, occupying ½ part of the surface; and taking the entire average resistance of the plough's body, as before, at 336 lbs., we have ½ of this, equal to 48 lb., as the greatest amount of resistance produced by the sole of the plough. But this is under the supposition that the resistance arises from a uniform degree of friction spread over the whole rubbing surface of the body; while we have seen, on the contrary, that the coulter, when acting alone, presents a resistance equal to the entire plough. It is only reasonable, therefore, in absence of further experiments, to conclude, that the fore-parts of the body, the coulter and share, yield a large proportion of the resistance when turning the furrow-slice; but since we cannot appreciate this with any degree of exactness, let the sole have its full share of the resistance before stated, namely, 48 lb. If a wheel is applied at or near the heel of a plough, it can only bear up the hind-part of the sole, and prevent its ordinary friction, which, at the very utmost, cannot be more than half of the entire friction due to the entire sole. A wheel, therefore, placed here, and acting under every favouring circumstance, even to the supposed extinction of its own friction, could not reduce the resistance by more than 24 lbs., being the half of that due to the entire sole, or it is ¼ of the entire resistance. But we cannot imagine a wheel so placed to continue any length of time, without becoming clogged in all directions, thereby greatly increasing its own friction; and when it is considered that the necessarily small portion of any wheel that can be so applied will sink into the subsoil, to an extent that will still bring the sole of the plough into contact with the sole of the furrow. It will thus be found that the amount of reduction of the general resistance will be very much abridged, certainly not less than one-half, which reduces the whole saving of draught to a quantity not exceeding 12 lb., and even this will be always doubtful, from the difficulty of keeping such wheels in good working condition. This view of a wheel placed at the heel has been confirmed by actual experiments, carefully conducted, wherein Palmer's patent plough with a wheel in the heel, as patented many years ago (but in this case it was applied on the best principles), gave indications of increased resistance from the use of the wheel, as compared with the same plough when the wheel was removed; the difference having been 1½ stone in favour of no wheel. I hesitate not, therefore, to say, that in no case can wheels be of service in reducing the resistance of the plough, whether they be placed before or behind, or in both positions, and the chances are numerous that they shall act injuriously. That the use of wheels may, under certain circumstances, bring the implement within the management of less skilful hands than is required for the swing plough, must be admitted; but, at the same time, there may be a question whether, even with that advantage, the practice is commendable. I should be wanting in candour if, for myself, I answered otherwise than in the negative.

Having, says Mr. Stephens, in a general way described the construction of the frame-work and the acting parts of the wheel plough, there remains for me to say a few words on the wheels with which it is furnished. I have already adverted to wheels, as they appear to me to affect the draught of ploughs, and have expressed myself in sufficiently distinct language to show that, in my opinion, they must in all cases be injurious, and tend to increase the resistance of the plough to which they are appended, whether they be applied within the body, or under the front, or any other part of the beam. That wheels may be of advantage for the working of a plough in the hands of an unskilful ploughman may be true; but if this advantage is acquired by a certain additional expenditure of horse-power, which, however much the proprietor of the team may blind himself to, will ultimately, though probably unheeded, tell on his profit and loss account, there will be no gain, but an ultimate loss. It must be admitted, even by the advocates of the wheel plough, that though they may be handled with perfect regularity in ploughing along ridges, whether the holder be an experienced ploughman or not, yet in cross-ploughing they...
cannot be attributed to want of power in the horses, for English horses are at least not inferior to those employed in Scotland for agricultural purposes, neither can it be from unskilfulness in the ploughmen, for even the most skilful seem to come short in this respect, by not being able to plough more than a small section of ground in a day, while with the swing plough almost any ploughman will turn over his acre a day. From the remarks of the same writer, it is to be inferred that a Scotch swing plough was incapable of being drawn through a certain clay soil by 2 horses, while the wheel ploughs were found to perform the work with tolerable ease, though still a heavy draught. There may be such cases; but from the conditions of this particular case, where the draught that baffled the horses in the swing plough seems not to have exceeded 52 stones, there is an ambiguity in the matter that leads to doubts of the accuracy on the part of the observers of the experiment.

We know well that in working the Scotch swing plough in an 8 or 9-inch furrow on stiff land, the draught is not unfrequently as high as 7 cwt. or 56 stones; but 2 good horses never shrink from the task; and how a less draught, whatever be the soil, should have baffled the exertions of 2 good horses in a swing plough, even in the Oxford clay, requires some further investigation to be satisfactory.

Among agricultural writers, it seems, says Mr. Stephens, to be a prevalent opinion, that land when ploughed requires a curvature of surface; whereas, correct ploughing, that is, making the furrow-slices on the same ridge all alike, cannot possibly give the surface any other form than it had before it was ploughed. If the former surface were curved, then the newly ploughed surface would also be curved; but if it were flat, the new surface will be flat also. A thoroughly good ploughman, and I have known a few, but only a few of such valuable men, avoids so objectionable a practice, and ploughs always a true, sound furrow, making it larger or smaller as the particular state of the work may require.

Without putting much value on the information, it may serve as a fact to refer to, in case it should be wanted, to state the weight of earth turned over in ploughing. If 10 inches are taken as a fair breadth for a furrow-slice, there will be 18 such slices across a ridge of 15 feet in breadth; and taking 7 inches as a proper depth for such a furrow-slice, a cross section of the slice will have 70 square inches. A cubic foot of earth is thus turned over in every 241 inches and a little more of length of such a slice; and taking 27 as the specific gravity of ordinary soil, every 24½ inches and a fraction more of such a slice will weigh 12 stones 1 lb. imperial.

The usual speed of horses at the plough may be ascertained in this way. A ridge of 5 yards in breadth will require a length of 968 yards to contain an imperial acre; and to plough which at 9 hours, of 10-inch breadth of furrow-slice, counting no stoppages, will make the horses walk 95 miles, which in 10 hours gives a speed of 1742½ yards per hour. But as ridges are not made of 968 yards in length, and as horses cannot draw a plough that distance without being affected in their wind, and as allowance must be made for time lost in turning at the ends of the ridges, as well as for affording rest to the horses, that speed will have to be considerably increased to do that quantity of work in the time. By experiment it has been found, that 1 hour 19 minutes, out of 8 hours, are lost by turnings while ploughing an acre on ridges of 274 yards in length, with an 8-inch furrow-slice. Hence, in ploughing an acre on ridges of 250 yards in length, which is the length of ridge I recommend as the best for horses in draught, in 10 hours, with a 10-inch furrow-slice, the time lost by turnings is 1 hour 22 minutes. I presume that the experiment alluded to does not include the necessary stoppages for rest to the horses, but which should be included; for however easy the length of ridge may be made for draught, horses cannot go two hours walking in the plough for 5 hours together (one yoking) without taking occasion rest. Now 250 yards of length of ridge give nearly 4 ridges to the acre, or 36 bolts; and allowing a rest of 1 minute in every other bolt, 18 minutes will have to be added to the 1 hour 22 minutes lost, or very nearly 1½ hour of lost time, out of the 10 hours, for turnings and rest. Thus 18,000 yards will be ploughed in 8½ hours, or at the rate of 1 mile 422 yards per hour. I think this result is near the truth in regard to the ploughing of lea in spring; it is too little in ploughing red land in summer, and perhaps too much in ploughing stubble land in winter; but, as ploughing is the criterion by which all others are estimated, this result may be taken as a near approximation to the truth.

The comparative time lost in turning at the ends of long and short ridges may be seen from the following table, constructed from data furnished by the experiment above alluded to:

<table>
<thead>
<tr>
<th>Length of ridge</th>
<th>Breadth of furrow-slice</th>
<th>Time lost in turnings</th>
<th>Time devoted to ploughing</th>
<th>Hours of work</th>

Thus it appears that a ridge of no more than 78 yards in length requires 5 hours 11 minutes of time to turn at the lands, to plough an acre in 10 hours, with a 10-inch furrow-slice; whereas a ridge of 274 yards in length only re-
quires 1 hour 28 minutes for the same purpose, making a difference of 3 hours 43 minutes in favour of the long ridge in regard to saving of time. Consequently, in the case of the shortest ridge, only 4 hours 49 minutes out of the 10 can be appropriated to ploughing, whereas in that of the long ridge, 8 hours 32 minutes may be devoted to the purpose. Hence, so very short ridges require double the time of long ones to plough, and are thus a decided loss to the farmer. This is a subject well worth your experimenting on, by ascertaining the time usually taken in ploughing and turning and resting on ridges of different lengths, in the different seasons, and in different soils. A watch with a good second-hand to mark the time will be required, and the observations should be made unknown to the ploughmen, at their usual rate of work: for if you be constantly in the presence of the men, more than the usual work will be done, and less than the usual rests taken.

The whole value of ploughing, scientifically speaking, depends upon its having the effect of loosening the texture of the soil, and thus permitting a free circulation of air and moisture through its interstices, for the double purpose of increasing the rapidity of the disintegration of its stony portions, and of re-reducing to powder what had formerly been pulverized, but which, from the joint action of pressure, and the binding effect of root-fibres, had become agglutinated together. However well you may manure your land, however thoroughly you may drain it, you will never obtain the crops it is capable of yielding, unless you pulverize it; nay, so important did Jethro Tull think this, that he felt firmly persuaded that if you pulverized your soil well, you need not manure at all. I need hardly tell you, that we shall prove hereafter Jethro Tull to have carried his conclusions too far; but still so direct and unqualified a statement, from such a writer, should have its full influence upon all who wish to learn thoroughly the art of agriculture. Always bear in mind that the immediate result of applying the active part of soil, and that no other portion has any direct influence upon vegetation, and you will then, at all times, be sufficiently impressed with the necessity of thorough ploughing, harrowing, &c.; indeed, you may rest assured that, except upon some few very light sands, you cannot pulverize the soil too much—economy alone must fix the limit of this useful operation.

Tempering, Sr.—A good ploughman will have his plough so "tempered," or its different parts so regulated or adjusted, that it will neither have a tendency to take more or less earth, or, in other words, go deeper or more shallow than is necessary. The width of the furrow-slice will be at the same time regulated, so that neither more nor less land be taken than is requisite. Some ploughmen, says Mr. Stephens, habitually make the plough lean a little over to the left, thus giving it in effect less land than it would have, were it made to move upon the flat of the sole; and to overcome the consequent tendency of the plough to make a narrower furrow-slice than the proper breadth, they move the draught-bolt a little to the right. The ploughing with a considerable lean to the left is a bad custom, because it makes the lowest side of the furrow-slice, when turned over, thinner than the upper side, which is exposed to view, thereby delecting you into the belief that the land has all been ploughed of equal depth; and it causes the horses to bear a lighter draught than those which have turned over as much land in the same time, with a more equal and therefore deeper furrow-slice. Old ploughmen, becoming infirm, are very apt to practise this deceptive mode of ploughing. The plough should always move flat upon its sole, and turn over a rectangular furrow-slice; but there are certain exceptions to this rule, depending on the peculiar construction of parts of certain forms of ploughs.

None assume the habit of leaning the plough over to the right, because it is not so easy to hold it in that position as when it moves upon the sole along the land-side.

Other ploughmen, especially tall men, practise the habit of constantly leaning hard upon the stilts, or of steeping; and as this practice has the tendency to lift up the fore-point of the plough out of the ground, they are obliged, in order to keep it in, to put the draught-bolt farther from the ground than it should be. A little leaning of the hands upon the stilts is requisite at all times, in order to retain a firm hold of them, and thereby have a proper guidance of the plough.

A good ploughman will use none of these expedients to make his plough go steadily, nor will he fall into any of these reprehensible habits. He will temper the irons so as there shall be no tendency in the plough to go too deep or too shallow into the ground, or make too wide or too narrow a furrow-slice, or cause less or more draught to the horses, or less or more trouble to himself, than the nature of the work requires to be performed in the most proper manner. He will temper the irons so as to make the ploughing work three-elevenths the way of the ploughman himself, and, at the same time, have plenty of leisure to guide his horses aright, and execute his work in a creditable manner. I have known such ploughmen, and they invariably executed their work in a masterly way; but I never yet saw a ploughman execute his work well, who had not acquired the art of tempering the irons of his plough. Until he learns this art, the best-made plough will be comparatively worthless in his hands.

The state of the irons themselves has a material effect on the temper of the plough. If the cutting edge of the coulter, and the point and cutting edge of the sock, are laid with steel, the irons will cut clean, and go long in smooth soil. This is an economical mode of treating plough-irons destined to work in clay-soils. But in gravelly and all sharp soils, the irons wear down so quickly, that farmers prefer irons of cold iron, and have them laid anew every day, rather than incur the expense of laying them with steel, which perhaps would not endure work much longer in such soil than iron in its ordinary state. Irons are now seldom
if ever steeled; but whether they are steeled or not, they are always in the best state when sharp, and of the proper lengths.

An imperfect state of the mould-board is another interruption to a perfect temper of the plough. When new and rough, it accumulates the loose soil upon it, whose pressure against the turning furrow-slice, causes the plough to deviate from its right course. On the other hand, when the mould-board is worn away much below, it is apt to leave too much of the crumbled soil in the bottom of the furrows, especially in ploughing loose soils. Broken side-plates, or so worn into holes that the earth is easily pressed through them into the bosom of the plough, also cause rough and unequal work; and more or less earth in the bosom affects the balance of the plough, both in its temper and draught. These remarks are made upon the supposition that all ploughs are equally well made, and may, therefore, be tempered to work in a satisfactory manner; but it is well known that ploughs sometimes get into the possession of farmers, radically so ill-constructed, that the best tempering the irons are capable of receiving will never make them do good work.

When all the particulars which ploughmen have to attend to in executing their work,—in having their plough-irons in a proper state of repair, in tempering them according to the kind of ploughing to be executed, in guiding their horses, and in ploughing the land in a methodical way,—when all these particulars are considered, it ceases to surprise that so few ploughmen should be first-rate workmen. Good ploughmanship requires greater powers of observation than most young ploughmen possess, and greater judgment than most will take time to exercise, in order to become familiarized with all these particulars, and to use them all to the best advantage. To be so accomplished, implies the possession of talent of no mean order. The ship has been aptly compared to the plough, and the phrase "ploughing the deep" is as familiar to us as ploughing the land; to be able to put the ship in "proper trim," is the perfection aimed at by every seaman; so, in like manner, to "temper a plough" is the great aim of the good ploughman; and to be able to do it with judgment, to guide horses with discretion, and to execute ploughing correctly, imply & discrimination akin to that a ship. (Stephens.)

Plough Handles.—The handles should be sufficiently wide apart to allow the ploughman to walk in the furrow, and long enough to give him a full command of the plough, so that he can lift or depress it readily in work, guide it to the right or left hand, and swing it round at the land's end out of the furrow into another.

Plough-beam.—The beam should be of such a length, that its end, commonly called its head, shall cut at the point of draught, upon a line drawn from that part of the collar to which the truces are attached, to the share or that part of it where it first raises the soil. On the right arrangement of the point of draught in the structure of the plough depends much of its steady working at its proper depth. It is from the principle of balancing from a point adjusted to the line of draught, that the plough takes its name of newm, in contradistinction to the names of foot and wheel ploughs.

The beam should be curved upwards at the coulter and throat of the plough, to clear itself of rubbish which sometimes accumulates, and should be inclined slightly from the land, or, in other words, towards the furrow, because its tendency is to yield towards the loosened land, and it therefore requires this counteraction in the line of draught to keep it in a right line. This is supposing a pair of horses to be harnessed abreast; if they be harnessed at length, the beam should be still more inclined; for as neither horse then walks on the "land," the direction of the force towards the land-side is still further decreased.

Plough-head.—The cross-head of the plough forms a ready means of increasing or decreasing the inclination last spoken of, and the rake, or draught-iron, which moves in the arc of a circle along the cross-head, has notches by which the depth of the plough can be regulated in unison with the line of draught. There are various contrivances for these purposes, most of which involve the use of a screw as a means of adjustment; but the plan of pins and notches is sufficiently accurate, and not liable to be out of order. Sketches of two, the one English, h, the other Scotch, i, are given in Pl. 17.

Plough-share.—The plough-share is the apex of the sole, as the hind part is called the heel. It varies in shape for different purposes. On stony lands it is best with a point, as figured Pl. 17, k. But where the land is free from stones, the wing is best when angular, and the cutting edge in a line, or nearly so, as figured in Pl. 17, l.

For different work, "hard lands" and "summer lands," shares of a greater "dip" or "pitch" are requisite. A common plan is to use new shares on hard lands, and to wear them a day or two, and then lay them aside for summer lands.

Mould-board.—The upper part over the box of the share should form the first part of the rise of the mould-board. After the coulter and share have made the vertical and horizontal cuts for the depth and width of the furrow-slice, the mould-board has to complete the work by turning it over and leaving it in its proper position. On the precision with which this part of the plough performs its work, much, indeed nearly all, of the beauty of the ploughing depends; hence the importance of discovering its true form for the land on which it has to be used. Desirable, however, as this is, there does not as yet appear to be any precise rule for the formation of the mould-board, that has met with so uniform an approval under the test of practice, as would lead us to speak with entire confidence of it. We have looked at the mechanical principles laid down by Small, Bailey, Gray, Amos, Jefferson, Cleyer, and others, but are not aware of any plough-makers of the present day who strictly adhere to either the one or the other; and so long as the mould-board cannot be used on even the same farm.
PLOUGH.

under circumstances always similar, as its operation will necessarily be affected by the weather, the state of the land, with the varying depth and width of the plough, it is not an easy matter to determine which form is best for general purposes. It is clear that different soil conditions in the evidence of the mould-board, shallower, require mould-boards almost the opposite of each other; and such they are. The Norfolk mould-board is short, with rather a hollow or concave surface, whilst that used in the hundreds of Essex is long and convex.

Lord Western, many years ago, improved upon the form of the heavy land mould-board in use in that part of the county of Essex where he resides, by cutting away a considerable portion of the lower and hinder part of the figure, and by making it in a straight line lengthwise from the nose to the hind part.

Were the circumstances always the same, there can be no question but that one mathematical form of the mould-board would be preferable to all others; but, under circumstances so various, the plan hitherto adopted has been to prove, by experience and from practical operation, the forms best suited to different lands under an average depth and width of work, keeping as nearly as possible to the principle of the wedge, as necessary for the proper lifting, turning, and laying over the soil. Provided the mould-board be made so that the work, while in operation, goes on as it should do, a good practical criterion as to its figure will be found in the evidence of friction it has undergone, and this, with the fine cast metal now in use, can be determined to a nicety. If, on a given soil, the mould-board becomes brightened uniformly—if the mould appears to slip with light friction and with the same pressure from one end of it to the other, it cannot be far, if any thing, out of its proper shape for the purpose intended. And yet, if the same mould-board be used on some other lands, it will immediately show its inapplicability to them by the soil adhering to it in parts, not slipping well through it, and thus evidencing a want of proper design or form. Therefore, considering that neither depth nor width of furrow is always the same, and that scarcely one circumstance affecting its use is unvarying, it is difficult to find a rule which shall apply suit these changes. At the same time it is not presumed that such will not or cannot be found; and the theory which most accords with our view, is one which has recently been laid down by the Rev. W. L. Ram, rector of Winkfield, Berkshire, a gentleman whose scientific and agricultural knowledge entitles his opinion to considerable deference. His theory is, that the mould-board should be composed of straight lines in the direction of its length, with continually increasing angles to the line of the furrow: these last lines being either straight, convex, or concave, horizontal sections of the mould-board.

Coulter.—Simple as the coulter may appear to be, it is a very important part of the plough, and much depends upon its being properly formed and fixed for the work it has to perform in the operation of ploughing. It should be made of iron and steel, and of sufficient substance to stand firmly to the position in which it is set for its work, not bending either to the right hand or to the left. The blade or cutting part should be about 23 inches wide, and formed by the meeting of two curves, as this shape cuts the contour off, when the edge is either in a straight line or curved forward. The land side of the coulter should be flat, and the opposite side a gradual taper from the edge to the back: the thickness must be determined by the strength of the work it has to perform.

The angle at which the coulter is usually set, is about forty-five degrees from the plane of the ground; but in summer lands it requires to be placed in a more slanting position, and to take the lead of the share about three-quarters of an inch, to prevent the grass or rubbish driving in a heap, as it otherwise might do. On the contrary, when used for ploughing up hard fallows, it requires to be fixed in a more upright position, and rather more backward than the point of the share. It should be placed about half an inch above the share, and a quarter of an inch to the land side of it. Every good ploughman has his own notions on the subject of setting the coulter, but the above directions are given from practical observation.

The usual mode of fixing the coulter in the socket of the frame or beam, is by means of wood or iron wedges driven above or below the socket, or by a coarse cut screw-bolt, which turns into the side of the socket and presses against the coulter-stalk. Each of these modes is defective, there being a complication in the details of all that appears not quite adapted to the class of workmen who have to use them.

Skim Coulters.—Skim coulters are sometimes used for the purpose of burying the surface-grass or rubbish. Sketches of two kinds are given in pl. 17, m, m. The usual plan is to fix the skim about six inches before the common coulter.

Wheel Coulters are used in the fen lands, and are useful when ploughing up turf. One of these coulters is represented in pl. 17, n. The diameter of the cutting-disk is made of steel, with a nave sufficiently long for it to be steady, and the box should be bored true, and revolve on a well-fitted steel pin, as on the perfect fitting of the box and axle the correct working of the disk, and consequently the effective operation of the plough, depends.

Swing Ploughs.—The advantages attributed by Mr. Ransome to the swing plough are as follows:—

1. It admits of being set into its work at a given depth, either shallower or deeper, by the alteration of the draught iron at the point of draught, or by increasing or decreasing the distance at which the power of the horses is applied.

2. The ploughman has also the power of regulating, in some degree, the depth of the work, by either lifting or bearing upon the handles.

3. It is a plough of more simple construction than any other, and less expensive in its first cost.

4. A skilful workman can plough across ridge and furrow at very nearly a uniform
PLough.

Plough, says Mr. Ransome, our minds turn at once to James Smith, of Deanstone, as the gentleman who has opened a very interesting and important view of tillage, by the system of subsoil ploughing, and thereby breaking the under soil without turning it up to the surface. His practical knowledge has long been devoted to the interests of agriculture, and the results have been most beneficial. The plough he invented for the purpose is too well known to need a description, though we should consider our Essay incomplete without a sketch of it. See pl. 17, 3; also g.

Following the invention of James Smith, of Deanstone, was another of a different and much lighter description, the invention of Sir Edward Stracey, Bart., Rackheath, and the plough is called by the latter name. It answers the purpose of deep ploughing, that is, from 10 to 16 inches below the surface, and when preceded by the common plough, which is plan recommended, the depth below the surface-ground is just as much again as the in plough effects.

This plough answers admirably for under-ploughing great lands, and is made into a sub-turf plough by changing the wheel gear in front, to that of a carriage and two wheels.

P. Pusey, Esq., in an interesting paper in the Eng. Agr. Soc. Jour. (vol. i. p. 434), gives an account of a plough, made to his order by Charles Hart, of Wantage; at the hinder part of this plough was fixed a strong tine, something like those on Biddell's scissor, for the purpose of under-ploughing the soil. This tine was made to rise or lower at pleasure; and from the description of its use and operation, given in the above paper, we should think it a valuable invention, as it may be easily attached to a plough of the common sort, and removed when not wanted.

Skeleton, or Cleaning Ploughs, are often the transformations of common ploughs for that purpose, by taking the mould-boards and shares off, and substituting for the shares subsoil or cleaning shares, with prongs. See Pl. 17, f.

The plan of laying furrows in one direction, so as to have neither ridge nor water furrows, has within the last year attracted more than common attention in Britain. It has led to a careful inquiry into the the system of ploughing pursued in Kent, and there seems to be a disposition among many first-rate agriculturists to try the plan, provided lighter implements can be furnished for the purpose, not exceeding the power of two horses' draught. To this object some eminent practical farmers have turned their attention, and a plough, made under the direction of Mr. William Smart, a farmer of great respectability and experience at Rainham, in Kent, bids fair to open a new and very important view of the mechanical principles of the turn-rest plough, which he has remodelled; and it may be made equally applicable to the power of two or four horses.

This gentleman, after many trials, arrived at the conclusion that, inasmuch as the work of the turn-rest plough depended on its wedge-like construction, its form could only be correct in proportion to its approach to the perfect wedge; and this form, obtained by straight
PLOUGH.

lines in the direction, first, from the point of
the share to the throat of the plough, to pro-
duce the effect of elevating the furrow-slice;
and, second, from the edge of the coulter to the
heel of the rest, to effect the turning of the flag,
that is which he has adopted; making these
lines tend to an angle of 15 degrees. With the
assistance of an ingred, a ploughwright in his
own neighbourhood, several ploughs on this
principle were constructed, and these have
been the basis upon which still further im-
provements in the detail have been carried
out. They are now so constructed that the
ploughman can readily shift his coulter by
means of a lever, which reaches the bottom of
the handles, and also his rests or mould-boards
from side to side, without leaving his station
between the handles of his plough, they being
so arranged that, by withdrawing a small pin
and pressing the projecting rest towards the
body of the plough, the mould-boards on either
side become alternately the land side when not
in work.

Ploughs for the purpose of turning the fur-
rrows all in one direction, and laying the slices
at an angle with the horizon, as is done by
the common plough, have been within the
last year or two brought before the public, but
we cannot learn that they have been generally
adopted.

In going thus at length into the subject of
the plough, we have shown the present state
of agricultural mechanics as respects those in
general use. To have gone more fully into
the description of those out of the common
routine of farming, would have carried us beyond
what we imagine to be the proper limit of
this portion of the work. At the same time it
must be observed, that there are a variety of
purposes for which ploughs of a particular
form, different from any already described, are
required; such as paring ploughs, draining
ploughs, drill ploughs, &c. &c. On each, in-
deed on all of which, a considerable amount
of judgment and ingenuity has been expended.

Ploughs even for common purposes have
been long in arriving at their present state;
and the latest improvement, which may yet be
accomplished.

In the construction of ploughs, the first ob-
ject to be borne in mind is the proper perform-
ance of the work to be done; the next, that this
should be effected with the least expenditure
of animal power, and with the greatest econo-
y; and, lastly, that they should be made as
simple as possible in reference to the plough-
man who will have to use them. The circum-
stance of repairs, which will be continually re-
quired as the parts wear out, should also be
kept in view, and the whole require to be made
on an accurate plan, so as to insure every part
fitting properly; the workman may then fix
them on the spot as readily as a mechanic at
his manufactory. Nor should it be forgotten
that quality of materials and workmanship are
main points in economy, and that to dispense
with either is to pave the way to dissatisfaction
and trouble to all parties concerned.

It is difficult to suggest alterations on the
present implements, which appear adapted
to the purpose, and likely to agree with the
description of the requisites just given; but
there is no doubt that the plough, in its various
forms, is capable of great improvement; and
amongst the points to which attention may be
usefully directed are the following:—

Amount of draught that different forms of
mould-boards and shares require, in order to
determine those best suited to the purpose.

A mould-board that will best turn the work
on either side of the plough, so as to admit of
its being changed from one to the other, after
the plan of the Kent turn-rest.

A ready means of altering the depth or pitch
of the swing plough while in motion, without
stopping the horses, so that it may be accom-
modated to any difference in the nature of the
soil, or inequalities on its surface, which the
plough may meet with.

The same as respects the wheel plough, with-
out placing any of its forces in opposition to
each other.

Many papers on ploughs and ploughing are
contained in the best modern agricultural pe-
riodicals. Wilkie's turn-rest plough is de-

The Plough in the United States.—While in
Europe, and particularly in Great Britain,
the plough has been improved, American in-
elligence and ingenuity have been rewarded
with great success in the same pursuit.
The implement which the pioneer is obliged to
make use of in first stirring and partially turn-
ing up the soil filled with roots and stones, is
necessarily very rude, sometimes almost equal
in this respect to those of the primitive ages of
husbandry. One of these rough contriv-
ces is, in New England and the Northern
States, familiarly called the Bull plough. The
several improvements on the plough in the
United States seem to have progressed, for the
most part, with little or no reference to Eu-
ropean plans or models, and to have been
almost exclusively confined to swing-ploughs,
wheel-ploughs being scarcely ever seen. Sim-
plicity and economy seem to have been kept
in view by all who have undertaken to improve
or modify the implement. As the various sec-
ctions of the Union present varieties in the con-
ditions of the soil, the ploughs are constructed
with reference to these conditions, so that in

911
the Northern, Eastern, Middle, and Western States, different ploughs are vaunted for their excellence. It has been observed as a singular circumstance, that to the celebrated author of the Declaration of Independence the United States should be also indebted for the first theory of the plough formed on mathematical principles. President Jefferson's letter to Sir John Sinclair, president of the British Board of Agriculture, addressed in 1798, is published in the Transactions of the Am. Philosophical Society, vol. iv. p. 314. It describes the mould-board, and the principles upon which it is properly constructed. (See American Farmer, vol. ii. p. 185, and Domestic Encyclopedia, vol. iii. p. 113.)

In England the most complete set of experiments yet made to ascertain the particular merits of different ploughs, are those instituted by Mr. Pusey, president of the Royal Agricultural Society, and described by him in the 3d No. of the Journal of that Society. A condensed view of the objects and results of these experiments may be found in the Cultivator, (vol. viii. p. 10), together with the results obtained with American ploughs at the Worcester ploughing match in 1840.

The points embraced in the English experiments were:

1. The comparative lightness in draught, of wheel and swing ploughs.
2. The lightest plough absolutely, of whatever kind.
3. The effect of different soils upon the qualities, and chiefly on the draught of the plough.
4. The comparative tenacity of different soils.
5. The power of two horses to plough the strongest or clay soil.

Ten ploughs, embracing some from the most celebrated makers in England, the highly famed Scotch swing plough, and several of those in common use in the different districts of the kingdom, were selected by Mr. Pusey for his experiments, and he was aided by the presence and advice of some of the most distinguished agriculturists in the country. The ploughs were worked by skilful ploughmen; and, as much interest was attached to the experiment on the Scotch ploughs, a Clydesdale span of horses and a ploughman accustomed to the plough were sent up by Lord Morton to manage that part of the trial. The Scotch plough has obtained considerable celebrity from the strong praise bestowed upon it by Mr. Loudon, who declares the improved Scotch plough to be superior to any similar implement known in England. They are constructed on the principles laid down by Mr. Jefferson, in his celebrated Report on the true shape of the mould-board, addressed to the French Institute, which, he showed from mathematical data, should be in the form of a gentle hollow curve; other ploughs constructed more full and short, not raising the earth gradually like a wave, but throwing it over at once. In condensing Mr. Pusey's experiments, we shall select, as sufficient for the present purpose, from the list given by him, three ploughs—1st, the improved Scotch plough made by Fergusson; and entirely of iron—2d, a one-wheeled plough of wood, with an iron breast, by Mr. Hart, but commonly known as the improved Berkshire plough; and 3d, an old-fashioned plough made of wood, and such as is in general use in many parts of England, where it is called the old Berkshire plough. Some previous experiments had convinced Mr. Pusey that the Hart plough was of easy draught, and the ones now instituted showed that his impressions were correct.

The Clydesdale horses were much admired in the work; and it was the opinion of the bystanders that such land, usually worked with four horses in line, might be ploughed with two such horses abreast; though it was said it would cost as much to keep two horses in that condition, as to support the four in their usual working state. On this ground, where the horses had a firm footing, they worked with perfect ease.

In summing up the trials, Mr. Pusey remarks that the plough requiring the least draught was Hart's, though in the last trial it was beaten by the Scotch swing plough. But that all modern ploughs the Scotch swing plough was the heaviest, "out of the question on a light soil, and by no means the best on a heavy one." The following table shows the average draught of all the ploughs on the several soils in which the experiments were made:

A drawing of Hart's improved Berkshire one-wheel plough is given in the Cultivator, (vol. viii. p. 16.)

The trials at the Worcester ploughing match in 1840, were made to determine the award of two premiums offered by the Massachusetts Agricultural Society, of $100, and $75, for the best ploughs, one for laying furrows and the other for laying them flat. The following remarks by the reporting committee will enable the reader to understand the experiments, whilst the list of ploughs will show the number of inventors and improvers whose implements have acquired most celebrity in the eastern portion of the United States.

The power required to turn over a given quantity of earth by a plough is a very important consideration. This power can be measured with great accuracy; greater than many of the committee supposed, before they witnessed the operation. The dynamometer, inserted between the plough-beam and the chain, measures with great accuracy the strength exerted by the team. Suppose the strength applied be the same that would be required to raise 336 lbs. over a single pulley; suppose also that the depth of the furrow is 6 inches with a width of 13 inches. Multiply by 0.64, and you will have 84 with a fraction. Now, if 336 lbs. of power will take up and turn over 84 inches of earth, then 112 lbs. will turn 28 inches. Tried in this way, the ploughs exhibited showed the following results. The power in each case is 112 lbs.

never asked whether the plough is of a construction so defective as to require 5 cwt. to move it, or whether it works with ease, with a force of 2 cwt. applied. Mr. Pusey estimated the fair draught of the Clydesdale horse at 168 lbs. or 13 stone, and that of a common English farm-horse at 112 lbs. or 8 stone.

At a fair held by the New York Agricultural Society, at Syracuse, in 1841, the first of the regular premiums, $30, was awarded to the plough made by Howard Delano of Mottsville, the second premium of $20 to E. G. Holliday, for his plough, favourably known as the Laughlin plough. The Wisconsin and other ploughs attracted considerable notice; but the double mould-board plough of Barnaby and Mooers, from the excellence and novelty of its construction, the facility with which it would operate on side hills as well as on level land, and its ease of draught, rendered it deservedly a favourite implement, and the honorary premium was deemed well awarded. It was supposed by many very good judges of ploughing, that the resistance offered by the land-side share would increase the draught sensibly, but the result showed that such was not the case.

The trial of ploughs which took place under the direction of a committee of the American Institute, at New York, was very well conducted; and although the number of ploughs on the ground was not as great as at Syracuse, the trials with the dynamometer were more satisfactory. It is to be regretted that some of the favourite ploughs of this country, is more easily made. The following table, which we find prepared at our
hand in an account of the New York trials, given in the Brooklyn Star, we transfer to our columns with pleasure, merely remarking that we have verified the correctness of the foreign results, by reference to the reports in the Journals of the English Royal Agricultural Society and the Scotch Highland Agricultural Society, from which they were taken. The reader will see that the best British plough, Yester No. 1, weight 170 lbs., draught 380 lbs., removed a furrow-slice of only 10 inches by 6, while the best American, Barnaby and Mooers' double mould-board side-hill plough (the same that received the premium at Syracuse), weight 142 lbs., draught 350 lbs., removed a furrow-slice of 12 inches by 8, or nearly twice as large. We are gratified to learn, that this plough, which received the premiums at Syracuse and New York, has been presented by the Institute to the Royal Agricultural Society, and that doubtless it will be subjected to comparison with the ploughs of that country. In examining the list of English agricultural implements, we have often remarked the fact, that English ploughs range in prices from $20 to $30, while the best improved American ones do not cost more than from $10 to $15. The table will be understood without further explanation.

In a report of a committee appointed to superintend a trial of ploughs near Baltimore, in 1843, the following results are stated:

<table>

The committee remarks, "the task to the committee, of deciding where such excellence was to be found in each of the implements contending, was one of difficulty, and would have been more so, but for the various purposes to which the Barnaby and Mooers' plough is adapted, it being in fact a plough of all work, and from the fact of its executing its work with so much less draught than either of the others."

In commenting on the qualities of the several ploughs submitted to trial, the committee say of Barnaby and Mooers' side-hill plough, the one used:—"There is a peculiarity about this plough which is worthy of note. On the bottom of the furrow, and on the land side, it cuts out fully 12 inches of the earth, so as to reduce resistance to the turning of the succeeding furrow, thereby facilitating, not only that operation, but insuring the exactitude with which it is performed, leaving a clean and broad furrow behind, in which the furrow-horse can walk, and preventing the treading of the ground in turning."

Although the trials made at the various exhibitions have thus far resulted so much in favor of the double mould-board plough of Barnaby and Mooers, still this has been less extensively adopted than it would appear to deserve. Associated with its great merits, there may yet remain some obstacle to its general use, of easy removal. The objection from great weight requiring unusual exertion in throwing out and turning, might possibly be obviated by the addition of a wheel or some other device.

The price of this plough varies from $4 for No. 3, a 7 inch seeding plough, to $10 for No. 8, a heavy two or three horse, 12 inch plough.

The following is a summary notice of the ploughs best known to the farmers of the Middle States. The order in which they are mentioned is not intended to express the precise dates of their invention or their relative merits.

Beech's Self-sharpening Plough has a concave mould-board. Its price varies with the size, from $6 to $10, the average price being $8.

Miles' Plough, known also by the name of Dickson's, has the bar-share, land-side, and lock-couler of wrought iron. They cost about $13. This plough still retains precedence in the old counties of Pennsylvania, its execution being excellent, and its strength enabling it to contend successfully against obstacles met with in stony ground and tough swards.

Peacock's Plough.—This has been long known and is still extensively used. It has a bar-share and lock-couler, and is best adapted to soils of a light texture, where shallow work will answer. It does not turn a sod so well as is desired.

Wiley Plough.—One of the oldest of the cast-iron ploughs still in use is that of B. H. Wiley. The share of this has two points capable of being turned once. It is adapted to stubbles, but does not perform so well in tough sward.

Woodcock's Plough.—For the last few years this has been in extensive use in Lancaster county, Pennsylvania, and Newcastle county, Delaware. It is a self-sharpening implement, with a slightly concave mould-board. A cast-iron angular cutter supplies the place of a couler, and is sometimes constructed so as to have the mould-board on either the right or left side, thus adapting it to the habits of a few old farmers who retain a partiality for ploughs turning the furrow-slice to the left hand.

Prouty and Mears' Centre-draught Plough.—One of the chief late improvements on American ploughs consists in lengthening or extending the mould-board, and still retaining the centre-draught principle, a construction which enables the instrument to turn a sod or furrow-slice so as merely to lap, or to lie completely flat, at the discretion of the ploughman. The cost of these ploughs, which possess high merits, varies, according to size, from $7 to $12. The larger sizes are provided with a small wheel to each, attached near the beam, a rare thing in America, but which in the present instance serves to render it more easy for the plough to follow the horses with proper steadiness, thus serving to ease the ploughman as well as the horses, the tendency to sink too deeply into the soil being completely checked. With regard to the wheel to ploughs, it is worthy of remark that there is a disposition beginning to be manifested in the United States in favour of at least one such appendage.

Subsoil Ploughs, now so extensively used in
PLoughing.

Great Britain, are rapidly coming into use in the United States, where various sizes are made, the largest being a heavy tug for four horses, whilst the smallest may be worked by two mules or one stout horse. Those made by Prouty and Mears are very efficient implements, the prices varying from $8 for the single horse, and $10 to $12 for the larger sizes. A more simple and cheaper subsoil plough, which has proved very successful on trial, has lately been made in the city of New York, adapted to one or more horses. These consist of a common plough from which all the upper portion of the mould-board has been cut away, so as to leave the mere skeleton, which strikes deep and stirs up the subsoil very effectually. The price of these varies from $4 to $6, according to size, &c. They may be had in New York at most of the agricultural implement stores, and in Philadelphia, of E. Chandler, agricultural implement maker, 196 Market street. See Subsoil Ploughing.

PLoughing. The art of turning round the soil by means of the plough. There are various kinds of ploughing. Trench ploughing is effected by the plough passing twice along the same furrow: the first time for the purpose of throwing the surface soil into the bottom of the furrow, and the second time for raising a furrow-slice from under that which had been already turned over, and raising it up, &c., turning it upon the first furrow-slice, by means of which the surface soil is entirely buried, and a stratum of subsoil laid over it: thus effecting in the field what trenching with the spade does in the garden. Trench ploughing can only be employed with advantage when the subsoil is naturally dry and of good quality, or where it has been rendered so by draining and subsoil ploughing; for bad subsoil brought to the surface, unless considerably altered in composition and texture, would be unfit for receiving seeds or plants.

To excel in the art of ploughing, the ploughman should take a pleasure in his work, and not rest satisfied till he can make his furrows in a straight line, and lay the slices as much as possible at the same angle from the bottom of the furrow. He should open his first furrow in a uniform manner, and proceed with regularity of width and depth of the furrow-slice, and "shut up" clean at last.

Ploughing matches, which of late years have been so general, have given a very increased interest to ploughmen and ploughboys. The face of the country is in many parts strikingly improved by the change which sound ploughing has effected, and much of this may be traced to the lively interest which has been paid to this part of tillage by agricultural societies and by practical farmers. I never knew a ploughing-match meeting established in any rural district without very beneficial effects being produced on the character of the peasantry. It never fails to elevate the ploughman in his own opinion; it induces him to strive to excel in his honourable vocation, to please his employer, and to stand well in the estimation of his richer neighbours. The very assemblage of the neighbouring farmers and gentry to wit-
exhibition, is entitled to receive, over and above, the Society's plough medal of silver, bearing a suitable inscription, with the gainer's name. About 40 applications are made for the medals every year, so that at least 600 ploughmen annually compete for them; but the actual number far exceeds that number, as, in many instances, matches comprehend from 40 to 70 ploughs, instead of the minimum number of 15. The matches are usually occasioned by the welcome which his neighbours are desirous of giving an incoming tenant to his farm, and its heartiness is shown in the extent of the assistance which they give him in ploughing a field or fields at a time when he has not yet collected a working stock sufficient for the purpose.

Ploughing matches are generally very fairly conducted in Scotland. They usually take place on level ground, the ploughing of which is considered the best test of a ploughman's skill, though I hold that drilling is much more difficult to execute correctly. The best part of the field is usually selected for the purpose, if there be such, and the same extent of ground, usually from 2 to 4 ridges, according to the length, is allotted to each portion of ground to be ploughed. A pin, bearing a number, is pushed into the ground at the end of each lot, of which there are as many marked off as there are ploughs entered in the competition. Numbers corresponding to those on the pins are drawn by the competing ploughmen, who take possession of the lots as they are drawn. Any idle time is allowed to finish the lot, and in this part of the arrangements I am of opinion that too much time is usually allowed, to the annoyance of the spectators. Although shortness of time in executing the same extent of work is not to be compared to excellency of execution, yet it should enter as an important element into the decision of the question of excellence. Every competitor is obliged to feed his own lot, guide his own horses, and do every other thing connected with the work, such as arresting his horses and trimming his plough-irons, without the least assistance.

The judges, who have been brought from a distance, and have no personal interest in the exhibition, are requested to inspect the ground after all the ploughs have been removed, having been kept away from the scene during the time the ploughs were engaged.

The primary objects of the institution of ploughing matches must have been to produce the best examples of ploughmanship; and by the best must be understood that kind of ploughing which shall not only appear to be well done, but must be thoroughly and essentially well done. In other words, the award should be given to the plough that produces not only work of a proper surface finish, but which will exhibit, along with the first, the property of having turned up the greatest quantity of soil and in the best manner. (Book of the Farm.)

The following will be found a useful table, showing the distance travelled by a horse in ploughing or scarifying an acre of land; also the quantity of land worked in a day, at the rate of 16 and 18 miles per day of 9 hours.

PLUM (Prunus, from prunus, its Greek name) A genus of trees and shrubs, several of which are indigenous to Britain. Having already noticed the bird cherry (P. padus), the wild cherry tree (P. cerasus), the wild bullace tree (P. isittsita), the blackthorn or sloe (P. spinosa),
PLUM.

under their several heads, it only remains to speak in this place of the wild and cultivated species of plum tree. The wild plum tree (P. domestica) is a moderate sized tree, without thorns, found growing sometimes in woods and hedges, flowering in May. The fruit is rather oblong, seldom quite globular, its colour and flavour very variable. "Whether all our cultivated plums have originated from this species, or from the wild bullace tree" (P. insititia), says Sir J. E. Smith, "its thorns having disappeared by culture like those of the pear tree, is a question which perhaps no botanist can ever solve." Indeed, its varieties, Gerard declares that "to write of plums particularly would require a peculiar volume, and yet the end not be attained unto, nor the stock or kindred perfectly known, neither to be distinguished apart." He adds that each country has an abundance of its own peculiar varieties. All the kinds of plum grow well in any common soil, and are increased by seeds or suckers, or by grafting or budding to perpetuate the particular kinds. There are 274 varieties named in the catalogue of the Horticultural Society. As a choice selection for a small garden, Mr. Smith recommends the following twelve varieties: Janne Háttive, Wilmot's Orleans green gage, red magnum-bonum, white ditto, Coes golden drop, Caledonian, mussel, damson, wine-sour, white bullace, blue impératrice.

The best plums for cultivation may be thus classified—

a. Purple Round.—Shoots smooth.—Purple gage, nectarine plum; Kirkes; virgin; queen-mother.

b. Orleons.—Shoots smooth.—Blue impératrice; Inkworth impératrice; Cooper's large red.

c. Pale Round.—Shoots smooth.—Green gage; Knight's large green drying; Lucombe's nonsuch.

d. Washington.—Shoots smooth.—Coe's golden drop; St. Catherine; White magnum bonum.

PLUM TREE WEEVIL.

If plum trees are much pruned, they grow too luxuriant to produce fruit, and often gum and spoil. The choice varieties of plums are much esteemed for the dessert; the more common sorts are used for pies, tarts, preserves, &c. The wood is employed for turnery and cabinet work, and for the manufacture of musical instruments.

The following information relative to the cultivation and management of plum trees, is from a communication made by Mr. S. Reeve, of Salem, N. J., to that valuable American work, Holly's Orchardist's Companion. Plum trees, like other fruit trees, when first transplanted, and for a few or several subsequent years, should be managed and cultivated alike; but when the plum tree has arrived to maturity and ready to bear, the soil around it should be thrown into a hard texture, for instance, of the consistency of a gravel walk.

A pig and poultry yard which remains uncultivated, and never suffered to become a sward, is also very appropriate, from the circumstance of its being promenaded over constantly by bipeds and animals so as to preclude the possibility of grass growing.

In a soil of this description, owing to its being compact and consequently remaining drier, the trees do not grow so fast as in cultivated grounds, the beneficial result is, that the sap centres itself more in the fruit; whereas, when the sap is too abundant, it is more apt to flow from the fruit into the branches, and thus ultimately from a want of nourishment, the plums drop off in profusion, owing to their starved condition, and not so much, as it is often supposed, from the bore or sting of the curculio, of which it is frequently found divested when picked from the ground.

From a compact position or nature of soil as before described, another important advantage arises: although not operating as a perfect antidote to the attacks of the curculio, it is nevertheless a great preventive to its depredations, from the circumstance of the insect, when the tree does fall, not meeting with a surface or soil such as sward, garden ground, &c., in which to take shelter until the following spring, when it hatches and assumes the winged form, and again commences its destructive attacks upon the fruit.

Mr. Reeve submits it therefore as his opinion, that it would fully repay any person for his trouble or expense in removing (which should only be done when vegetation is checked) from the plum tree, when it has arrived to the age of 8 to 10 years, all the rich subsoil from around the tree in a circumference of from 10 to 12 feet; down to the clay soil, and fill up the space again with poor earth, sand, or gravel, so as to check the growth of the tree for the benefit of the fruit, in accordance with the first principles stated in this article.

Since it is now well known that the falling of unripe plums, apricots, peaches, and cherries, is caused by little whitish grubs, which bore into these fruits. The loss of fruit, occasioned by insects of this kind, is frequently very great; and, in some of our gardens and orchards, the crop of plums is often destroyed by the depredations of grubs, which have been ascertained to be the larvae or young of a small beetle of the weevil tribe, called Rhynchosaurus (Conocrocalles) Nenufar, the Nenuphar or plum-weevil. "I have found the beetles," says Dr. Harris, of Boston, "as early as the 30th of March, and as late as the 10th of June, and at various intermediate times, according with the forwardness or backwardness of vegetation in the spring, and have frequently caught them flying in the middle of the day. They are from three-twentieths to one-fifth of an inch long, exclusive of the curved snout, which is rather longer than the thorax, and is bent under the breast, between the fore-legs, when at rest. Their colour is a dark-brown, variegated with spots of white, ochre-yellow, and black. The thorax is un-

917
PLUM TREE WEEVIL.

The wing-covers have several short ridges upon them, those on the middle of the back form the two considerable humps, of a black colour, behind which there is a wide band of ochre-yellow and white. Each of the thighs has two little teeth on the under side. They begin to sting the plums as soon as the fruit is set, and, as some say, continue their operations till the first of August. After making a suitable puncture with their snouts, they lay one egg in each plum thus stung, and go over the fruit on the tree in this way till their store is exhausted; so that, where these beetles abound, not a plum will escape being punctured. The irritation arising from these punctures, and from the gnawings of the grubs after they are hatched, causes the young fruit to become gummy, diseased, and finally to drop before it is ripe. Meanwhile the grub comes to its growth, and, immediately after the fruit falls, burrows into the ground. This may occur at various times between the middle of June and of August; and, in the space of a little more than three weeks afterwards, the insect completes its transformations, and comes out of the ground in the beetle form. The history of the insect thus far is the result of my own observations; the remainder rests on the testimony of other persons.

In an account of the plum-weevil, by Dr. James Tilton of Wilmington, Delaware, published in the Domestic Encyclopedia, (article Fruit,) and since republished in the "Geographical Papers for 1809" of the Massachusetts Agricultural Society, and in other works, it is stated, that peaches, nectarines, apples, pears, quinces, and cherries are also attacked by this insect, and that it remains in the earth, in the form of a grub, during the winter, ready to be matured into a beetle as the spring advances. These statements, says Dr. Harris, I have not yet been able to confirm. It seems, however, to have been fully ascertained by Professor Peck, Mr. Say, and others, in whose accuracy full confidence may be placed, that this same weevil attacks all our common stone-fruits, such as plums, peaches, nectarines, apricots, and cherries; Dr. Burnett has recently assured me that he has seen this beetle puncturing apples; and it is not at all improbable that the transformations of some of the grubs may be retarded till the winter has passed, analogous cases being not infrequent occurrences. Those that are sometimes found in apples must not be mistaken for the more common apple-worms, which are not the larva of a weevil. The Rev. F. V. Melsheimer remarks in his catalogue, that this insect lives under the bark of the peach-tree. Professor Peck raised the same beetle from a grub found in the watery excrecence of a cherry tree, and from this circumstance named it Rhynchus Cerasi, the cherry-weevil. The plum, still more than the cherry, is subject to a disease by the small limbs, which shows itself in the formation of large irregular warts, of a black colour, as if charred. Grubs, apparently the same as those that are found in plums, have often been detected in these warts, which are now generally supposed to be produced by the punctures of the beetles, and the residence of the grubs. Professor Peck says, that "the seat of the disease is in the bark. The sap is diverted from its regular course, and is absorbed entirely by the bark, which is very much increased in thickness; the cuticle bursts, the swelling becomes irregular, and is formed into black lumps, with a cracked, uneven, granulated surface. The wood, besides being deprived of its nutriment, is very much compressed, and the branch above the tumour perishes." The grubs found by Professor Peck in the tumours of the cherry tree, went into the ground on the 6th of July, and on the 30th of the same month, or 24 days from their leaving the bark, the perfect insects began to rise, and were soon ready to deposit their eggs in healthy branches.

In speaking of the difference between the grub of the plum-weevil and apple tree caterpillar, Dr. Harris observes, "It must be borne in mind that this plum-weevil, an insect unknown in Europe, when arrived at maturity, is a little, rough, dark-brown or blackish beetle, looking like a dried bud, when it is shaken from the trees, which resemblance is increased by its habit of drawing up its legs and bending its snout close to the lower side of its body, and remaining for a time without motion and seemingly lifeless. In stinging the fruit, before laying its eggs, it uses its short curved snout, which is armed at the tip with a pair of very small nippers; and by means of this weapon it makes, in the tender skin of the young plum or apple, a crescent-shaped incision, similar to what would be formed by indenting the fruit with the finger-nail. Very rarely is there more than one incision made in the same fruit; and in the wound, the weevil lays only a single egg. The insect hatched from this egg is a little whitish grub, destitute of feet, and very much like a maggot in appearance, except that it has a distinct, rounded, light-brown head. By means of the microscope I have satisfactorily ascertained that the grubs from the fruit and from the warts were exactly alike, and that both were without feet. It appears, furthermore, that the tumours on plum and on cherry trees are infested not only by these insects, but also by another kind of grub, provided with legs, and occasionally by the wood-eating caterpillars of the Ageria extinsoa, or peach tree borers. When the grubs of the plum-weevil are fully grown, they go into the ground, and are there changed to chrysalids of a white colour, having the legs and wings free and capable of some motion; and finally they leave the ground in the form of little beetles, exactly like those which had previously stung the fruit. Further observation seems to be wanting before it can be proved that the cankerous warts on plum and cherry trees arise from the irritant punctures of the plum-weevils, and of the other insects that occasionally make these warts their places of abode; although it must be allowed that the well-known production of galls by insects on oak trees and other plants, would lead us to suppose that those of the plum tree have a similar origin. In addition to the means already recommended for preventing the ravages of plum-weevils, I would observe that wall-fruit can be perfectly secured by a screen of millinet or close netting, which should be put on as
soon as the fruit is formed, and should remain till it begins to ripen.

The following, among other remedies that have been suggested, may be found useful in checking the ravages of the plum-seeal. Let the trees be briskly shaken or suddenly jarred every morning and evening during the time that the insects appear in the beetle form, and are engaged in laying their eggs. When thus disturbed they contract their legs and fall; and, as they do not immediately attempt to fly or crawl away, they may be caught in a sheet spread under the tree, from which they should be gathered into a large, wide-mouthed bottle or other tight vessel, and be thrown into the fire. All the fallen wormy plums should be immediately gathered, and after they are boiled or steamed, to kill the enclosed grubs, they may be given as food to swine. The diseased excrecescences should be cut out and burned every year before the last of the June. The moose plum tree (Prunus Americana), which grows wild in Maine, seems to escape the attack of its pests, for no warts are found upon it, even when growing in the immediate vicinity of diseased foreign trees. It would, therefore, be the best of stocks for budding or engrafing upon. It can easily be raised from the stone, and grows rapidly, but does not attain a great size. For further suggestions and remarks, the account of this insect by Dr. Joel Burnett, in the 18th volume of the New England Farmer, may be consulted. (Harris.)

Plums, nectarines, and apricots have been saved after being stung, by extracting the stung parts. There are ways with the point of an eel’s knife or nippers properly adapted to the purpose. The wounds heal and the fruit grows and attains to perfect maturity.

POA (From poa, signifying grass or herbage). The meadow-grass. A genus of grasses of considerable extent, and very abundant in the pasturages of Europe. This genus contains some valuable hay and pasture grasses, succeeding well in rich loamy soil; some of the species are aquatic, growing only in water, or in or very moist situations; and increased by seeds or divisions of the roots. Poa annua, pl. 6, c, is the most common of all grasses. P. trivialis and P. pratensis are sown extensively as a part of the artificial grasses for pastures and lawns, which are now commonly made with picked grasses instead of “hay seeds.” In general these grasses appear to be nutritious and agreeable to cattle. There are, in England, nine indigenous species, besides several varieties.

1. Flat-stalked meadow-grass (P. compressa), pl. 7, h. This is a very common species in dry, barren ground, flowering from June to September.

The root is moderately creeping, with downy fibres; stems obliquely ascending in the lower part, then erect and often crowded together, from 1 to 1½ foot high, remarkably compressed, by which this species may readily be known, as also by a sudden contraction where the panicle begins. Leaves short, narrow, roughish, especially at the edges, with long compressed sheaths, and a short obtuse stipule. The whole plant is more or less glaucous.

Florets from three to eight or nine, connected at the base by a mass of white folded threads, as fine and soft as a spider’s web, which may be drawn out to a considerable length. This grass, though not succulent, is eaten by all cattle, but cannot be cultivated in moist or manured ground. It never forms a close turf, and although it possesses superior nutritive powers, its produce anywhere is far from abundant.

A variety of this species (P. c. var. erecta) is mentioned by Sinclair, which differs from the last, in having culms more upright, less compressed, and produced in greater quantities. It grows closer, forms a pretty good sward, and the roots are less inclined to creeping. But it is nevertheless inferior in point of early growth, and the produce of the foliage. See Blue Grass.

2. Alpine meadow-grass (P. alpina), pl. 6, l. This species is chiefly confined to alpine regions and lofty mountains.

3. Wavy meadow-grass (P. laza). This species grows generally throughout the Highlands of Scotland. It possesses no agricultural merit.

4. Bulbous meadow-grass (P. bulbo). This species tenants the sandy sea-shore, and other dry, barren ground. It is perennial, and flowers in April and May.

5. Roughish meadow-grass (P. trivialis), pl. 5, i. This is a very common species, in meadows and pastures, especially such as are rather moist. Perennial, flowering from June to October. The root is fibrous, and tufted; the stems several, about eighteen inches high, erect, leafy, with several knots, the naked part cylindrical. The superior produce, at the edges and backs of the flat, slightly spreading, lax, linear, deep-green leaves. In their long compressed sheaths also a slight roughness is sometimes perceptible. Panicle large, spreading with half-whorled, horizontal, wavy, angular, rough-compressed, unequal branches. Mr. Curtis, deeply versed in the practical economy of grasses, declares this to be one of the most valuable for pastureage and hay, yielding abundantly, though not particularly early; and of the most excellent quality. Mr. G. Sinclair, another practical authority on the grasses, also observes, “The superior produce, of this Poa over many other species, its highly nutritive qualities, the seasons in which it arrives at perfection, and the marked partiality which oxen, horses, and sheep have for it, are merits which distinguish it as one of the most valuable of those grasses which affect moist, rich soils and sheltered situations: but in dry, exposed situations it is altogether inconsiderable; it yearly diminishes, and ultimately dies off, not unfrequently in the space of four or five years. Its produce is always much greater when combined with other grasses than when cultivated by itself; with a proper admixture, it will nearly double its produce, though on the same soil, so much does it delight in shelter. Those spots in pastures that are closely eaten down, consist for the most part of this grass.”

6. Smooth-stalked meadow-grass (P. pratensis), pl. 5, h. This is a very common species in all meadows and pastures. It is perennial, flowering in May and June. The root is strong and creeping, with horizontal runners. The
general aspect of the plant is very like the last, with which it has usually been confounded; but the stems and leaves betray no roughness when drawn through the hand. Spikelets four-flowered; florets inconspicuous, sterile, connected by a web. But the clear and essential mark of this species, compared with the last, consists in its very short, abrupt, pointless stipe, which in every leaf of every variety proves constant and invariable.

As an object of agriculture, this species is not less valuable than the P. trivialis, especially for permanent pasture. It is earlier in leaf, and will thrive with less moisture, though the rough-stalked meadow-grass produces, at last, a better root. Mr. Curtis, and several other able botanists, have rendered great service to the farmer in directing his attention to such objects; and it is undoubtedly worth his while to be select in seeds for grass lands. But, after all, Nature is supreme in the accommodation of particular grasses to certain soils and situations, and whatever we may sow, unless we have well studied her laws, she finally triumphs. The great objection to this grass is the property of the creeping roots to scourge the soil.

Mr. Sinclair notices, in his experiments on the grasses, two varieties, the short blue meadow-grass (P. pratensis subseciulea) and the narrow-leaved meadow-grass (P. pratensis angustifolia), pl. 6, c, which requires some notice here.

The discriminating characters of the first-named are as follows:—Panicle diffuse; spikelets oval, generally three-flowered; the culms shorter, and somewhat glaucous; and the leaves much shorter and broader than those of the Poa pratensis. It may be further distinguished by its delicate sky-blue or glaucous colour. From its creeping roots and other demerits, this is evidently one of the inferior grasses. Although the botanical characters of the narrow-leaved meadow-grass (P. angustifolia) are not sufficient to constitute it a distinct species, its agricultural merits cause it to differ from P. pratensis, to which it is much superior. Its spring produce is considerable, and its properties of early growth and great nutritious matter would rank it with the most valuable grasses, but for its powerful creeping root. The culms are most valuable for the manufacture of the finest straw-plait, in imitation of the celebrated "Leghorn." See Blue Grass.

7. Annual meadow-grass, Suffolk-grass (P. aemula), pl. 6, c. This is an exceedingly common species everywhere, as well in waste as cultivated ground, flowering from April to November. The root is fibrous. Stems pale, very smooth, oblique, compressed, 3 to 12 inches long. Leaves of a fine light-green, spreading, linear, bluntish, flaccid, roughish at the edge only. Panicle small, widely spreading. Spikelets ovate, five-flowered; florets little or none, five-ribbed, without a web.

This is a good grass for fodder, abundant in proportion to the richness of the soil, easily raised, but not durable. The diminutive size of the plant, however, renders its cultivation unprofitable, compared with that of any other of the pasture grasses. It is the most troublesome weed that infests gravel walks, stone-pitchings, and the like. The most effectual way to extirpate it in such situations is to sprinkle salt on it; some recommend boiling water and a layer of litter, &c.

This grass, which Dr. Darlington calls meadow-po'a, in the Middle States goes by the name of green grass, spear-grass, and meadow-grass. Although it is styled an annual, it has a perennial root. This species varies considerably, in size and appearance, when growing in different soils and situations. In our best soils, the radical leaves are very long and luxuriant, when it is known by the name of green grass. This has by some botanists been made a distinct species, under the name of P. viritis; but it is probably nothing more than a variety. It is, indeed, as Muhlenberg terms it, "optimum pasturium," being decidedly the most valuable of all the grasses known in our pastures. It has not been found necessary to cultivate it, by sowing the seed; for when the land is duly prepared by lime and manure, it soon takes possession of the soil,—or comes in, as the farmers term it; and supersedes the artificial grasses. In very poor land, it deteriorates so much that it would scarcely be recognised as the same plant. It is generally believed by the American botanist to be a naturalized foreigner in the United States.

8. Glaucescent meadow-grass (P. glauca). This species is found on the mountains of Wales, Scotland, and the north of England.

9. Wood meadow-grass (P. nemoralis). This is a very common species in some districts in groves and woods, especially on chalk soils. The whole plant is very slender and delicate, 1½ or 2 feet high. Stems several, slightly compressed, smooth, striated, leafy, with 4 or 5 joints. Leaves almost all on the stem, grass-green, narrow, flat, more or less rough, tapering to a fine slender point. Mr. George Sinclair speaks favourably of a variety of this species, which he names P. nemoralis var. angustifolia. Although the produce is inconsiderable compared to that of many others equally nutritious, yet the early growth of this grass in the spring, and its remarkably fine, succulent, and nutritious herbage, recommend it strongly for admission into the company of the superior permanent pasture grasses. It flowers in the third week of June, and ripens the seed in the end of July.

The P. aquatica, Pl. 5, m, or water meadow-grass, of some botanists, is the reedy sweet-grass (Glyceria aquatica) of Smith. The decumbent meadow-grass (P. decumbens) is the decumbent heath-grass (Triodia decumbens) of Smith's English Flora. The reflexed meadow-grass (P. distans) of Sinclair is the reflexed sweet-grass (Glyceria distans) of modern botanists. The Glyceria fluitans is also sometimes called the Poo fluitans.

One or two exotic species are mentioned in Sinclair's work on the grasses, viz.,

The soft meadow-grass (P. cenisia). This alpine species is a native of Germany, and attains to a greater size than most of ours of the same class. The root is fibrous.Panicle diffuse, nodding. Its nutrient properties, as indicated by the quantity of nutritive matter it
POCKET.

contains, are not superior to those of several other grasses, which afford a greater abundance of herbage throughout the season.

The fertile meadow-grass (P. fertile). It produces flowers about the first and second weeks of July, and seeds in the second week of August. This grass, which is also native of Germany, seems to be allied to the Poa nemoralis. It differs in having the panicle more loose and spreading, and less attenuated. The spikelets are more oval, and crowded. The culm rises from a foot and a half to 2 feet in height, and sometimes more, ascending at the base, afterwards erect, somewhat compressed. The root is slightly creeping. In regard to early growth, this grass stands next to the meadow foxtail, cock's-foot, and tall oat. The herbage is more nutritious than that of either of those grasses; and from its agricultural merits it deserves a place in the composition of rich pastures, and ranks with the superior grasses of irrigated meadows. It flowers in the beginning of July, and the seed is ripe towards the end of the month.

The nerved meadow-grass (P. nervata). This species is a native of North America. Panicles upright, often half a foot or more in length, with slender branches, pressed close and subdivided. Spikelets small, of a green colour. Valves of the blossom smooth, having five raised nerves on each valve. Leaves in two rows, resembling a fan, somewhat rough. Culm a little compressed. This grass is remarkably hard, and possesses many very excellent properties: it will be found a valuable ingredient in permanent pastures, where the soil is not too dry, but of a medium quality as to moisture and dryness. The root leaves are produced on a shoot, and stand in two rows after the manner of a fan. This shoot, which is formed by the union of the base of the leaves, is very succulent, and contains a greater proportion of nutritive matter than the leaves, which accounts for the superior nutrient qualities of the latter. It flowers in the third week of June, and the seed is ripe in the last week of July.

POCKET. A large kind of bag in which hops are packed up.

POLE. A term used to express the siliqua and silicula of botanists. A seed-vessel of some plants, consisting of two valves, separated by a linear receptacle, along each of the edges of which the seeds are alternately ranged. The wall-flower affords an example of the silique, which differs from the silicula merely in being oblong instead of being short and round. The satín-flower, or honesty, bears a pouch or silicula.

POISON (Fr.). Any substance which in small quantity disturbs, suspends, or destroys one or more of the vital functions. Poisons are classified by Orfila under the four heads of irritants, narcotics, narcotico-acrids, and putrefiants, or septic, and, we may add, sedatives. The same poisons which affect men usually affect horses, cows, and dogs; but goats and swine eat many things that are virulent poisons to other animals. Sweet almonds and aloes are poisonous to dogs; sugar is poison to pigeons, parallegy to parrots, and pepper to hogs.

POLE. A measure of length equal to 16½ feet.

POLLIARD. A name given to a tree that has been frequently polled or lopped, and its top taken off, or headed down to the stem, for the purpose of fire-wood or small poles for hurdle-wood and other similar uses, as well as for hop-poles, &c. The term is most commonly in use in the southern and eastern districts of Great Britain. Pollard is also applied to the fine bran or inner husk of wheat. It is a substance much used in feeding hogs and different domestic animals.

POLLEN. In botany, the pulverulent substance which fills the cells of the anthers of a plant, consisting of a multitude of little hollow cases, filled with a fluid holding very minute molecular matter in suspension. The latter is eventually discharged by the grains of pollen through their hollow tubes, and is supposed to be the spermatic fluid of a plant. When the pollen alights on the stigma of the plant, the membrane lining the shell is protruded to a tube, which enters the stigma, and lengthens until it reaches the ovule, into which it pours the impregnating fluid. The pollen grains vary in form and magnitude, being globular, angular, compressed, simple, and compound. Pollen is also a provincial name given to the hen-roost. It is sometimes written hen-pollen.

POLLY. An accident which sometimes occurs to horses, from the animal's rubbing or striking his head against the lower edge of the manger, or hanging back in the stall and bruising the part with the halter. Such injuries are serious in their nature and difficult of treatment, and will usually require the skill and anatomical knowledge of the veterinary surgeon.

POLYPODY. (Polypodium, from poly, many, and pous, a foot; having numerous root-like feet. This is an extensive genus of very ornamental ferns. The hardy kinds are well adapted for ornamenting rock-work, or they may be grown in pots, in light loamy soil. All the species may be readily increased by dividing the roots, or by seeds.

There are in England four indigenous species.
POPPLE.

POPPLE (Populus; some derive the word from potipello, to vibrate or shake; others suppose it obtained its name from being used in ancient times to decorate the public places in Rome, where it was called Arbor populi, or the tree of the people). Most of the species of poplar are very ornamental, more especially in early spring, when the catkins of the males are produced. Their favourite place of growth in moist soil, near a running stream; but they do not thrive in very marshy situations. All the species are readily increased by cuttings or layers, and some by suckers. There are in England four indigenous species of poplar: the white poplar, already noticed under the head ABELE TREE; the gray or common white poplar (P. canescens); the trembling poplar (See ASPEN); and the black poplar (P. nigra).

The black Italian, or necklace-bearing poplar (P. monilifera), appears to have been first introduced into Britain from North America, in 1772. Of all the poplars hitherto introduced, it is by far the most valuable, looking to it in the light of a useful and profitable timber tree, as it grows with astonishing rapidity, and produces a timber of large scantling and excellent quality, equal, if not superior, to that of any other of its genus. The wood is of a grayish-white colour, tough when seasoned, and, if kept dry, very durable; its great size renders it fit for the largest buildings, and as flooring for manufactories and other erections, nothing can surpass it; for, in addition to the property of not splitting by percussion, it possesses the peculiar advantage of not easily taking fire, and, even when ignited, burning without flame or violence. As an ornamental tree, it well deserves a place in extensive grounds, its spiny height and pyramidal form, before it becomes aged, being well calculated to break long horizontal lines, or the monotonous effect of round-headed trees; it also in a great measure, from its semi-fastigate growth in the young state, supplies the place of the Lombardy poplar in such scenery, either of wooded landscape or in combination with buildings, as is improved by the presence of that tree.

The Lombardy poplar (P. fastigiata). In its close fastigate growth and cypress-like form, which seems to be retained during the whole of its existence, the Lombardy poplar is too conspicuous not to be immediately recognised and readily distinguished from all other species of the genus. As a useful and profitable timber tree it is greatly inferior to some of the species already described, the twisted and deeply-furrowed trunk, even of the tallest and largest trees, cutting to much waste, and affording boards of only a moderate size when sawn up. The wood is also softer and more spongy than that of the black and the black Italian poplars, and rapidly decays unless kept perfectly dry. In Britain, therefore, it is cultivated almost exclusively as an ornamental tree, for which its towering height and spire-like form eminently qualify it.

The Lombardy poplar (P. Greda) as an ornamental tree is superior, in many respects, to the aspen (to which it is closely allied). It grows rapidly, young trees often making shoots in one season of 5 or 6 feet in length, and, though a slender-stemmed tree, it has the valuable property of resisting the wind, and is never seen, even in the most exposed situations, but an erect and perpendicular trunk.

The bark of all the poplars is more or less antiperiodic and tonic, containing an alkali, which can be procured separate, and is known by the name of Salienea. It may be used for curing agues in the same manner as Quinine, an alkali got from Peruvian bark.

There are many North American species of poplar, among which is the tulip tree (Liriodendron tulipifera), the largest of the most majestic trees of the American forests, but which has been improperly classed among the poplars. See TULIP TREE.

The other and more genuine species is the Carolina poplar (P. angustata). The lower part of Virginia, says Michaux, is the most northern point at which this species is found.

In the shape of its leaves and other characteristics, it bears a very strong resemblance to the cotton tree. The two species may, however, be readily distinguished by their buds, those of the Carolina poplar being short, of a deep green, and destitute of the resinosous, aromatic substance which covers those of the cotton-wood, and of which the vestiges remain till late in the season. The wood of the Carolina poplar is white, but so very soft as to be of little value.

The Cotton-wood (P. Candensis)—I have found this tree, says Michaux, in the upper part of the State of New York, on the banks of the Genesee, in some parts of Virginia, and on several islands in the Ohio, always on a fat, alluvial soil.

The leaves of this tree are trowel-shaped, approaching to heart-shaped. The seeds are surrounded with a beautiful plume which has the whiteness of cotton, and the young buds are covered with a resinous, aromatic substance of an agreeable odour. In the Atlantic States this poplar is rare, and has received no specific name.

American poplar (P. Hudsonica).—This species, Michaux says, he found only on the banks of the Hudson, above Albany, where it attained a height of 30 or 40 feet, with 12 to 15 inches in diameter. Several large poplars of this kind grow in and near the city of New York, where it is usually called American black poplar.

Virginia poplar (P. monilifera).—This species
POPPY.

was not found by the Michaux, but has been long cultivated in Europe as a North American tree. It is also called the Swiss poplar, and is confounded with the cotton-wood.

Cotton tree (P. argentic). This species is scattered over a great extent of country comprising the Middle, Western, and Southern States; but it is so rare as to escape the notice of the greater part of their inhabitants. It is called cotton-wood on the Savannah in Georgia, where it is confounded with the Carolina poplar.

Tacamahaca or Balsam poplar (P. balsamico). This species belongs to the northern regions of America, being very abundant in Canada, in the districts watered by the river Sagney, between the 47th and 49th degrees of latitude, where, notwithstanding the severity of the winter, it rises to the height of 80 feet, with a diameter of 3 feet. In the spring, when the buds begin to be developed, they are abundantly coated with a yellowish, glutinous substance, of a very agreeable smell.

Heart-leaved poplar (P. cndicans). In the Northern and Eastern States, this tree, which Michaux says is a genuine balsam, is commonly seen growing before the houses in town and country. In spring, a fragrant resinous balsam exudes from its buds; but it differs from the Tacamahaca, its leaves being three times larger and more heart-shaped.

American balsam (P. tremuloides). See Aspen, American.

American large aspen (P. grandidenta). This species belongs rather to the Northern and Middle than to the Southern States. It is larger than the preceding species, with which it is usually confounded.

POPPY (Papaver, from papa, pap, or thick milk; the juice of the poppy was formerly used in children's food to make them sleep). These plants succeed best in a light, rich soil. The perennial kinds are increased by dividing at the roots. All the species are narcotic. In England there are six indigenous species of poppy, which are nearly all annuals. They are arranged under two sections:—1. Those with bristly capsules; 2. Those with smooth capsules.

The 1st section contains the round, rough-headed poppy (P. hybridum), which grows in sandy or chalky fields. This is not a hybrid, as its name implies, but a true permanent species.

Long, rough-headed poppy (P. argemon). This grows in grain fields and thin borders, also on gravelly or sandy soils. It is annual, and flowers in June and July. The herbage resembles the preceding, but the bristles are less closely pressed to the stem, and the segments of the leaves are somewhat broader. Petals pale-scarlet, black at the base, soon falling, often jagged.

The 2nd section contains the long, smooth-headed poppy (P. dubium). This species is found in cultivated fields, especially on a light soil. Annual, and flowering in June and July. It is of a stouter, more luxuriant habit than the foregoing, with broader leaves. The stem is clothed with spreading hairs; the flower-stalks with close-pressed bristles. Petals broader than they are long, of a light-scarlet, the margin mostly crenate.

Common red poppy, or corn rose (P. rhoeas) See Corn Poppy. This is the only official species of the British poppies; but it is used in medicine merely as a colouring agent.

White poppy (P. somniferum). This species appears to grow wild on sandy ground in the neighbourhood of some of the fen lands. But it is probable, in places where it is found apparently wild, the seed from the cultivated poppy has been deposited by birds. The somniferous poppy is a native of Asia and Egypt. It is cultivated in Hindostan, Persia, and Egypt, on account of its opium; in Germany for the oil expressed from its seeds; and in England for the capsules, which are used in medicine. It is universally known in our gardens as an ornamental flower, and is much cultivated in the vicinity of London. The whole herb is glaucous, and generally smooth, though the flower-stalks now and then bear several rigid, spreading, bristly hairs. The stem is 3 or 4 feet high, the roots strong, bony, leafy. Leaves broad, wavy, lobed, and bluntly notched, clasping the stem with their heart-shaped base. Flowers 3 inches broad, white or bluish-white, with a broad violet spot at the base of each petal. In gardens, double varieties of every shade of purple, scarlet, crimson, and even green mixed with white, are common, though nothing can be more liable to change. The capsule is nearly globular. Seed small, whitish-brown, oily, sweet, and eatable. There are two varieties, namely, P. album and P. nigron, chiefly distinguished by the form and under the stigma being absent in the former, and present in the latter. The milky juice of the capsules, when abstracted by transverse incisions and inspissated, forms opium, which, as Haller well observes, is far more potent and dangerous in hot countries than in our cooler climates. The capsules boiled afford a mild, narcotic decoction, more generally used for fomentations in inward pains, and for making a syrup, which is used by lazy nurses, who administer it to restless infants, and sacrifice them to their own love of ease. Nothing is more to be condemned than the indiscriminate use of syrup of poppies. No opium, except as experiment, is made from poppies in England; and, could it be made, both it and the foreign opium should never be employed except by the advice of those who alone ought to direct its use.

Yellow poppy (P. cembricum). This is a perennial species (and the only indigenous one) which flourishes in moist, rocky situations in Wales and Westmoreland. It flowers in June. The herbage is tender, brittle, of a light, slightly glaucous green; its juice lemon-coloured. Stem a foot high, many-flowered, thinly covered with upright hairs, leafy, branched. Flowers of a most elegant, full lemon colour, delicately fragrant.

Field poppy (Papaver dubium), bastard poppy. This foreign annual, says Dr. Darlington, has made its appearance in some of the cultivated grounds of Pennsylvania and other parts of the United States, and, if neglected, may become a troublesome weed.

POPPY, THE HORNE D. See Horned Poppy.

923
POPULATION. As very erroneous notions with regard to over-population are often entertained, and as many of the most philanthropic men in England have, at considerable personal trouble and cost, promoted emigration, to avert the evils of war, pestilence, and famine, from what Mr. Malthus supposes to be the tendency of mankind to excessive population, it may be well for the public to peruse a paper (Quart. Journ. Agr. vol. iii. p. 89), which, in detail, ably examines and refutes many of Mr. Malthus's data, calculations, and conclusions. Mr. Malthus states, from data derived through a variety of sources, that the average births from each marriage are—

<table>

</tr>
</tbody>
</table>

But, from returns made to government, it appears that the average births in England and Wales, during the 30 years ending 1820, fell considerably under 4 from each marriage; and of these, from personal deformity, and a hundred other causes, a considerable portion of women must remain unmarried.

But supposing every woman, married or single, who lived to 18 years of age, should have 7 children, and the rate of mortality as favourable as at Carlisle, the population would require more than 26 years to double itself; and 25 years is the lowest rate of increase Mr. Malthus has contemplated. But, supposing one-tenth part of all the women who attain 20 to remain in a state of celibacy, and the rest were to bear each 3-66 children, which is stated by Mr. Sadler to be the average prolificness in England, and the mortality continued as at Carlisle, the population would remain entirely stationary. In the rich and fertile country of France, the population is nearly stationary, and in Ireland, population increases faster than in England; which can only be accounted for by the institutions which encourage increased forethought before entering on the married state. Amongst barbarous nations, the period of marriage is almost always early; but as countries become civilized, a portion of early life is devoted to labour of mind and body; and the desire of distinction in some, and, amongst all, the pursuit of gain, delays marriage; and, happily for mankind, nothing is less consistent with universal experience than the terrible succession of evils Mr. Malthus fears from over-population. Natural evils, and the more dreadful effects of misrule, have, indeed, spread death and desolation; but the consequences have not been increased plenty to the survivors: on the contrary, the page of history shows that, in the fairest portions of the habitable world, poverty and want have followed decreasing numbers.

Whereas the wiser the laws, and, consequently, the more severe and properly, the slower men are to marry till they have secured for themselves and families, in a habitation of their own, the conveniences they were used to under their paternal roofs; and, consequently, the less tendency to the excessive multiplication of mankind; and we refer to Scotland, France, &c., as existing proofs.

Not society, well governed, we repeat, has been known to outgrow, or tend to outgrow, its means of subsistence. When, in our own country, one of the most populous in the world, we see how far the earth is yet from producing all that labour, well-directed, can bring forth, when we look at the tracts lying waste or half-cultivated, we must see how little it is to be feared as a possible evil, that our population will ever increase beyond the means of supplying itself with food. We have only to look to what minute care can effect in multiplying the produce of the earth, to feel in what a prodigious ratio it may be multiplied. A piece of heath land, the most worthless, converted into a cottager's garden, yields a return of food exceeding that of the richest land of the cultivated fields. And nothing prevents the increase of this species of culture but the want of hands to cultivate and of mouths to consume. Every vegetable that grows, and is consumed, affords new materials for fertilizing the earth, and increasing its productions; and thus every increase of the number of consumers is a means of calling new food into existence.

The introduction of a single plant from ancient Asia or Europe has more than doubled the power of this and of every country in Europe to support their inhabitants. An acre of potatoes will supply food sufficient for the support, in healthful existence, of a family of 6 human beings for one year; a square mile of land producing potatoes, therefore, will support 3840 persons for the same time. But the produce of the potato is as nothing to that of the banana and other plants of the tropical regions. Nor does the produce of the potato in our fields show the full power of the earth to produce food. By the minute care of the gardener, successive crops of vegetables may be produced from the same surface, and in the same season. Our present knowledge of agriculture shows us, that throughout the whole kingdom the productions of the earth may be prodigiously multiplied; but what our present knowledge of this art is in comparison with what it may become, we know not. What other plants are yet to be applied to the support of animal life, what other means of fertilizing the earth are yet to be discovered, what other application of mechanical power may yet take place in aid of human labour, we know not; nor need we, with relation to our present subject, be too curious in inquiring. It suffices that, with our present means and knowledge, limited as they are, we can multiply our means of subsistence in a degree to furnish food for increasing numbers for more generations of men than the cares of the living race need extend to.

And if such be the case with a long-peopled country, what must we think of the fear that the entire world will be over-peopled! The richest regions of the globe have yet been scarcely trodden by the foot of the hunter; a great part of Europe is still a desert; and a long desolation has overspread lands that once were the seats of nations, and which only demand security that they may be blessed with abundance again. Such as Asia Minor, Syria,
and Greece, and such the long-desolated shores of Northern Africa. It is not Nature that is barren of her gifts, but it is man that has abused them all; and, in the climates and the lands where we might look for the verdure of an eternal spring, we find only the moving mountains and interminable tracts of the desert.

It is unnecessary, perhaps, to enlarge upon this statement, but one or two facts will surely convince the most incredulous that we are not yet nearly arrived at the maximum available produce of the earth. Even as regards the saving in the seed-corn, we have witnessed in our time that the drill has done much, and the dibbling system still more; but, by transplanting, greater things may yet be done. I will illustrate this position by only one or two facts out of many of a similar kind that I am acquainted with. At the Battle Horticultural show (in 1837), R. White received a prize for 61 fine ears of wheat growing from one grain, which are deposited at the apartments of the London Horticultural Society, and another prize at the Society for Encouragement of Arts, &c., in the Adelphi, and similar premiums are again offered there and elsewhere. P. Brown raised that year 345 roots, with 4250 ears, from one grain, since June, 1836, the plants having been divided three times; and it is recorded in the Philosophical Transactions for 1768, that in the same space of time, one grain of wheat produced 21,109 ears, containing 576,810 grains, or nearly a bushel of clean grain; thus, an acorn cup would hold seed-wheat enough to raise plants for an acre of land, and full 10,000,000 bushels of seed-wheat might be saved on the 4,000,000 acres under wheat in England and Scotland; which quantity, allowing 8 bushels to each person, would support 1,250,000 persons, who, if employed in weeding the crops, would double the produce, as is shown by the increased crops raised by the tenants under the allotment system.

And again, as regards manuring the soil, agriculture is yet only in its infancy; crushed bones, now so extensively employed, were unknown as fertilizers 25 years since; gypsum, which abounds in England, is only slowly coming into use; and millions of tons of the richest manure are now annually wasted in our cities and towns—suffered to putrefy in cesspools, or poured into the sea through a thousand sewers; "and yet," says the Thames Improvement Company, "strange as it may appear, England is almost the only nation in Europe, notwithstanding its advance in agricultural knowledge, which suffers the peculiar manure in question to be wasted and cast away; while all the other nations on the Continent, and even China, husband it, and treasure it up for their lands, make it an object of extensive and lucrative traffic, and some export it to their colonies. The principal London sewers have been carefully gauged, and are found to convey daily into the river Thames 115,608 tons of mixed drainage."

By these and other certain improvements, we may safely conclude that, as regards the cultivation of the most barren tracts, the drifting sands of Norfolk, the heath lands of the north of England, and even the shingle of its sea-coast, hardly a tithe has yet been effected in the way of cultivation. At the suggestion of the Archbishop of Dublin, an acre of shingle at East Bourn was covered with 3 or 4 inches of clay, at a cost of only 16d. This has formed a plate to retain what mould, &c., the tenant has added, who has hired this ground for fourteen years at 40s. per acre. So no land is hopelessly barren. Let such improvements proceed; let science go hand in hand with the farmer; let the naturalist find new cultivatable vegetables, or new varieties of those already known; let the chemist yield his magic aid to demonstrate the best mode of promoting their growth and increasing the fertility of the soil; and then, I fearlessly assert that many times the present inhabitants of Britain may be amply supported by the produce of the land of our birth.

POpULATION, AGRICULTURAL, OF THE UNITED STATES. By the census of 1840, it appears that the number of all the states, of the Union, and Territories, exclusive of the naval service, was 5,907,755. The whole population of the Union was 17,069,453, of which the number engaged in agricultural pursuits is more than a fifth part of the whole population. When this is compared with the proportions engaged in some other pursuits, we find the next most numerous class comprised of those engaged in the various manufactures and trades, which, in the non-slave-holding states and territories, amounts to 1 in 17, and in the slave states to 1 in 40. The largest proportion of inhabitants. The largest proportion of manufacturers is in Rhode Island, where it constitutes about four-fifths of all the males above 20 years of age; next in Massachusetts; next in Connecticut; next in New Jersey; next in New York. The proportion employed in commerce comprises, in the free states, 1 in 122, and in the slave states 1 in 197—the average in all the states being 1 in 146 of the whole population. The largest proportion is in Louisiana, which contains the great depot for the commerce of the Mississippi Valley. The next largest is in Wisconsin Territory, and the next in Rhode Island. The proportion employed in ocean navigation is greatest in Massachusetts, where it amounts to 27,153, being 1 in 31 of the whole population of the state, and nearly one-half of all those engaged in the same pursuits in the whole Union, viz., 50,021, or 1 in 305. The next greatest is in Maine, where it amounts to 10,091, being 1 in 4972 of the state population. New York has 5511, Connecticut 2700, and Pennsylvania 1815, employed in ocean navigation. The proportion engaged in the learned professions, including engineers, amounts to 45,162, or 1 in 217 of the whole population of the free states, and 29,093, or 1 in 361, of the whole inhabitants of the slave states.

PORES. In botany, apertures, more or less visible, in the cuticle of plants, through which transpiration takes place. They may exist on the cellular tissue; and when there they are the organs of insensible perspiration of the
POTATO. The name of one of the alkalies, composed of 35-15 parts of peculiar metal called potassium, 8 parts of oxygen, and 9 of water. It derives its common name from being first obtained from the ashes of vegetable substances which had been burned in iron pots, hence named pot-ashes. Potash is found in almost all land plants, in combination with the tartaric, citric, or other vegetable acid. The potash in these is no doubt an essential food or constituent of vegetation, and there is no fertile soil which does not, in some form or other, contain this alkali. It exists, however, in plants in varying proportions. See ALKALI. The potash of commerce is an impure compound mingled with salts of lime and other substances. In its separate or pure state, free from carbonic acid, it is a white salt, powerfully attracting moisture from the air, very soluble in water and in alcohol, corroding animal substances, consequently destroying the skin when applied to it. But potash usually means the carbonate. The quantity procured from different plants varies. Fumitory yields 70-90 in 1000 parts, wormwood 72-0, young wheat-stalks 47-0, thistles 35-0, vetch 27-0, common nettle 25-3, the sunflower 20-0, bean-stalks 30-0, barley straw 5-8, vine-shoots 5-0, wheat-straw 3-9, and flax 5-0. The younger a plant is, if full-grown, the more potash it yields.

"The perfect development of a plant," says Liebig (Organic Chem. p. 104), "according to this view, is dependent on the presence of alkalies, or alkaline earths, for when these substances are totally wanting, its growth will be arrested, and when they are only deficient it must be impeded. In order to apply these remarks, let us compare two kinds of trees, the wood of which contain unequal quantities of alkaline bases, and we shall find that one of these grows luxuriantly in several soils, upon which others are scarcely able to vegetate. For example, 10,000 parts of oak wood yield 250 parts of ashes, the same quantity of firewood 83, of limed wood 500, of rye 440, and of the herb of the potato plant 1500 parts. Firs and pines find a sufficient quantity of alkalies in granitic and barren, sandy soils, in which oaks will not grow, and wheat thrives in soils favourable for the limed tree, because the bases which are necessary to bring it to complete maturity exist there in sufficient quantity. The accuracy of these conclusions, so highly important to agriculture, and to the cultivation of forests, can be proved by the most evident facts. All kinds of grasses, the equisetaceae, for example, contain, in the outer parts of their leaves and stalks, a large quantity of silicic acid (silica), and potash in the form of acid silicate of potash. The proportion of this salt does not vary perceptibly in the soil of corn-fields, because it is again conveyed to them as manure, in the form of putrefying straw. But this is not the case in a meadow; and hence we never find a luxuriant crop of grass on sandy and calcareous soils, which contain little potash, evidently because one of the constituents essential to the growth of plants is wanting. Soils formed from basalt, grauwacke, and phorphy, are, cæteris paribus, the best for meadow land, on account of the quantity of potash which enters into their composition."

In the experiments of the Rev. E. Cartwright with various manures applied to potatoes, wood-ashes, which contain potash, were found to produce very superior effects to several others: thus, where the soil, without any dressing, produced 157 bushels per acre, the land dressed with 60 bushels of wood-ashes yielded 187; with 60 bushels of malt-dust, 184 bushels; with 363 bushels of decayed leaves, 175 bushels; with 363 bushels of saw-dust, 158 bushels; with 121 bushels of lime, 150 bushels per acre. (Com. Board of Agr. vol. iv. p. 370.) See GREEN SAND, ALKALI, and SALTS.

POTATO (Solanum tuberosum). A valuable, well-known root, first imported from America into England by Sir Walter Raleigh, and first grown at Youghall, in Ireland. In many parts of England this tuberous plant is very extensively cultivated, both in the field and in the garden; but, in districts removed from large towns, or convenient markets, its cultivation is of necessity restricted to the garden, or for the consumption of the live-stock of the farm. As regards the field management of the crop, a writer in a popular journal remarks, when speaking of the preparation of the ground—

"It is, I know, customary, upon a large scale, to plough the land and make it tolerably fine before potatoes are planted; but if it is ploughed 5, 6, or 7 inches deep, and made fine and mellow, still at the bottom of such ploughing the land is hard and smooth; and as the potato is a root that sends out fibres not only near the surface, but deeply, if possible, it can never produce such a crop as where the land is broken 18 inches to 2 feet. The potato, like the cucumber, only enjoys itself in deeply pulverized soils, which causes them to flourish so much in well-managed sandy land.

"I should therefore recommend that, in all land where potatoes are to be grown, if the land be springy, or otherwise damp, that it be drained deep enough to take off all springs or surface water. When this is done, the land should either be fully treched, or bastard-trenched, by the spade or plough, but I prefer the spade. The width of the drills from each other must depend entirely upon the goodness of your soil: the richer the land, the wider apart must be your rows and sets in your rows; say, in ordinary land rows, at 2 feet from each other, and 12 inches from set to set may do; but if your land be very rich, 3 feet from row to row, and 18 inches from plant to plant, will not be too much."

In preserving your sets, always select the largest and finest potatoes you can procure; do not use the small refuse or middling-sized,
the plant and produce from the latter being much inferior.

The potatoes most valued in field culture are the ox-noble, yam, champion, purple-red, rough-red, hundred-eyes, kidney, and Moulton white. The nutritive qualities of these were examined by Mr. George Sinclair, with his usual accuracy. “The yam,” he observes, “is a very productive variety, attains to a large size, but is often hollow, and less nutritive than most others; 64 drachms afford of nutritive matter 190 grains, which consist of starch 164 grains, and saccharine and albuminous matters 31.”

The ox-noble is a productive potato, adapted for stock; and 64 drachms of it contain 194 grains of nutritive matter, consisting of starch 164, and saccharine, mucilaginous, and albuminous matters 31.

The purple-red is smaller than the ox-noble, but well-flavoured, and very prolific in light, moist soils: 64 drachms afford 200 grains of nutritive matter, consisting of starch 169, and albuminous and saccharine matters 31 grains.

The hundred-eye is very prolific on dry loams; 64 drachms afford 218 grains of nutritive matter, composed of 170 grains of starch, and the rest albuminous and other matters.

The rough-red produces plentiful crops on soils or climates of a moister nature than that adapted for the hundred-eyed variety; it is well-flavoured, and 64 drachms afford 250 grains of nutritive matter, which is composed of 199 starch, and 46 mucilage, sugar, and albumen.

The champion grows to a moderate size; is very productive, and little subject to the disease called curl.

It is, hence, of great importance, in choosing seed potatoes, to consider the nature of the soil and climate; thus some of our finest varieties, which yield abundantly when planted in suitable soils and moist situations, will yield but inferior returns when planted in drier situations.

The soluble matters consisted of gum, mucilage, extractive, and saline matters.

The potato, although a tender plant, is grown in nearly all parts of the world, from the equator to Norway; and although it is usual to plant only in the spring, yet it is possible, by choosing a quick-ripening variety, to plant it successfully even as late as July.

The best manures for the potato crop are common farm-yard compost, only partially decomposed, decayed leaves, sea-weed, the potato haulm, and any organic manures, that, while they afford nutrition, have a tendency, by rendering the soil lighter, to facilitate the extension of the roots. Lime is injurious to it. Pond mud or ditch scrappings, to each cubic yard of which, a month previously, a bushel of bacon salt, or other refuse common salt, has been mixed, is excellent. The soils best adapted for the cultivation of the potato are of the light, sandy, drained, peaty, or loamy description. It delights in fresh soils; those of a newly broken-up meadow, old woodlands, or the site of old yards or buildings, are excellent. It does not do well on wet clays.

Potatoes are readily consumed by live-stock in their unboiled state; but, generally speaking, they are best when steamed and mixed with chaff.

The cultivation of the potato is thus described by Mr. George Johnson; and although his remarks were intended for the gardener, yet they apply in a great measure to the field culture of this valuable root.

The varieties of the potato are numerous, and continually increasing, as well as becoming extinct; the number, however, is very largely increased by local names for the same variety being classed distinct.

For forcing, or first crop in the open ground:—there are Broughton Dwarf, Early Warwick, Ash-leaved Kidney; Fox’s Seedling, Early Manly, Early Mule, earliest for general cultivation, Early Kidney, Nonsuch, Early Shaw, Goldfinger.

For main crops, the varieties are ranged in this class, according to their forwardness in ripening:—Early Champion, Ox Noble, Red-nose Kidney, Large Kidney, Bread-fruit, Red-streak or Lancashire Pink-eye, Black Skin, Purple, Red-eye, Rough Red.

No inhabitant of the garden varies more in quality in different gardens than the potato; for a variety will have a strong, unpleasant flavour in one soil, that has a sweet, agreeable one in another. In a heavy, wet soil, or a rank black loam, though the crop is often fine and abundant, it is scarcely ever palatable. Silicious soils, even approaching to gravel, though in these last the tubers are usually corroded or seedy, are always to be planted in preference to the above. A dry, moutidy, fresh, and moderately rich soil is unquestionably the best for every variety of the potato; and, for the earliest crop, it may be with advantage more silicious than for the main ones. The black-skinned and rough red thrive better than any in moist or strong, cold soils. If manure is necessary, whatever may be the one employed, it is better spread regularly over the surface previous to digging, rather than put into the holes with the sets, or spread in the trench when they are so planted. Stable dung is, perhaps, the best of all factitious manures: sea-weed is a very beneficial addition to the soil, as is salt. Coal-ashes and sea-sand are applied most advantageously in the same crops; but calcareous matter should never be used.

The situation must always be open.

It is propagated in general from cuttings of the tubers, though the shoots arising from thence and layers of the stalks may be employed. New varieties are raised from seed. Planting in the open ground of the early kinds may commence towards the close of February, in a warm situation, and may thence be continued until the same period of March; and it is only during this latter month that any considerable plantation should be made, as the late frost are apt to injure, or even to destroy, the advancing plants. In the course of April, 1997.
the main crops for winter's use should be inserted; for although in favourable seasons they will succeed if planted in May or even June, yet it ought always to be kept in mind that the earliest planted, especially in dry soils, produce the finest and most abundant crops.

Of the preparation of the sets, there is a great diversity of opinion. Some gardeners recommend the largest potatoes to be planted whole; others, these to be sliced into pieces, containing two or three eyes; a third set, to cut the large tubers directly in half; a fourth, the employment of the shoots only which are thrown out, if potatoes are kept in a warm, dark, upper room, and another, that merely the parings be employed. Cuttings of the stalks, 5 or 6 inches in length, or rooted suckers, will be productive, if planted during showery weather in May or June; and during this last month, or early in July, it may be propagated by layers, which are formed by pegging down the young stalks when about 12 inches long, they being covered 3 inches thick with mould at a joint. These three last modes are practised more from curiosity than utility, whilst at the same time none of the first five mentioned plans can be individually followed to advantage. In my opinion, for the main crops, it is evident, from experiment, that moderate-sized sets, having two healthy buds or eyes, are most advantageously employed; middling-sized whole potatoes are the best, from which all but the above number of eyes have been removed, but especially having the crown, which is a congersy of small eyes always present, first removed; for from these proceed an equal number of little spindled stalks, which are comparatively worthless, and injure the main stem.

For the early crops, almost the very contrary to the above is the most advantageous to be practised. The set should have the crown eye, which is one growing in the centre of the congersy of small ones above mentioned, preserved. Some potatoes have two such eyes, but the generality only one. This is always the most prompt to vegetate; and if not known by this description, may be evinced by placing two or three potatoes in a pan of moist earth, near the fire; if the earth is kept moist, the crown eye will be in a state of vegetation in five or six days. Again, as Mr. J. Knight remarks, although abundant crops of late varities may be obtained from very small sets, by reason that tubers are not produced until the stem and roots become capable of supplying them with nourishment; yet, to obtain early crops, where tubers are rapidly formed under a diametrically opposite state of the plant, large sets must be employed; in these, one or two eyes, at most, should be allowed to remain. Mr. Knight plants the largest undivided tubers, which, from experiments, evidently support the plants, and finally produce the earliest and largest produce he ever obtained. Another remark, which he makes, restrictively for the early crops, but may well be attended to for all, is, that if the sets are placed with their leading buds upwards, few and very strong early stems will be produced; but if the position is reversed, many weak and later shoots will arise, and not only the earliness, but the quality of the produce be depreciated. For the earliest crops, there are likewise several modes of assisting the forward vegetation of the sets. These should be prepared in November, by removing every eye but one or two; and being placed in a layer, in a warm room, where air and light can be freely admitted, with a covering of straw, they soon emit shoots, which must be strengthened by exposure to the air and light as much as possible, by taking off the covering without injuring them. During cold weather, and at night, it must always be renewed. The leaves soon become green, and if tolerably healthy, when two or three inches planted out, the leaves being left just above the surface, and a covering of litter afforded every night, until the danger of frost is passed. The only modification of this plan that is adopted in Cheshire, where they are celebrated for the early production of potatoes, is, that they employ chaff or sand for a covering instead of straw. The most preferable mode of inserting them, is with the dibble, in rows, for the early crops, 12 inches apart each way; and for the main ones 18. The set should never be placed more than 4 inches beneath the surface in the lightest soil, but in the more tenacious ones, 3 is the extreme. The potato dibble is the best instrument that can be employed; one person striking the holes, and a second dropping the sets, the earth being afterwards raked or struck in with the spade. There are several other modes of insertion, as opening a small hole with a narrow spade, and the set being dropped in, it is covered by the earth taken out in forming the next hole: or, at the time of digging over the ground, a second person follows the one so employed, and places the sets in the trench he opens in the pursuance of his work; but both these modes are open to numerous obvious objections.

The compartment may be laid out level and undivided, if the soil is mouldy and favourable; but if a heavy one is necessarily employed, it is best disposed in beds, 6 or 8 feet wide. If the staple of the soil is good throughout, the alleys may be 3 feet wide, and dug deep, otherwise they must be made broader, and only one spit taken out, the earth removed being employed to raise the beds. If the land is low and wet, it is still further of advantage, after the beds, which should not be more than 4 feet wide, have been thus raised, if they are dug in parallel ridges, and the sets inserted along their summits. Some gardeners, on such soils, without digging the surface, lay some long litter on the intended beds; upon this the sets being placed, some more litter is thrown regularly over them; the earth is then dug from the alleys, and turned to the requisite depth over the whole. As soon as the plants are well to be distinguished, they should be perfectly freed from weeds; and, of the early crops, the earth drawn round each plant, so as to form a little heap, as a shelter from the cold winds, which are their chief enemy at that season; but the main crops need not be earthed up until the plants are 6 inches in height. It is contended by some that this practice is immaterial in its effect. If the earth is brought so as to be of 928
POTATO.

considerable depth about the stems, it must be even injurious; but if properly performed, it is certainly beneficial. Throughout their growth they should be kept perfectly clear of weeds. It is very injurious to mow off their tops, as is sometimes recommended. The foliage ought to be kept as uninjured as possible, unless, as sometimes occurs on fresh ground, the plants are of gigantic luxuriance, and, even then, the stems should be only moderately shortened. It is, however, of considerable advantage to remove the fruit-stalks and immature flowers as soon as they appear. This has been demonstrated by the experiments of President Knight and others; indeed, that such would be the case is a reasonable expectation, since it is known that the early formation of tubers prevents the production of blossom. It is also worthy of notice, that a potato plant continues to form tubers until the flowers appear, after which it is employed in ripening those already formed.

The very earliest crops will be in production in June, or perhaps towards the end of May, and may thence be taken up as wanted, until October, at the close of which month, or during November, they may be entirely dug up and stored; in all but the severest frost any severe frost. Their fitness to be taken up for keeping is intimated by the decay of their foliage, which generally loses its verdure with the first frosts. The best instrument with which they can be dug up is a three-flat-pronged fork, each row being cleared regularly away. The tubers should be sorted at the time of taking them up; for as the largest keep the best, they alone should be stored, whilst the smaller ones are first made use of. The most common mode of preserving them throughout the winter is in heaps or clamps, sometimes called pyeung then. These are laid in pyramidal form, on a bed of straw, and enveloped with a covering of 6 or 8 inches thick, of the same material, last even, as in thatching, and the whole enclosed with earth, in a conical form, a foot thick, taken from a trench dug round the heap, well smoothened with the back of the spade. Potatoes should not be stored until perfectly dry, nor unless free from mould. refuse, and wounded tubers. It is a good practice to keep a hole open on four different sides of the heap, entirely through the mould and straw, for a week or two after the heap is formed; for in proportion to its size it always ferments, and these orifices allow it escape of the vapours, and perfect the drying. An equally good mode, and much more convenient, is to have them heaped in a dry shed, and covered thick with straw, as opportunity is given to look over them occasionally for the removal of decayed tubers, shoots, &c. If carefully preserved, they continue in perfection until late in the following summer. A variety of the potato is generally considered to continue about 14 years in perfection. after which period it gradually loses its good qualities, becoming of inferior flavour and unproductive. Fresh varieties must therefore be occasionally raised from seed. For doing this there are two modes; the first of these, about to be detailed, is, however, the one usually pursued.

POTATO.

The berries or apples of the old stock having hung in a warm room throughout the winter, the seed must be obtained from them by washing away the pulp during February. This is thoroughly dried, and kept until April, and then sown in drills about half an inch deep, and 6 inches apart, in a rich mouldy soil. The plants are weeded, and earth drawn up to their stems when an inch in height; as soon as this has increased to three inches, they are moved into a similar soil, in rows 16 inches apart each way, and during their future growth earthed up 2 or 3 times. Being finally taken up in the course of October, they must be covered until the following spring, to be then replanted, and treated as for store crops. (Dr. Hunter's Georg. Essays.)

Some gardeners sow in a moderate hot-bed, very thin, in drills, the same depth as above, and 9 inches apart. Water is frequently and plentifully poured between the rows, and earth drawn about the stems of the seedlings, until they are a few inches in height. They are then transplanted into rows, water given, and earthing performed as usual. The only additional advantage of this plan is, that as the seed can be sown earlier, the tubers attain a rather larger size at first year.

It is to be remarked, that the tubers of every seedling should be kept separate, as scarce 2 will be of a similar habit and quality, whilst many will be comparatively worthless, and but few of particular excellence. If the seed is obtained from a red potato, that flowered in the neighbourhood of a white-tubered variety, the seedlings in all probability will in part resemble both their parents, as a cross fertilisation may take place; but seldom or never does a seedling resemble exactly the original stock. At all events, only such should be preserved as are recommended by their superior size, flavour, or fertility. It may be stated as an indication before these qualities can be positively ascertained, that President Knight remarks, that the rough, uneven surface of the foliage, which in excess constitutes the curl, appears to exist as, and form a characteristic of every good variety; for he never found one with perfectly smooth and polished leaves which possessed any degree of excellence, though such are in general more luxuriant and productive.

The early varieties, on account of their never flowering, were, until 1807, obtained by choice from plants that might now and then be produced from seed of the late kinds. In that year, Mr. Knight discovered that the cause of their deficiency of bloom was the preternatural early formation of the tubers. His mode of causing them to produce seed is to plant the sets on little heaps of earth, with a stake in the middle, and when the plants are about 4 inches high, being secured to the stakes with shreds and nails, to wash the earth away from the bases of the stems, by means of a strong current of water, so that the fibrous roots only enter the soil, and these being perfectly distinct from the runners that furnish the tubers, and which spring from the base of the stem, none of these are produced, and the effect is, that blossoms appear and perfect seed.

There are numerous valuable communications.
tions with regard to the potato dispersed through the agricultural journals, among which is one "On the Manures best adapted for Potatoes," by the Rev. E. Cartwright. He remarks, "The soil on which my experiments were tried is a ferruginous sand, brought to a due texture and consistence by a liberal covering of pond-mud. Of this soil, in its improved state, I mean by the accession of pond mud (for, having been used merely as a nursery for raising forest trees, previous to these experiments, the nurseryman had not thought it necessary to make use of any other manure), the following is the analysis 400 grains gave:

"The weight of the crop of potatoes was not taken. The superior size of the roots produced by No. 4, left no room to doubt of the advantage of 13 bushels of salt per acre, applied to the soil previous to planting, over the other modes of application; still the superiority was not very great." "I may notice here," observes Dr. Holland, "a practice pursued at Weston, near Frodsham, in the culture of potatoes, which seems deserving of attention. At this place, situated close to the junction of the Mersey and Weaver, sea mud is used as a manure for crops of potatoes; 20 loads being the usual quantity laid on an acre. The ground thus manured not only gives a larger produce of potatoes, but is in a state of excellent preparation for a succeeding crop of either wheat or barley. The adoption of this practice has increased very greatly the value of land about Weston."

There is also a paper by Mr. Knight "On the advantages of employing large tubers for Seed." "The good effects," he observes, "which I have proved to arise from planting large tubers of the potato plant, obviously spring from the large accumulation of fecula in them. By means of this, not only a large breadth of foliage is produced, and exposed to sight more early in the year, but that foliage contains much disposable organic matter, which once formed a part of the parent tuber." Knight thought that the ordinary produce of potatoes might be very materially increased. He remarks, "My opinion is, that more than a thousand bushels of potatoes may and will be obtained from an acre of ground."

Potatoes are fermentable, and are consequently employed along with barley by the Scotch distillers; and, also, by the London bakers in the manufacture of bread. The fecula is also separated and sold as arrow-root: it is a good and sufficiently pure starch; but it is less nutritive than the potato itself, owing to the separation of the saccharine matter and the albumen.

**POTATO-FLY or BEETLE.** The green cantharides, or Spanish-flies, as they are commonly called, are found in the south of Europe, and particularly in Spain and Italy, where they are collected in great quantities for exportation. In these countries they often appear in immense swarms on the privet, lilac, and ash, which are quickly stripped of their foliage by these leaf-eating beetles. In like manner the American species of cantharides devour the leaves of plants, and sometimes prove very destructive to them, especially to those of the potato. Four native species of the cantharides found in the United States, have been tried and ascertained to be as effectual in raising blisters as the imported species. The kind found on the potato is the striped cantharis (Cantharis vitellata). It is of a dull, tawny yellow or light yellowish-red colour above, with two black spots on the head, and two black stripes on the thorax and on each of the wing-covers. The under-side of the body, the legs, and the antennae are black, and covered with a grayish down. Its length is from five to six-sixteenths of an inch. In this and the three following species the thorax is very much narrowed before,
POULTRY

and the wing-covers are long and narrow, and cover the whole of the back. The striped cantharids is comparatively rare in New England; but in the Middle States it often appears in great numbers, and does much mischief in potato-fields and gardens, eating up not only the leaves of the potato, but those of many other vegetables.

The most destructive kind of Cantharis, found in Massachusetts, is of a more slender form than the preceding, and measures only from five and a half to six-sixths of an inch in length. Its antennae and feet are black, and all the rest of its body is ashen gray, being thickly covered with a very short down of that colour. Hence it is called Cantharis cinerea, or the ash-coloured cantharis. When the insect is rubbed, the ash-coloured substance comes off, leaving the surface black. It begins to appear in gardens about the 20th of June, and is very fond of the leaves of the English bean, which it sometimes entirely destroys. It is also occasionally found in considerable numbers on potato-vines; and in Cambridge, Massachusetts, it has repeatedly appeared in great profusion upon hedges of the honey-locust, which have been entirely stripped of foliage by these voracious insects. They are also found on the wild indigo-weed. In the night, and in rainy weather, they descend from the plants, and burrow in the ground, or under leaves and tufts of grass. Thither also they retire for shelter during the heat of the day, being most actively engaged in eating in the morning and evening. About the 1st of August they go into the ground and lay their eggs; and these are hatched in the course of one month. The larvae are slender, somewhat flattened grubs, of a yellowish colour, banded with black, with a small reddish head, and six legs. These grubs are very active in their motions, and appear to live upon fine roots in the ground; but I have not been able to keep them till they arrived at maturity, and therefore know nothing further of their history.

About the middle of August, and during the rest of this and the following month, a jet-black cantharis may be seen on potato-vines, and also on the blossoms and leaves of various kinds of golden-rod, particularly the tall golden-rod (Solidago altissima), which seems to be its favourite food. In some places it is as plentiful in potato-fields as the striped and the marginated cantharids, and by its serious ravages has often excited attention. These three kinds, in fact, are often confounded under the common name of potato-flies; and it is still more remarkable, that they are collected for medical use, and are sold in our shops by the name of Cantharis viatica, without a suspicion of their being distinct from each other. The black cantharis, or Cantharis atrata, is totally black, without bands or spots, and measures from four-sixths to half of an inch in length. I have repeatedly taken these insects, in considerable quantities, by brushing or shaking them from the potato-vines into a broad tin pan, from which they were emptied into a covered pail containing a little water, which, by wetting their wings, prevented their flying out when the pail was uncovered. The same method may be employed for taking the other kinds of cantharides, when they become troublesome and destructive from their numbers; or they may be caught by gently sweeping the plants they frequent with a deep muslin bag-net. They should be killed by throwing them into scalding water, for one or two minutes, after which they may be spread out on sheets of paper to dry, and may be made profitable by selling them to the apothecaries for medical use.

A species of the genus Meloe (angusticollis), or narrow-necked oil-beetle of Say, about an inch long, and of a dark indigo-blue colour, is very common on butter-cups in autumn, and is also found on potato-vines.

POGATO-FLY. See Caterpillar.

POULTRY. An external application employed for promoting the suppuration of tumours, or abating painful inflammation. The chief intention of the poultice is to retain the stimulus of heat on the tumour for a sufficient length of time, consequently the worst conducting of farinaceous matters are the best fitted for this service. The poultice, when added is to give softness to the poultice, which is otherwise apt to harden as the moisture evaporates. Poultices for animals are generally prepared with linseed meal, to which is added oil, lard, or other unction matter to prevent adhesion to the inflamed part. Bran, although frequently used for poultices, is objectionable, because it so soon becomes dry. Few farmers are aware of the value of these simple applications in abating inflammation, relieving pain, cleansing wounds, and disposing them to heal. The poultice may be rendered more soothing by opium, or increased activity may be given by the addition of common turpentine or chloride of lime, and in cases of foul ulcers, powdered charcoal may be added. As an emollient poultice for grease and cracked heels, and especially if accompanied by much unpleasant smell, there is nothing preferable to a poultice of mashed carrots with charcoal. See POMENTATION.
of live-stock; but those best known are the game breed, the white or English breed, the black or Poland breed, the turk or Shokebag breed, and the Malay breed. The two first are much smaller breeds than the others. This kind of stock affords profit in the eggs, as well as the chickens; therefore such as are the best layers and sitters should be chosen, which are in general the game and Poland breeds, but the other breeds have probably the advantage in respect to the size of the eggs: as food, the game and the white breeds are said to be the most delicate.

The care and management of the poultry-yard usually devolves upon the farmer's wife, and the instructions householders will do well to see to their food and rearing, &c., herself, and not trust too much to servants. For the most economical methods of keeping and managing poultry, &c., I refer the reader to the different heads of Dovecote, Ducks, Fowls, Goose, Turkey, &c. See also Eggs, Feathers.

The comparative value of the keep for domestic fowls is as follows: geese 5 per cent., ducks 7½ ditto, pigeons 10 ditto, dunghill fowls 40 ditto, turkeys and Guinea fowls 50 ditto. From a series of observations made on the diseases of domestic poultry, Mr. Frouenirs makes the following conclusions: these animals which can exercise a constant and determinate action on their lungs. 2. The effect of this action is the more rapid and more severe, the younger the animal is. 3. When cold does not cause acute and speedily fatal inflammation of the lungs, it produces a chronic inflammation, which is pulmonary consumption itself. [This, however, is a mistake, as pulmonary consumption is the deposition of tubercles in, not inflammation of, the lungs.] 4. Heat always prevents the attack of pulmonary disease: when the latter has taken place, heat suspends its progress, and even sometimes arrests it entirely, and effects a complete cure. 5. Pulmonary consumption in any stage is never contagious: fowls affected with that disease were not only all day along with the healthy fowls, but at night roosted in the same places, without communicating their disease to them. 6. Lastly, the action of too long confined air exposes these animals to abscesses of the cornea, and inflammation of the ball of the eye. These abscesses and inflammations are also caused in a still more cruel manner by cold, especially when accompanied with moisture. (Annales des Sci. Nat.) The reader will find an interesting essay by Mr. England on the rearing and management of domestic poultry, in the fourth volume of the Trans. of the Highl. Soc., to which a premium was awarded. There is also a paper on the same subject in the eighth volume of the Quart. Journ. of Agr. p. 509.

FOUND. In law, a place where cattle and goods which have been distrained are to be lodged and kept until redeemed. The common meaning in the United States is, a place where cattle are enclosed and kept. See Distress. POVERTY GRASS, or Forked Aristida, frequent in the Middle States, on dry, sterile soils.

PREGNANCY. In cattle, the state of being with young. Under the heads Abortion, Calving, Gestation, &c., I have gone very fully into this subject. The following excellent observation by Mr. Youatt, on the detection of pregnancy in the mare and the cow, are highly practical and useful.

Among healthy animals, the impregnation of the female rarely fails to be the result of an intercourse between the sexes. The assurance, however, of this having taken place, is, occasionally, an affair of considerable interest, and of no little difficulty; and the value and the destiny of the female may very much depend on the decision of the question. A certain time having elapsed, the thing will speak for itself; but are there any symptoms of which will warrant the veterinary surgeon, or the agriculturist, in giving a decided opinion on the case in an early period of supposed pregnancy?

It occasionally happens that the fifth or the sixth month arrives, and, even to the practised eye, there are few or no indications of conception having taken place. There are, also, but somewhat unfrequently, diseases which very closely simulate this natural process. Can the veterinary surgeon or the breeder decide? The answer is in the affirmative, and plainly and unequivocally. This is because the female, which will warrant the veterinary surgeon, or the agriculturist, to undertake the altered character of the female is regarded, and very properly, as a circumstance of no little weight. She is comparatively calm and quiet; her appetite returns, and she regains her former condition and former habits. Five or six weeks pass, and there is no outbreak of any kind. The owner concludes, and he is not often wrong, that she is impregnated. He, however, has had little to do with mares or with cows who has not witnessed the return of the most furious oestrus, after a much longer period of time has elapsed. I have known more than 3 months pass in this delusive quietude, and then a salaciousness worse than at first has indicated that no actual impregnation had taken place. On the other hand, the oestrus, but not with all its former fury, has returned, 2, and 3, and 4 months after the connection; and yet, as the result finally shows, impregnation had taken place at their first intercourse.

Many circumstances may cause the owner to be anxious to know the truth of the matter. He may wish to sell her, or he may be unusually desirous to breed from her. Let the animal be examined per vaginam. Let the hand be slowly and cautiously passed up the vagina until it reaches the os uteri. Let there be no attempt to penetrate farther. No information can be gained from introducing the fingers into the uterus. It is simply wished to ascertain the character of the os uteri. In its natural and unimpregnated state it will be closed; but it will not be tightly or spasmodically so, and the contraction of the mouth of the womb will form a kind of cup, with the base towards that viscus. If she is impregnated, the entrance to the uterus will be more firmly closed, and the protrusion will be towards the vagina. This is the only exploration per vaginam which I would allow; it is easily made, and it will be satisfactory. If an exploration of this kind is
PRIMROSE.

England, its give but cruel from cause plunge should to how noyed animal tator, life exhibiting, of be domicile, enlargement by and am produce is an attempt to giving shift the the may beginning, I observe that it and is connected with, the embryo; cannot the intestines, by embryo; I am to the cold, and I have begun to take occasional exercise in its first domicile, and then would become more evident, but not more satisfactory proof of the life of the fetus; its motion strong enough to be seen through the integument.

I might, perhaps, wish to give this assurance of the life of the fetus to some curious spectator, or to some intended purchaser. I would not gallop the mare in order to effect this: I would not so far disturb her or the young animal that she bore within her. Much less would I give her cold water to drink, and which is usually cold drink until she annoyed the fetus, and the unborn animal told us how much we annoyed him by endeavouring to shift his quarters and get away from the action of the cold. I would not run the hazard of giving her the colic, and perhaps destroying him or her by this unscientific and somewhat cruel method of exploration; but I probably should give a tap or two on the outer wall of his dwelling, just sufficient to rouse him from his slumbers, and induce him to express his anger at the annoyance by a tolerably distinct plunge or kick.

Most certainly, if it was a cow that I was exhibiting, I would not give, nor would I suffer any one else to give those terrible punches in the right flank which I have no doubt are the cause of much unsuspected injury, and, occasionally at least, connected with, or the origin of a difficult or a fatal parturition.

I may here observe that the fetus of the mare, from the beginning, occupies nearly the centre of the belly. In the early stage, Mr. Mogford generally found it "lying across the pelvic cavity, the spine being immediately under; the head on the left side, and the tail on the right side." In the latter portion of its fetal state its motions are pretty equally distributed on either side, and the beating of the fetal heart is most plainly heard at the very base of the abdomen.
coloured, with a darker radiating spot in the middle; their scent agreeable, though slight. There are cultivated varieties, white, purple, or brown, single or double, of which the double sulphur-coloured is particularly elegant.

2. Oxlip primrose (P. elatior). This is a less common species, found in woods and pastures, but rare. It is perennial, and flowers in April.

3. Common cowslip, or paige (P. veure). See COWSIL.

4. Bird's-eye primrose (P. farinosa). This species is found growing in wet pastures and by rivulets, on mountains in the north of England as well as in Scotland. It flowers later than the preceding species, in June and July, and is only about half the size of the cowslip. It is distinguished by the white mealliness of the flower-stalks and backs of the leaves, whose upper sides are green, smooth, and even, as well as by the beautiful rose-coloured flowers, whose mouth is surrounded with a notched, yellow, glandular border.

5. Scottish primrose (P. scotica). This species is met with occasionally in the north of Scotland, and is near akin to that last described.

PRIMROSE PEERLESS, or Narcissus.

PRIVET (Ligustrum, from ligare, to tie; in addition to the very flexible branches). The common privet, privet, or priv-prim (L. vulgare), is a hardy shrub, growing from 6 to 8 feet in height, in its wild state, containing rather moist thickets and hedges, on a gravelly or chalky soil; but it grows well in any situation, and in all soils. It may be propagated by seeds, layers, or cuttings. These plants are well suited for making cut-hedges in gardens, especially the evergreen varieties of the common privet. The branches are straight, filled with pitch, and the wood is hard.

PROPAGATION OF PLANTS. The greater number of plants are propagated naturally by seeds; but, in addition to these, many plants are extended over the surface on which they take root by the production of runners, or lateral shoots, which spread along the surface, and root at the joints or buds, from which they send up new plants, by suckers, or side shoots from the roots, by bulbs, by tubers, rhizomes, and by various other natural means. Artificially, plants are propagated by seed, by runners, suckers, offsets, dividing the tubers, layers, cuttings, grafting, budding, inarching, &c. Seeds are gathered when mature, and sown on freshly-stirred soil, and covered to different depths according to the size of the seed, the nature of the soil and situation, and other circumstances. The plants formed by runners are separated from the parent plant by cutting through the runner, and removing the young plant, in order to plant it elsewhere. Suckers, slips, or side-shoots from the roots are separated from the parent plant by being slipped down, or cut off, so as to carry with them a portion of fibrous roots; and they are afterwards planted in suitable soil, &c. Offsets are small bulbs which are produced round the base of other bulbs, or on stems, in the axilis of the leaves, and, being taken off and planted, become plants. Tubers are underground stems containing leaf-buds; and these may be separated and planted entire; or cut into as many pieces as there are buds, in either of which cases new plants will be formed. Layers are branches or shoots of either woody or herbaceous plants, which are bent down, and a portion of their length buried a few inches in the soil; that portion having been previously wounded by cutting, bruising, or twisting, which, by checking the descent of the sap, gives rise, after a certain period, to the production of roots.

After these roots are formed, the portion of the layer which has produced them is separated from the main stock or parent plant, and planted by itself, or in units, and allowed to increase as before described.

Cuttings are portions of shoots, either of ligneous or herbaceous plants, and they are made of the young shoots with the leaves on, or of the ripened wood, either with or without its leaves; and after they have, either in an herbaceous state with the leaves on, or with the wood mature, and with or without the leaves, been properly prepared and planted, they form roots at the lower extremity, each cutting becoming a perfect plant. In general, cuttings should be taken from those shoots of a plant which are nearest the soil; because, from the moistness of and shade there, such shoots are more prone disposed to emit roots than those on the upper part of the plant.

The young, or last-formed shoots, are to be taken in preference to such as are older, as containing more perfect buds in an undeveloped state, and a bark more easily permeable by roots; and the cutting is to be prepared by severing its lower extremity across at a joint, the lenticells, or root-buds, being there most abundant. When the cutting is planted, the principal part of the art consists in making it quite firm at the lower extremity, so as completely to exclude the air from the wounded section. Cuttings emit roots at this section, either in consequence of the action of the accumulated sap in the cutting, as in the case of the ripened wood in deciduous trees and shrubs; or in consequence of the joint action of the accumulated sap and of the leaves, as in the case of cuttings of soft wood with the leaves on, and in a living state. A few plants are propagated by cuttings of the leaves, the petiole of the leaf being slipped off from the parent plant, and probably containing the latent embryos of buds. Grafting, inarching, and budding, are processes which have been already explained. See Budding, Grafting, INARCHING, &c.

PULSE. A term applied to all leguminous plants, as peas, beans, tares, vetches, lupins, &c. All the species of pulse afford excellent manure when turned into the soil in a green state. The custom of ploughing in green succulent plants of this kind is very ancient. All the Roman agricultural writers commend it highly. Columella, particularly advises lupins as a manure, which, if cut down and turned in while green, will have as good effect as the best and strongest dunging whatever. They may be sown upon poor land about the middle of
PUTREFACTION. 

September, and be ploughed in before they attain their full growth. In gravelly soils they should be cut down after they have put forth their second flower; and in strong lands, where a little more advanced. In the former of these grounds they are turned in while young and tender, that they may quickly rot; and in the latter, are let stand till they grow stronger, that they may produce a better effect on the stiff clods of earth, and render them more mellow and friable. This practice is still extensively followed in northern Italy.

Peas, beans, lupins, vetches, and other succulent plants, have also been strongly recommended by the older writers on husbandry, as excellent manures, especially for sandy ground; these plants enriching the earth greatly if ploughed in, either green, or when in bloom. In strong land they are advised not to be turned down till the pods begin to harden. See Green Crops, Leguminous Plants, Peas, Rotation of Crops, &c.

PUMPKIN (Cucurbita pepo). The pumpkin is extensively cultivated in the United States, where there are many varieties, some of them attaining the enormous size of a barrel, and bore in different portions large ones are not so highly esteemed. The better sorts are often used at table, affording the celebrated pumpkin pie of New England; and the coarser varieties are esteemed for feeding stock. When growing in the vicinity of squashes, the fruit of this is liable to be converted into a hybrid, of little or no value. Crops of pumpkins have been totally spoiled by that cause, the fruit becoming very hard and warty, unfit for the table, and unsafe to give to cattle. Flora Cestrica.

PURGATIVES. In farriery, such medicines as tend to evacuate the crudities of the bowels by stool, and which are sometimes called cathartics. See Purgina.

The purgatives most frequently employed for horses and cows are sulphur, jalap, aloe, gamboge, Rhamnus catharticus, and calomel. Saline purgatives are not often required; but when they are, Epsom salts (the sulphate of magnesia), is adequate for every purpose.

PURGING is necessary in a variety of cases, for different sorts of animals, particularly in diseases of the inflammatory kind, swellings in the extreme parts. Aloe is the best form of physic; but Epsom salts, linseed, and olive oil, are sometimes used in certain occasions as laxatives with great propriety and benefit, and in gross, full horses, in some disorders of the stomach, liver, &c., but it should always be directed with caution.

Violent purging or scouring, attended with inflammation, will sometimes arise when a horse is worked hard upon green meat. The remedy is change of diet or less labour. Astringents should be used with much caution. It is probably an effort of nature to get rid of something that offends. A few doses of gruel will assist in effecting this purpose, and the purging will cease use in an astringent medicine. See Aloe, Balls, Drenches, Linseed Oil, &c.

PURSLANE (Portulaca; from poro, to carry, and lag, milk; juicy nature of the plants). purslane is now but little noticed as a garden flower, but in Britain is still cultivated as a salad and pot-herb. The species usually grown in the kitchen garden are the green or garden purslane (P. oleracea), and the golden purslane (P. sativa).

PUTREFACTION (Lat. Putrefactio). The spontaneous decomposition of animal and vegetable substances, attended by the evolution of fetid gases. The putrefactive fermentation of animal substances is usually attended by more fetid and noxious exhalations than those arising from vegetable products. This appears principally to be due to the presence of nitrogen in the former; and, hence, those vegetables which abound in nitrogenous principles, such as most (if not all) of the cruciformal plants, exhale peculiarly nauseous effluvia; hence, also, such animal products as are destitute of nitrogen, are either unsuitable of what is commonly called putrefaction, or suffer it slowly and imperfectly. The formation of ammonia or of ammoniacal compounds is a characteristic of most cases of animal putrefaction; while other combinations of hydrogen are also formed, especially carburetted hydrogen, and sulphuretted hydrogen, together with complicated and often highly infectious vapours or gases, in which sulphur and phosphorus are frequently discerned. These putrefactive effluvia are, for the most part, easily decomposed, and resolved into new and comparatively innocuous compounds by the agency of chlorine; hence the importance of that body as a powerful and rapidly acting disinfectant. The rapidity of putrefaction and the nature of its products are, to a great extent, influenced by temperature, moisture, and access of air; they do not ensue below the freezing point, nor in dry substances, nor under the entire exclusion of oxygen; and hence various means suggest themselves of retarding or preventing putrefaction, as well as of modifying its results. A temperature between 60° and 80°, a due degree of humidity, and free access of air are the circumstances under which it proceeds most rapidly. The most effective antiputrefacatives, or antiseptics, are substances which either absorb or remove a portion of the water or moisture, and enter into new combinations with the organic matter. The astrin- gent or tannic principle of vegetables is also a powerful preserver of most organic tissues; it enters into chemical combination with the albuminous and gelatinous membranes and fibres; and the resulting compound, of which leather furnishes a characteristic example, is comparatively little prone to change, although the tanning material itself, as well as the animal principles with which it unites, are separately liable to decay. Among saline substances, the antiputrefactive powers of salt are commonly known: when a piece of flesh is salted, brine runs from it, in consequence of the energy with which the salt abstracts the component water of the muscular fibre; the flesh becomes less susceptible to putrefactive changes is greatly diminished; but it becomes at the same time less easy of digestion as an article of food. Corrosive sublimate is a far more powerful preservative than common salt; and it appears to act not by the mere abstrac-
PYROLIGNOUS ACID. This term is generally applied to the acid liquor which passes over along with tar and gaseous products, when wood is subjected to destructive distillation. This acid liquor is an impure vinegar, from which acetic acid is obtained. It has in its impure state a powerful smoky odour, not unlike that of Westphalia ham. The acid is purified by converting it into acetate of soda, and decomposing that salt by means of sulphuric acid. This acetic acid, after distillation, is in a high state of concentration; but it differs from concentrated acetic acid, by being neither combustible nor crystallizable. It is usually lowered by the addition of water. If intended for the table or for domestic use, as a substitute for other forms of vinegar, it is usually coloured with a little burned sugar. This manufacture of vinegar is now carried on upon a very large scale, and the greater part of the vinegar used for domestic purposes and in the arts, in many of which it is largely consumed, is derived from this source. Ordinary vinegar, besides containing acetic acid and water, contains also sulphate of lime, some cerebral matter, a portion of sulphuric acid, and a colouring principle. See Vinegar.

QUINOA. QUINOA, or PERUVIAN RICE (Chenopodium quinoa). Humboldt speaks of this plant as one of the few cultivated in the highest and coldest regions of the Andes and the Mexican Cordilleras, where it ranks in utility with the potato, Indian corn, and wheat. Whilst young, the leaves are used as spinach, oxalis (sorrel), or common greens, whilst the seeds are boiled in soups and used as a substitute for rice. The plant is an annual, and resembles French spinach, or its kindred Lamb's-quarter (Chenopodium album), which is so widely diffused throughout the United States. The seeds are small, about the twelfth of an inch in diameter, yellowish-white, flat, resemble those of millet, and are easily pulverized. The plant attains about 3 feet in height, and produces greenish flowers about the 1st of August. Mr. Gideon B. Smith has raised the quinoa at Baltimore, and found it very productive. (Am. Farmer, vol. 13.) There are a great many species of chenopodium, many of which are enumerated under the head of goose-foot. In Peru, it would seem the quinoa is subjected to a process of salting or part-bolting, before it is disposed of by the cultivator, whether for the purpose of assisting in its preservation, or to prevent its cultivation in other countries, is not ascertained. To this fact may probably be ascribed the failure of all previous attempts to cultivate it. Having, says Mr. Smith, eaten the quinoa, prepared in several ways, we are of course enabled to speak of its qualities from experience. Gentlemen who have eaten it in Peru, speak
of it in the highest terms of praise. It has a very pleasant flavour, although this is peculiar and may not at first be relished. The taste more resembles that of oat-meal than rice. The grain is chiefly composed of a grain or sprout of the young plant, closely coiled, and imbedded in farina. In boiling, this spiral germ is detached, and the dish presents the appearance of being full of skippers, something similar to a dish of boiled beans. If the description of the mode of sowing and cultivating the quinoa in Peru, together with the seed, was furnished Mr. Smith by Lieut. Fitzbagh, U. S. N. From this it appears that it is sown broadcast, and gathered in the same seasons as wheat. When ripe, the grain shells off very easily, and to prevent loss, it is cut carefully and gathered in on cloths of cotton or lines.

QUITTEE. In farriery, an ulcer formed between the hair and hoof, usually on the inside quarter of a horse's foot; it often arises from treads and bruises, sometimes from gravel, which, by working its way up through the open part of it, if it is only superficial, it may be cured by cleansing dressings, bathing the coronet every day with spirits of wine, and dressing the sore with lime-water, or a detergent application, such as red precipitate.

R.

RABBIT. (Lupus cuniculus). A well-known animal, resembling the hare, smaller in size, belonging to the order Rodentia. The rabbit has shorter hind-legs than the hare, and the ears are more thinly covered with hair. Rabbits abound in England, and are in many cases preserved in warrens. They are very prolific, and begin to breed at six months old, and have several broods in a year, and from five to seven young ones in a brood. The young are blind at birth, and nearly naked. Their fur, in a wild state, is of a brown colour; but varies when domesticated. It constitutes a principal article in the manufacture of hats. Owing to its slight conducting power, it is, next to hare's fur, an excellent thing to wear over the shirt for those predisposed to consumption.

RACEME (Lat. racemus, a bunch of grapes). In botany, a form of inflorescence, in which the flowers are stalked along a common unbranched axis, as in the hycacinth.

RACHIS (Gr.). A branch which proceeds in nearly a straight line from the base to the apex of the inflorescence of a plant. It is also applied to the petioles of the leaves of ferns.

RACK. A raised convenience formed above the manger in a stable for the reception of the hay. It should be constructed with openings at the bottom for the seed or dust to pass through.

RADICLE. In botany, that portion of an embryo which eventually becomes the descending axis or root. It is the lowest of the two opposite cones of which an embryo plant consists.

RADISH, CULTIVATED (Raphanus sativus). There are two kinds of cultivated radish, the fusiform, or spindle-rooted, and the globular, or turnip-rooted; and these again are divided into the spring and autumn varieties. As for the designation of short and long top, by which the old gardeners divided the varieties, I perfectly agree with Mr. Sirachan, the gardener of the London Horticultural Society, in considering it as giving importance to a difference that is by no means permanent. The first may be sown at all times of the year; but the last, requiring a greater length of time to perfect their roots, can only, as the name implies, be obtained during the latter part of the year.

Spring Varieties.—Fusiform-rooted: 1. Long white, called also the white transparent, white Italian, and Naples radish. 2. White Russian, probably the Raphanus sativus of Gerard. 3. Twisted radish of Mons. 4. Scarlet or salmon, or scarlet-transparent radish. 5. Purple, formerly called exclusively the short-topped. 6. Red-necked white.

Turnip-rooted: 7. White turnip is the only one noticed by Gerard, as the Raphanus orbicularis. 8. Early white turnip. 9. Pink, rose coloured, scarlet, and crimson turnip. 10. Purple turnip. 11. Yellow turnip.

Autumn and Winter Varieties.—These are all of the turnip-rooted kind; and in the following list they are described in the order they follow in coming into use. 1. Yellow turnip. 2. Round brown. 3. White Spanish, is Miller's Raphanus albus orbicularis. 4. Oblong brown. 5. Black Spanish. 6. Large purple winter, or purple Spanish.

The soil best suited for this vegetable is a mouldy loam, rather silicious than otherwise, and moderately fertile. It should be dug a full spade deep, and well pulverized. The subsoil is best to be rather hard. Manure should not be applied at the time of sowing, if avoidable, as it is apt to cause the roots to be fibrous. If employed, it should be in a finely-divided, potaceous state. The situation should always be open; but for early and late crops, warm and sheltered. Radishes are propagated by seed, which may be sown at all times throughout the year. For the earliest productions, during December, January, and February, in a hot-bed; and in the open ground once a month during winter, and every fortnight during the other seasons of the year.

The time of drawing radishes is by no means indifferent. They eat in the greatest perfection if pulled in the morning before the sun has attained any power, and laid in a cool, damp place until wanted. The bed should have a plenteous watering the morning before that on which they are taken, but none afterwards until subsequent to the drawing. In November, those wanted for winter must be taken up during dry weather, and preserved in sand.

Forcing.—A moderate hot-bed is required for this crop, of a length according with that of the frame to be employed; the mould, about eight inches deep, on the surface of which the seed is to be sown as soon as the violent heat is abated, and an additional half inch of mould sifted over it. The seedlings are in general up in less than a week, and in six they will be ready to draw. Throughout their growth air must be admitted as freely as is allowable. The glasses, however, must be closed on the
approach of evening, and mats or other covering put on in proportion to the severity of the season. When the mould appears at all dry, a light watering must be given during noon. The plants must not stand nearer than two inches to each other. The temperature required is from 50° to 70°; and it must be kept to this heat by moderate coatings as required.

If there is a deficiency of frames, hoops and mats may be employed, a frame of boards being formed round the bed, light and air being admitted as freely and as often as possible. If seed is sown within a frame without any bottom heat, the plants will be two or three weeks forwarder than if sown in the open ground.

RADISH, THE HORSE. See Horse-Radish.

RADISH, THE GREAT WATER. See Cranberry.

RADISH-MAGGOT. Radishes, while growing, are very apt to be attacked by maggots, and rendered unfit to be eaten. These maggots are finally transformed to small, ash-coloured flies, with a silvery-gray face, copper-coloured eyes, and a brown spot on the forehead of the females; they have some faint brownish lines on the thorax, and a longitudinal black line on the hind-body, crossed by narrower black lines on the edges of the rings. They vary in size, but usually measure rather more than one-fifth of an inch in length. They finish their transformations, and appear above ground, towards the end of June. The radish-fly is called *Anthomyia Raphani*, in my "Catalogue," from the botanical name of the radish, on the root of which its larval feed. It closely resembles the root-fly (*Anthomyia radicum*) of Europe. (Dr. Harris.)

RADISH, WILD (Raphanus Raphanisticum). A troublesome weed found in arable lands. See Charlock.

RAG. A torn piece of cloth of any sort: when of the woollen kind, they are used as manure. Woollen rags are the entire contents of the bark; they are found to contain a very large proportion of albumen, (a substance similar in appearance to boiled white of egg), minute portions of lime and silica, and traces of various salts. They form, therefore, an excellent manure, by slowly decomposing in the soil; and are found to remain dissolving in it, and forming soluble and elastic matters for the service of plants, when applied at the rate of 1200 weight per acre, for periods varying from two years on the heavy clays, such as those of the hop-gounds of the Weald of Kent, to three on the lighter soils of the valley of the Kennet, in Berkshire. The lightness of carriage, and its readiness, as well as cleanliness of application, render it peculiarly eligible as a fertilizer; it keeps, too, for any length of time, until the farmer is ready to apply it to his ground, and is much more slowly decomposed and consumed than either blubber, rape-cake, train-oil, or bone dust.

The consumption of these rags by the Berkshire and Oxfordshire farmers, and especially in Kent for the hop grounds, is very considerable. I am informed by an extensive dealer in these rags, that at least 20,000 tons are annually consumed by the farmers of the south of England. My informant himself has a sale of more than 500 tons per annum, which he delivers free on board a vessel, at any of the London wharves, for £5 guineas per ton. The custom of the farmer is, to cut the woollen rags, by means of a chopper and block, into shreds about the size of a crown-piece, and then spread them on their fields by hand, out of a common seed-basket, as evenly as they can; they find that this manure is admirably adapted for hops, wheat, turnips, &c., and that the beneficial effect is as great the second year as the first. It appears that one farmer in Kent, Mr. Ellis, of Barming, purchases annually 4 or 500 tons of these rags, almost exclusively for his hop grounds. The farmers of Kent think the application of the rags "warm" the ground, as they slowly purify in the soil; they certainly afford nourishment to the crop, for wool is composed almost entirely of a peculiar animal substance, with a slight portion of phosphate of lime, or earthy matter of bones.

RAGWORT (Senecio). A portion of the species of this extensive genus has already been noticed under the head Grænseke; but there are in England four or five species of ragwort, properly so called. These belong to that section of the genus which have flowers with spreading rays and pinnatfid leaves; the others to that with undivided leaves and radiant flowers.

RAIN (Ger. regen). In meteorology, water falling from the clouds. As the effects of rain upon vegetation are so highly important, it will be useful to ascertain the quantity or depth of rain that falls annually in various places, and the difference in the effects which are produced by it, more especially for the formation of reservoirs for agricultural purposes. To use the words of Mr. G. Tate—Although fully aware, that little reliance can be placed upon any theory founded on data so uncertain as the quantities of rain that fall in different years, I am convinced that something might be done towards establishing rules for the guidance of agriculturists and botanists, if observations were made at the same place for a series of years, and the results recorded." The average quantity of rain which falls in a year at any given place, materially affects the productiveness of the soil, and is necessarily influenced equally with the climate by a variety of general circumstances and local causes; such as latitude, altitude, proximity to the sea, configuration of the country and of the mountain ranges, exposure to the prevailing winds, &c.

Near the foot of high hills a greater quantity commonly falls than over a level country; the currents of the atmosphere in their course meeting with a hill, are forced to ascend, and gaining a higher, and of course colder situation, the vapour is condensed into clouds, and even into rain, so that a deposition in showers very frequently follows. Hence the reason why clouds are so often observed on the sides and tops of mountains, which have been incorrectly supposed to attract them. The quan-
Rain. Rain.

ty that falls, and the manner in which it falls, are the circumstances to be attended to. A great number of rainy days are more injurious to the soil, even where the quantity is not great, than heavy falls at distant intervals of time; the ground, in the first case, being constantly over-saturated, its fertility is much lessened; in the other, the superfluous moisture being soon drained off, only the portion necessary for the nourishment of plants is left, which is gradually given out in dry weather, during which the ground for a time is in its most productive state.

In general, more rain falls in the north of England than in the south. The east and southeastern counties have usually the driest seasons and years. The fall of rain is various, however, at any period of the year, as may be seen from the annexed tables. The mean quantity falling annually in England is reckoned to be 32 inches, or, according to Dalton, 31-3; but this is unequally distributed.

The annual amount in Westmoreland and Lancahire, according to Mr. Whistlecraft, usually ranges from above 40 to nearly 70 inches, while that noted by the gage in Essex and Suffolk is as low as from 14 to 32 inches; seldom, however, does it exceed 25 inches. It may, indeed, be fairly inferred, that these two parts of England produce extremes.

Mr. Howard gives the annual average at London equal to 21-9 inches; Professor Philipps at York 25-7; and Mr. Adie at Edinburgh 25 inches.

At Keswick, in Cumberland, the depth on an average of 7 years was found to be 67 inches; at Bavetstock, near Salisbury, during the same period, 32-1 inches; and at Plymouth, in Devonshire, 43 inches. In the western parts of Scotland the depth is from 30 to 35 inches, which is from 6 to 10 inches more than that on the east coast.

The mean monthly and annual quantities of rain at various places, deduced from the average for many years, by Dalton, is given in the following table:

</table>

The greatest depth of rain which has been registered at any place in a year, is at Maranham, lat. 53° 8', and which is stated by Humboldt to be 277 English inches; but this is greatly above the average, and, indeed, more than double the annual quantity which has been observed at any other locality. At St. Domingo, the annual fall is estimated at 120 inches; at Cayenne, 116 inches; at Havana, 91; at Calcutta, from 76 to 118; at Bombay, from 83 to 96; of the island of Martinique, 87 inches; and at Sierra Leone, 86. Of European countries, Portugal appears to be the most humid, 128 inches having been observed at Coimbra in a year.

Although winter usually produces more rainy days than summer, the quantity of rain which falls is less in the latter season. Dr. Dalton has ascertained that the first six months of the year may be regarded as dry, and the last six as wet months. Another ingenious author has inferred, from long observation, that in spring it rains oftener in the evening than in the morning, but that towards the end of summer, offener in the morning than in the evening. At St. Petersburg, rain and snow fall on 4 days annually of the winter, and the quantity amounts to about 5 inches; on the contrary, the summer produces 11 inches in the same number of days. In Canada, the average fall of rain usually is about 3 feet, which furnishes about 20 gallons of water for each square foot of surface during the year.

In the United States, the quantity of rain falling per annum increases in going south. At Philadelphia, a medium point, the result of 33 years’ observation of the rain-gauge have been estimated by Mr. Owen Evans as follows.—Whole quantity, from 1810 to 1842 inclusive, 1277 inches; average, 36-68 inches; greatest amount in any one year, 55278 inches (in 1841); smallest quantity, 23354 inches (in 1819). Mr. Evans has also constructed the following table, showing the monthly averages of rain, estimated for 5 years (1833 to 1842 in-
RAKE.

An instrument for measuring or gauging the quantity of rain which falls at a given place. It is also known under the several names of ombrometer, udometer, pluvimeter, and bytometer. Its principles and construction are of the simplest nature; but it is made in a variety of shapes.

A convenient form of the instrument is that where the rain which enters a funnel of certain size, is collected in a bottle or other vessel, and afterwards measured in a graduated cylindrical glass tube, the marks on which not only represent the tenths and hundredths, but even the thousandth part of an inch of water. The height is read immediately on the scale.

It is requisite to be particular in the situation of the instrument. The gauge is best placed about 3 or 4 feet from the ground. In all cases an open space, free from trees, shrubs, or buildings, must be chosen.

RAKE. A tool of the toothed kind, of various sizes and forms, made use of in gardening, and for different agricultural purposes. There are several others used for field operations, some of which are worked by horses.

The drag-rake, in its simplest form, is merely a long cross-head, with a row of teeth placed in it, in some these are straight; they are, however, generally bent, with their points projecting forward. A very excellent and light instrument, having the teeth of steel, and made with screws, so as to admit of their being easily replaced in case of accident, is well known in England as Badzley's improved drag-rake. These rakes had, from time to time, increased in length and weight, till they became too large to be balanced by the hand. Two small wooden wheels were then added, which rendered them manageable by women or boys. Further additions having been made to them, they are now sufficiently strong to be worked by a horse. Used on fallows when foul, to remove the couch-grass, they act as a harrow, to get together the rubbish; or in harvest-time they act as a rake to collect the loose corn which may have escaped from the sedge or sickle. In order to clear them readily, there are different contrivances. One of the most simple and efficient is an arrangement which, by lifting the handle, causes the teeth to be raised and brought between two iron bars, which constitute part of the framing; by this means all the rubbish is stripped off from the teeth of the rake.

In "Wedlake's Horse Hay-Rakes," the weight of the rake is balanced upon the carriage by two heavy balls projecting in front of it; so that a slight lifting power applied to the handle will raise it from the ground, and disencumber it of the hay or stubble it may have gathered. This rake obtained the commendations of the Committee on Implements, at the meeting of the Royal English Agricultural Society at Cambridge.

The East-Lothian Stubble-Rake is a machine not so well known in England as its merits deserve. Its advantages over those previously described are as follows:—It has each tooth placed in a separate head, which, working upon a centre like the levers of a drill, adapt them selves to any inequality in the ground. To the handles, a bar the length of the barrow is firmly fastened, and from this bar each lever is suspended by a few links of chain. When it is necessary to clear the rake, these handles, on being elevated, lift all the levers between a framing of light iron rods.

An ingenious practical farmer, John Sayer, of Bodham, in Norfolk, made considerable improvement upon this rake, by altering the form of the teeth to avoid tearing the land; and in order to effect more work without increasing the width of the rake, the naves of his wheels were made to project inwards, so that two additional levers could be introduced, working quite close to the spokes.

But within the last few months a very improved implement of this character has been introduced and patented by J. C. Grant, of Stamford, which obtained the prize of the Royal Agricultural Society of England, at its meeting at Liverpool. Its advantages consist in the adaptation of a compound lever, by which the whole row of tines may be instantly raised, and as quickly allowed to resume their position, while the form of the teeth being such as to describe part of a circle, the centre of which is the axis of the separate levers to which they are attached, each portion of the curve is successively brought into a vertical position, thus rapidly disengaging the teeth from the material collected, so that, without stopping the horse, the process of collecting is resumed, leaving no interval beyond what is requisite for the deposit of the hay, corn, or stubble previously collected.

Several minor improvements are included in the patent, but as these mainly refer to modes of construction, it will not be necessary here to particularize them.

A hay-making machine invented by Robert Salmond, of Robehill, and patented in 1816, consists of a series of rakes revolving upon two skeleton frames, to which motion is communicated by cog-wheels attached to the naves of the wheels in which it travels. It has undergone considerable improvement by R. Wedlake, an ingenious manufacturer, residing at Hornchurch. These improvements consist in forming the cylinder in two parts, each of which has motion independent of the other, and in placing the tines or rake-teeth upon a bar, which, being supported by a spring, will yield to any obstruction caused by sudden unevenness of the surface of the ground, and return again to its original position. Its object is to spread the hay, and by thoroughly separating its parts, continually to expose them to the sun and wind, which it so thoroughly effects as to render the hay fit to cart much earlier than by the common process of shaking it by the hand. To the practical agriculturist, it will not be necessary to remark on the advantages accruing from the ability to hasten, if only by a few hours, the process of hay-making; but it will be valuable to know, that the universal testimony of all with whom we have conversed is,
RANUNCULUS.

that this implement is a time-saving machine, and therefore one of the greatest value.

American Revolving Hay-rake.—This rake is drawn by one horse; and it can be made to go either along or across the ridges, as may be required. It can carry between 100 and 200 lbs. of hay; and when that quantity is upon it, the hay can be deposited, by a simple revolution of the instrument, in rows, or at any particular place required, without stopping the horse.

The common horse-rake, much used in the United States, especially in the North, is described and figured in the Cultivator, vol. vii. p. 89. It is made of a piece of strong scantling, 3 inches square, and 10 feet long, into which about 15 teeth are inserted horizontally, and made of strong white ash or other tough wood. The teeth should be about 22 inches long, and 1 inch by $\frac{1}{2}$ at the place of insertion, and tapering on the under side, so as to give them a slight turn upward at the point, to prevent them from cutting into the wood while using. The draught-ropes are attached to the end of 2 projecting pieces of wood parallel to the teeth at each end of the rake. These projecting pieces should be about one-third of the length of the teeth. Those unskilled in the use of the rake sometimes attach the ropes at once to the ends of the head; in this way, it becomes almost entirely unmanageable. The forward ends of the draught-ropes are to be fastened to the horse's collar, leaving space enough between the horse and rake for the collecting hay. Handles are to be inserted in the head near the middle, for guiding the teeth and lifting the rake from the ground when necessary.

In using this rake, instead of the teeth moving onward upon their points, as in the common hand-rake, they run along flat upon the ground, passing under and collecting the hay; when full, the handles are thrown forward, the rake emptied, and lifted over the winrow for another load. The rake thus passes backwards and forwards across the field, always emptying opposite the last heap, and thus forming regular winrows at right angles with the path of the rake. A few hours' practice will enable any one to use this rake without difficulty; the only skill required consisting in keeping the points of the teeth just so low as to pass under all the hay, and yet not run into the ground. When small obstructions occur, the handles are depressed, thus causing the teeth to rise, and the rake passes freely over. Large obstructions, as stumps and stone-heaps, require the rake to be lifted from the ground.

The chief recommendation of this kind of rake, is its cheapness and simplicity. A good one need not cost more than $2. It may also be used on rougher ground than the revolving rake, as it is more easily lifted over obstructions. Where the ground is very uneven, the teeth should be made shorter. When one becomes well accustomed to the use of it, work may be done nearly as fast with this, as with a revolving rake, though much more laborious. Twelve acres of hay, part of it yielding nearly 3 tons to the acre, on a meadow of the writer, were raked into winrows, by means of one of these rakes, in about 6 hours' working time.

It possesses another advantage over the revolving rake—it may be used for scraping the winrows into heaps for drawing, and if the hay is stacked in the field, for drawing the hay to the stack. A man with a rake and horse not only raked the hay, but drew it at the same time to the stack, a distance of from 10 to 20 rods, as fast as an active man could pitch with a fork. A hand-rake, however, could not be used on the meadow, as all the scattered hay may be raked up in a short time after the rest of the hay has been drawn off.

The horse-rake is very useful in raking stubble of wheat, and eminently so in pulling and gathering peas.

Shafts, instead of ropes, have been attached to the head of the rake, and have been strongly recommended; but they diminish the simplicity of the rake, and appear to possess no advantage on the whole, and for gathering and drawing hay, are positively detrimental.

RAMPIONS, or RAMPION BELL-FLOWER (Campanula rosal studio). The esculent roots of this vegetable are far more delicate than turnips or radishes. They are long, white, and in the shape of a spindle. Like the radish, it is eaten raw, having a nut-like, pleasant flavour. The plant rises to the height of 2 feet, with blue flowers.

It is propagated by seed, which may be sown during March, April, and May; the plants from sowings in the two first months, soon, however, run up to seed. The insertions may be performed either in drills 6 inches apart, or broadcast; in either mode the seed to be buried $\frac{1}{2}$ an inch deep, excepting it in the latter by sifting mould over it; for, if the seed is raked in, from its minuteness, it is apt to be buried too deep. The plants are to remain where sown; though, in case of any deficiency, those which are taken away in thinning the crops may be transplanted successfully. The best time for performing the removal is of an evening. They are fit for thinning when about 2 inches in height, they must be set at a distance of 6 inches apart, being hoed at the time, and the same operation repeated two or three times, which, if performed in dry weather, will keep them free from weeds until used.

The plants of the sowings during the two first mentioned months will be fit for use at the close of August, or early in September, and continue throughout the autumn. Those of the last one will continue good throughout the winter, and until the following April. The soil, throughout their growth, must be kept moist, effecting it in dry weather by giving frequent but moderate waterings through the fine rose of a watering-pot.

The root, for which it is cultivated, either to be sliced, together with its leaves, in salads, or eaten as the radish, as well as to be boiled like asparagus, is most palatable when drawn young, and eaten fresh from the ground.

For the production of seed, a few of the winter standing plants are left unmoved. These shoot up in the spring, flowering in July and August, and ripening abundance of seed in early autumn. (G. W. Johnson's Kitch. Gard.)

RANUNCULUS (From rana, a frog; several of the species being found in moist places fre-
RAPE.

quented—by that reptile). Many of the plants belonging to this extensive genus are well worth the cultivator’s care, and they have long been favourites with the florist. The aquatic kinds require to be grown in water. The gumose-rooted species will thrive in any common soil and situation; they are increased by offsets from the roots, or by seeds. These plants are acrid, and most of them poisonous. See Crowfoot and Spearwort.

RAPE. A plant of the cole kind, greatly cultivated in Flanders for the sake of the seed, but extremely valuable also as green food for cattle and sheep in winter and spring. “The plants,” says Mr. Low, “usually cultivated under the name of rape, are the fusiform varieties of the following species of brassica. Cole or rape (B. napus), colza (B. campestris), fusiform common turnip (B. rapa), and early cole (B. piroca).” There are different modes of treating this plant, according to the uses for which it is designed. The whole plant is of great service in feeding cattle; and after the seed is threshed, the straw and chaff, on being burnt, afford ashes equally valuable as the best potashes. Are laid under the plough yields a most excellent crop after rape, and the plant is grown with great advantage on bog plant, where paring and burning has been practised. Rape is very hardy, and with fair treatment it never fails on any soil. Cattle are so successfully fattened with it, that many farmers prefer it to turnips. See Cole.

For garden culture, rape is propagated by seed, and, like mustard, and other small saladting, may be sown at any period of the year, when in request; being allowed a separate bed. For the production of seed, some plants of a sowing which has been made about the middle of July, must be thinned to about 18 inches apart; they will survive the winter in England, and flower in May and June of the next year. The seed, which is produced in great abundance, ripens in July and August, and must then be cut and laid upon cloths to dry, as it is very apt to shed.

In England, rape (Brassica napus sylvestris) is frequently called coloised, and in France variete. In both countries it is highly prized, not only for the value of the oil expressed from the seed, but for the cake left after pressure, which is extensively used for feeding cattle, its qualities for this purpose resembling those of the oil-cake left after pressure of flaxseed in making linseed oil. Rape belongs to the cabbage or turnip family, but it never heads, like the former, and its roots are of little value compared with the latter. Of the two kinds most commonly cultivated, one is biennial, sown one summer and harvested the next, whilst the other is a spring or summer crop.

Rape, though but little known in the United States, has been tried in various parts, and found to stand the winters even in New York and New England. Whenever, therefore, a demand shall be made for this valuable production of the soil, or its near kindred of the cabbage family, colza, the United States can yield them abundantly, in almost every part.

According to Loudon, the place which rape occupies in a rotation, is between two culmi-

ferous or grain crops. On rich soils it may be succeeded to the greatest advantage by wheat, as it is found to be an excellent preparation for that sort of grain; and by its being taken off early, there is sufficient time allowed for getting the land in order for sowing wheat.

In Notes on the Agriculture of Germany, by Mr. Carr, an English gentleman, he says the after course is as follows:—

1 year fallow, well dunged,
2 rape,
3 "
4 " barley,
5 " peas, light dunging,
6 " rye,
7 " oats, with rye, or timothy grass-seeds, and red clover.

The clover and peas plastered in May. The clover is mown twice for hay, and left two years for pasture, when it is heavily manured, fallowed, and again sown with rape. “The rape-seed is sown broadcast in the last of July or first of August. This crop is greatly benefited the following spring by dusting gypsum over it, about 100 lbs. to the acre. In July the seed is ripe, and as the weather is usually fine, is trodden out by horses very expeditiously on large canvas sheets in the field. The oil of this seed pressed out, when purified, is without smell, gives a brilliant, clear-burning flame, and is universally used all over Germany, in the saloon of the rich, and the cottage of the poor. The value of the crop is somewhat precarious, because it is subject to so many contingencies; the turnip-fly and caterpillar prey upon it when young, and when in flower, a small beetle (Halicta nemorum) often eats away the blossom-bud, or lays its minute larve in the petals, ultimately furnishing every seed-pod with a maggott which either eats the seeds away, or, forcing the pod open when nearly ripe, causes it to fall out. When spared these calamities, it is, however, a very remunerating crop, worth from 10l. to 20l. an acre, especially if there is a foreign demand. The straw is generally burned, and the ashes scattered over the field; it is sometimes sold to the soap-makers, who prize it highly. Two furrows are now given for wheat sown broadcast in September.”

Mr. Blackie, in his Essay on the Improvement of small Farms, says, that the produce of rape, when well manured, is beyond any thing almost that can be imagined, if let stand until it gets into blossom. Manure, he adds, makes the stalk tender and juicy, which would otherwise be hard and dry, so that if cut into small pieces for the purpose of feeding green to cattle, not a bit will be lost, and it grows to a height of 6 feet. I am, he says, almost afraid to say, that I believe, with the addition of some straw, an acre will keep 30 head of cattle in full milk for a month.

RAPE, edibole-rooted. This name may be applied to a variety of the rape mentioned by Mr. Dickman, one of the vice-presidents of the Horticultural Society. Its root is white, and carrot-shaped, about the size of the middle finger. It is much more delicate in flavour than the turnip, like which root it is cooked, only that it is not peeled, but scraped, its skin being re-

942
RAPE-CAKE.

markedly thin. It has been cultivated for a great length of years on the continent, and for about 30 years in England, but only by one person, as far as Mr. Dickson is aware. It is propagated by seed, which, for the main crop, may be sown from the middle of July to the end of August, or even later: these will supply the table until April; and, if wanted throughout the year, a little may be sown in the latter end of October, the plants from which will be fit for use, if they succeed, during April and May: the last crop to be inserted from the middle of January to the middle of February, which will come in at the end of May and during June. On a north border, and if the soil is sandy and moist, it is possible to have them sweet and tender during the whole summer, to effect which the seed must be sown at the close of March and May. They require the same modes of cultivation and treatment as turnips. In dry weather the beds must be watered regularly, until the plants have got three or four leaves. One great advantage attending the cultivation of this vegetable is, that it requires no manure. Any soil that is poor and light, especially if sandy, is suitable to it. In rich manured earth it grows much larger, but not so sweet and good. For the growth of seeds, Mr. Dickson recommends, in February or March, some of the finest roots to be transplanted to 2 feet asunder; but it would, perhaps, be a better practice to leave them where grown.

RAPE-CAKE. The refuse or marc remaining after the oil has been expressed from the rape or cole-seed. (See LINSSEED CAKE.) The use of rape-cake as a manure is pretty extensive in some parts of England, and its effects are so immediate and powerful, that its expense alone retards its more general employment. It contains a large quantity of mucilage, some portion of albuminous matter, and a small proportion of oil. It should be kept dry, and used when recently made. It answers admirably for turnips. When first recommended as a fertilizer, it was used in the proportion of 2 manure to 1 acre; but by pulverizing it, and drilling it in with the seed, about half that quantity has been found sufficient. Rape-cake produces, when ploughed in with wheat, excellent crops. It has been found exceedingly noxious to the wireworm, and other field vermin, and when applied in compost, with 30 times its weight of farm-yard dung, it forms a very excellent manure.

Rape-cake, in common with all fertilizers of an oily nature, is much more decided in its effects in wet than in dry seasons. In Yorkshire and Lincolnshire the quantity applied is about 16 bushels per acre. It is more serviceable on clays and other moist lands than on dry soils; its benefit extends to only one crop, although there have been occasional instances of its extending to two. It may be either drilled with the seed or spread on the land before it is ploughed. See LINSSEED, OIL-CARE, PALMA CHRISTI, &c.

The practical benefits which are capable of being derived from a correct knowledge of the mode in which green manures operate, are considerable. It should teach the cultivator to carefully bury in the soil every portion of either animal or vegetable matter he can command; for every weed, every fragment of straw he thus employs, will again, under judicious management, be returned to him in new forms of beauty and usefulness.

RASPBERRY (Rubus idaeus). This shrub, in its wild state, is found growing in our mountainous woods and thickets: flowering in May and June. The root is creeping. The stems are biennial, erect, 3 or 4 feet high, branched, round, pale or purplish, more or less be sprinkled with small, straight, slender prickles, frequently rather resembling bristles than prickles, and sometimes altogether absent. Leaves primate, of five or three ovate, rather angular, lateral leaflets, serrated or cut, and angular, green, and nearly smooth above, very downy beneath, and a larger terminal leaflet. The footstalks are narrowed, downy, and prickly, with narrow lateral stipules. The flowers are small, white, or pinkish-white, pendulous, in drooping terminal clusters. Fruit crimson, of numerous juicy grains, beset with the permanent styles, and highly fragrant, with a very deliciously perfumed sweet and acid flavour, more exquisite in the wild state, in general, than when cultivated.

The wood of the raspberry bush produces fruit but one year, therefore that should be carefully cut down below the surface of the earth, and the young shoots should be shortened to about 2 feet high; and not more than three or four shoots should be left to each root, as these will produce a greater number of berries, and larger fruit, than would be obtained if twice that number of suckers were left. The middle or end of October is the proper time for this pruning. The fruit is produced from young branches out of the last year's shoots or suckers. The plants raised by layers are much preferred to those taken from suckers; they should also have plenty of room, for when there is not space for the air and light to pass between the rows, the fruit will be small, and not ripe well. They require a fresh, strong soil, deeply manured; and more than three or four shoots should be left to each root, as these will produce a greater number of berries, and larger fruit, than would be obtained if twice that number of suckers were left. The middle or end of October is the proper time for this pruning. The fruit is produced from young branches out of the last year's shoots or suckers. The plants raised by layers are much preferred to those taken from suckers; they should also have plenty of room, for when there is not space for the air and light to pass between the rows, the fruit will be small, and not ripe well. They require a fresh, strong soil, deeply manured; and more than three or four shoots should be left to each root, as these will produce a greater number of berries, and larger fruit, than would be obtained if twice that number of suckers were left.

The following selection is recommended for a small garden:—Barnet, Cornish, Double-bearing red Antwerp, Williams's preserving yellow Antwerp.

This fruit is employed for the dessert; it is also in very general use for jams and tarts, and is converted into wine and vinegar, which is a refreshing beverage, when diluted with water, in fevers. The young and fresh leaves of the common raspberry are eagerly eaten by kids. (See BRAMBLE.)

RAT. The name of a large, destructive, and very prolific species of the genus Mus, the brown, or water-rat (Mus decumanus, Linn.), introduced into the British islands from Asia, not, as is commonly believed, from Norway. It has spread over all the country, and multiplied at the expense of the old British species, called the "black rat" (M. rattus, Linn.).

Of all the four-footed animals (says the author of Brit. Husb.) included in the rank of vermin, rats and mice are the most pecuniuous,
for they build their nests under the floors and in the roofs of barns, nor are even the stacks exempt; and are so prolific that, if not destroyed, they occasion incalculable mischief. It therefore behooves every farmer to use all possible means to check the evil, and one might suppose that every exertion was invariably made for that purpose; yet we constantly find homesteads overrun with these pests, without any other pains being taken than an occasional rat-hunt by farm servants, aided by a terrier, which, though not to be neglected, is a very inefficient remedy. That the construction of the barn-door and roof in such a manner as to prevent them obtaining a permanent harbour in the building. The next is, before the entire clearance of the barn, while yet a little corn remains to prevent them from quitting it, to close every part of the barn, by carefully covering any holes there may be with sacks and tarpaulings, so as to prevent all access of the outward air, leaving only the door for a few minutes open while the process is going on. This done, some common iron chafing-dishes, which may be purchased for a trifle, should be spread across the barn floor, and the hatches; or, if they cannot be had, build up a few bricks, clay, or any rubbish that will secure a fire from spreading, leaving a cavity in the centre, and filling it up with charcoal. Then light the charcoal from the bottom, and when the heaps are all burning, quickly strew a good quantity of broken brimstone upon the top; retire immediately, shut the door fast, and leave the building entirely closed during a couple of days following. On opening it, the greater portion of the rats and mice will be found dead around the charcoal; and, although some may have been suffocated while in their holes, and if not discovered will occasion an unpleasant smell until their remains are dried up, yet it will not last long. The operation should be again repeated just previous to harvest, and if any opening be found into the barns while they are full, by the burrowing of the rats, brimstone matches should be inserted into them before they are stopped up. Traps and poisons are only partially efficient; but an effectual mode of trapping is detailed in a small pamphlet, published some years ago by Mr. B. Broad, of Thurnton, under the sanction of the Hereford Agricultural Society, which ought to be in the hands of every farmer in the kingdom.

The ferret is a decided enemy to the rat, and if kept in a hutch or cage, and only occasionally used, will be found very serviceable: but he should be well fed to induce him to return, or otherwise he will escape and become destructive to poultry. A cat or two should also always be reared about a barn. In new barns andouthouses, the entrance of rats is effectually prevented by steeping the joints, rafters, and flooring in a solution of corrosive sublimate. If a rat or a mouse attempt to gnaw wood so prepared, their saliva moistens the sublimate, they tread it into the stomach, and are so destroyed by it. See Mice and Vemin.

REAPING. Cutting down wheat or other corn, grain, or pulse with a sickle, hook, or scythe, or by a reaping-machine. These operations are more advantageously performed when the corn or pulse is not quite ripe, than when it is thoroughly ripe; because, in the latter case, the seeds are apt to drop out in the process of handling, turning, and drying.

Mr. Hannum enters into some elaborate calculations on the advantages of reaping wheat a fortnight before it is ripe, from which he deduces the following results; that, independently of a gain of 4 per cent. on the value of the grain, we have, 1st, straw of a better quality; 2dly, a better chance of securing the crop; and, finally, a saving in securing it. (See Wheat.) The smaller the sheaves are, the better, especially in a wet harvest; in general, the diameter of the sheaf should not exceed 30 inches. It is of some importance, also, not to tie the sheaves too near the ears. In making the shocks, they should be placed across the furrows, in order to procure a free circulation of air around them.

In some districts in England, the scythe has of late years been partially employed for the purpose of reaping, but with no satisfactory result; and in Berwickshire the scythe-hook is now generally used in preference to the toothed scythe, or sickle. The latter is a greater piece of workmanship than the scythe-hook, but it is universally considered preferable to mowing it with a scythe, unless the crop stands up well, and time presses. Barley and oats may be frequently mown with advantage; but wheat, which requires immediate and clean binding, and is too valuable to admit of any irregularities or wastefulness in harvesting, should be reaped. The mode of reaping called bagging, and practised a good deal about London, and part of the west of England, is thus executed—The left leg being pushed into the standing corn, and the straw inclined with the left hand over the left foot, is then cut close to the bottom with a stroke from the right hand. The increase of straw, where this is valuable, renders this a good method of reaping.

In England the mode of reaping varies with the nature of the crop. Barley and oats are generally cut with the scythe, beans with the sickle; peas with what are called faggings-hooks, which rather tear up than cut; and tares in the same way.

Reaping is a great part of the expense of a crop. The average price in England is from 1s. to 1s. 6d. an acre. See Bands, Barley, Harvesting, Wheat, &c.

REAPING-HOOK. An implement used to cut down corn. It is one of the oldest instruments employed in husbandry. There are two kinds of hooks; that which is principally used by the British labourer has a smooth blade of wrought iron and steel, about 25 inches long, and curved nearly to a semicircle; the other, which is universally preferred by the Irish reaper, has a finely serrated edge, and towards the lower point recedes from the curved direction to nearly a straight line. The real action of the reaping-hook is that of a saw, consequently the serrated edge is an advantage. See Sickle.

REAPING MACHINE. A contrivance for the purpose of reaping grain by means of animal labour. With this view, and to facilitate an operation of such importance to the farmer,
REAPING MACHINE.

different attempts have been made to construct machines, so as to despatch the work in a rapid manner by the assistance of horse labour, but the success with which they have been attended in England has hitherto been far from complete.

Many contrivances have also, of late years, been resorted to for supplying the place of the reaping-hook, but hitherto none have proved effectual, nor are the difficulties arising from roughness and irregularity of surface likely soon to be removed. No one will dispute the great utility and advantages of an efficient reaping machine, if it could be carried into operation, as these advantages are universally acknowledged. In England, such an implement is the more required now that the agricultural labourers are greatly reduced in number by emigration, and harvest work has become more expensive. There is now a much greater quantity of corn to cut down, and most of the grain ripens about the same period. In 1815, Mr. Smith, of Deanston, invented a reaping machine, which, in some experimental trials appeared to perform the work exceedingly well; but, upon longer trial, it has not answered the favourable expectation formed of it. Since that period, another invention of a similar nature, by Mr. Patrick Bell, has attracted considerable attention, but does not appear to be of sufficient merit to have come into general use. The original cost of these machines, 40l. or 50l., must, in many instances, preclude their employment.

An excellent article on the advantages of a reaping machine will be found in the first volume of the Quart. Journ. of Agr. p. 137; and Mr. Bell's machine is illustrated and described at p. 217 of the same volume.

American ingenuity has been active in the invention of machines for harvesting wheat and other grains. Among those which have been brought into the field, "Wilson's Moving Machine, or Grass and Grain Cutter," is highly commended by some who have tried it. It has been most in use along the Hudson river, and is considered an improvement of Smith's English reaping machine.

But the machine that is perhaps best entitled to the notice of farmers, is the one invented by Obed Hussey, which is recommended for its simplicity, durability, and the great regularity and cleanliness with which it performs its work. Even when the grain is too much lodged to be cradled, it will cut at the rate of two acres per hour, nearly as clean as if it had been standing. It can be adapted to the inequalities of the surface of a field, and has been so improved by its original inventor as to operate with great facility on stony land. This machine has received the most unqualified approbation of nearly all farmers who have tried it, or witnessed its operation. The Board of Trustees of the Agricultural Society for the Eastern Shore of this country, in their Report made in 1836, say, "We deem it a simple, strong, and effectual machine, and take much pleasure in awarding unanimously the meritorious inventor of it (Mr. O. Hussey) a handsome pair of silver cups."

The committee appointed by the Philadel-

phia Society for Promoting Agriculture, to superintend the operation of Mr. Hussey's machine, make a very favourable report, recommending it to the attention of the society and the agricultural community generally. They state that it was put in operation in a piece of several acres of heavy wheat, considerably lodged, and, contrary to their expectations, it performed remarkably well.

"The committee estimate the ordinary performance of the machine at from ten to twelve acres per day; although they fully believe, that on an emergency, it would accomplish twice this amount of work. In confirmation of this they would state, that it cut, on this occasion, 630 square yards in 2 minutes, doing its work in the most perfect manner." The cost of the machine is $150. (See Farmer's Cabinet, vols. ii. and iii., Cultivator, and other American agricultural periodicals.)

McCormick's Reaping Machine is used in Virginia, and spoken of very favourably by the editor of the Southern Planter, who has furnished a cut of it, and makes the following statement of one of that excellent periodical for January, 1843.

It is said to cut 15 acres per day without leaving a single stalk in the field, and some think the wheat saved in harvesting a large crop will more than repay the first cost of the machine. It weighs about 600 lbs., rests upon two wheels, and is drawn forward by two horses. The cost of the machine is $100.

A machine for harvesting grain has been invented by G. G. Carpenter, of Caledonia, New York, which not only reaps the crop, but threshes it out. In speaking of his machine and its merits, Mr. Carpenter observes, that the great saving in grain and labour is in finishing the work without laying the grain on the ground. It may be gauged to cut as high as the grain will admit, and the 9-feet swath streams from the cradles to the thrasher so evenly, that no more power is required to finish 15 to 20 acres a day than is necessary to drive a common thrasher, which only threshes say 200 bushels in a day, with many hands in attendance." This machine costs $600. The hands required to attend it are, one to drive the team, and one to take care of the machine. (See Cultivator, vol. vii.)

Other labour-saving contrivances for harvesting grain have been invented in the United States of late years, descriptions of which may be found in various agricultural periodicals.

RED BAY (Laurus Carolinensis). An American species of the laurus genus found in the Southern States. (See Michaux's North American Flora, vol. ii. p. 150.)

RED BUD. See Judas Tree.

RED GUM. A disease of grain, a kind of blight. See Brium.

RED-ROOT (Lathospermum araeace). Stoneweed. A worthless plant which has been introduced into the United States, where it has spread itself extensively, especially in some parts of New York, where it is considered even a worse pest of the fields than the Canada thistle. Dr. Darlington describes the plant as being hispid, or beset with bristle-like and rather short hairs; the root annual; stem 12 to 18 inches high, generally much branched from
the root, and often branched near the summit. Leaves 1 to 2 inches long, and ½ to ¾ wide, without stems, narrowed at the base, and spear-shaped flowers, which show themselves in May in the Middle States, have yellowish or milk-white and rather small corollas. The seed nuts are ovoid, with tapering points, rough, wrinkled, and brown, when mature. When this formidable weed, which is the pest of the northern wheat-crops, first appears in a field, it may be removed by carefully pulling it up while in flower, and thus preventing it maturing seed and propagating itself. Where it once gets possession, it is exceedingly difficult to destroy, as the seeds will lie many years in the soil without coming up, in this respect resembling those of charlock or the wild radish and mustard. One of the best methods of treating it, says the editor of the New Geneuce Farmer (vol. i. p. 93), is to harrow, or lightly plough the wheat-stubble immediately after harvest, to cause the fallen seeds to vegetate, and destroy the young plants the next season by summer crops, which should be repeated for a year or two, when the land may be summer fallowed for wheat. Successive crops of buckwheat are said to be admirably effective.

RED-ROOT (Cannothus Americana). New Jersey tea. A plant with a large, red, perennial root, found in the United States. The stem grows 2 to 4 feet high, and is branched. It possesses considerable astrangency, and during the revolutionary war the leaves were substituted for tea.

RED-ROOT (Skunkwariia Canadensis). The generic name is derived from the colour of the sap, which resembles blood. This American plant, which abounds in the forests, is variously called puceoo root, turmeric, and Indian paint. The root is perennial, with fibres attached to a reddish, horizontal stem, about 2 or 3 inches long and ½ an inch thick, growing under ground. It possesses emetic and other medicinal properties. It is the only species of its genus.

RED SPIDER (Acakes). A well-known pest of gardens. It may be destroyed by application to plants of whale-oil soap, in the manner directed in the destruction of plant-lace. See Aphids.

RED TOP. See Herd's Grass.

RED TOP, TALL (Triticeps Seklerioides). A perennial grass, found in the Middle States, on dry banks and sterile fields, flowering in August and September. It has an erect, jointed culm or stem, 3 to 4 feet high and very smooth. Pursh calls it “a most excellent grass,” and says he has seen “most excellent crops” of it, in the mountain meadows of Pennsylvania, where they mow it twice a year. Such crops may possibly pass for “excellent” in mountain meadows; but, observes Dr. Darlington, they would be not so considered in Chester county. If Mr. Pursh has not misapprehended the fact, he is certainly mistaken in the character of the plant; for it is a dry, rigid grass, with unusually hard culms, and altogether unfit for making grass hay. It is the only species of the genus in the United States. (Flor. Cent.)

RED-WATER. In Britain, a well-known disease in cattle. “The disease commonly called red-water, brown-water, black-water, moor-ill, &c.,” says Mr. R. Thompson, of Auchterarder, “is most prevalent in old, foggy pastures. It is seldom seen in hill pastures, or in new-sown pastures, in which there is abundance of clover; but it sometimes happens at the stall, where the animal has no other allowance than straw, turnips, and potatoes. It usually makes its appearance after a few days of rain, followed by cold, dry weather. As the disease appears at times in all situations, it is difficult to trace its existing cause, which may be the nature of the pasture, or the state of the weather, or both which is aimed. It attacks every breed and kind of cattle.

“The first symptom is the appearance of something like blood mixed with the urine. So trifling is the complaint in some instances, that no inconvenience seems to be felt by the animal, who eats and drinks as usual, chews the cud, and is free of the disease in a few days. In such cases a natural diarrhoea comes on, to which the cure may be attributed. In general, however, the disease is not observed until the animal refuses food, separates from the rest of the herd, appears dull and heavy, and manifests great languor and apathy. The urine droops, the urine is of a reddish or brownish colour, and if it be a milch cow, the milk is often similarly tinged. The pulse ranges from 60 to 70; there is obstinate constipation of the bowels; the urine is discharged in moderate quantity, and apparently without pain. If relief is not afforded by some brisk purgative, at the period when the urine changes colour from red to brown, the pulse begins to sink, and if a little blood be drawn at this time, its surface assumes a brownish colour; the eye appears of a yellowish-brown tint; the urine acquires a darker hue; the animal refuses to rise; the pulse sinks; the legs, tail, and horns turn cold; and the animal dies, to all appearance perfectly exhausted, although it has manifestly no symptoms of acute pain during the course of the disease.

“Purgatives of any kind, if given in large quantities of water, are found to be the best medicines that can be employed. Medicines given to cattle that have lost the power of chewing the cud, generally pass into the first and second stomachs, and if a good draught of water is not given to wash them from thence, if the animal dies, the greater part of the medicines will be found in these stomachs; and upon this principle, common salt, if properly managed, will be found among the best. Dissolve the quantity to be given in as much water as will enable it to pass freely from the bottle or drenching horn, and let the animal have plenty of water to drink afterwards. Should it refuse to drink, no time should be lost in drenching it profusely with water. Without a plentiful dilution, there is no certainty of purging cattle that have lost their cud. If purging does not commence in from 12 to 24 hours, a second dose should be given. Injections of strong castor oil should also be tried, if the case is obstinate, and when they operate, a pint of linseed oil should be given as a laxative. So obstinate is the constipation in some cases, that the salt acts only as a diuretic,
causing a plentiful discharge of urine. Diuretics and astringents combined seem only of service when the bowels are open, and their improper administration often causes inflammation of the bowels and kidneys. If, after purgation, the bowels are kept open by laxatives, such as linseed infusion, the disease will gradually disappear without their use. In the last stage of the disease, when the urine assumes a dark-brown or black colour, no remedy seems to have any efficacy; the animal is sunk beyond recovery, the bowels lose their action, suppression of urine follows, the animal stretches itself out and dies, as if perfectly exhausted.

"There are two diseases which in their symptoms bear some resemblance to red-water in cattle, viz., inflammation of the kidneys, and inflammation of the mucous membrane of the bladder or the urethra, which often happens at calving. In these cases the urine, which is discharged with pain, is mixed with blood, but not necessarily so in the case of true red-water, and it has generally more or less mucus mixed with it. Inflammation of the kidneys in cattle is comparatively rare. I have seen only one well-marked case, which terminated fatally. The animal experienced considerable pain upon pressure being applied to the region of the kidneys. The urine was small in quantity, and nearly as thick as blood; and pulse ninety and very hard. As the disease advanced, the urine became black and fetid. The animal all along exhibited symptoms of excoriating pain, until death terminated its sufferings. In most cases, the animal has disclosed extensive inflammation of the peritoneum. The abdominal cavity contained a large quantity of dark-coloured, fetid fluid; the fat surrounding the kidneys, as well as the kidneys themselves, was in part gangrenous; and the fat generally exhibited a yellow colour, as is usual in cases where death terminates inflammatory diseases." (Trans. High. Soc. vol. ix. p. 9.)

REED (Arundo). A genus of aquatic plants, in most instances mere weeds, infesting boggy low lands or meadows on the sides of rivers.

The best method of destroying reed beds is by draining the land; for if the drains be cut deeper than their roots, it will take away their nourishment, and consequently destroy them. Common salt, ashes, or soot, will likewise sometimes kill them; and so will ploughing up the land, and laying it in high ridges. Reeds always indicate a deep, good, moist soil, as a bad one will not nourish or support them. See Arundo, Aromatic Reed, and Bent or Stair.

The term reed is sometimes provincially applied to the straw of wheat, rye, &c., that has not been bruised.

REED-GRASS. See CANARY-GRASS.

RENNET, or RUNNET. The prepared inner membrane of the calf's stomach, which has the property of coagulating the albumen of milk, and converting it into curd and whey. The maw is cleaned, salted, and suspended in paper bags. Previously to its use, the salt is extracted by washing the rennet; which is then soaked in hot water during the night; and in the morning the infusion is poured into the milk to coagulate it. This is the result of the gastric juice, which is acid; and acts upon the caseous part of the milk, in the same manner as other acids. It sometimes happens that no rennet sufficiently good for curdling milk can be procured; hence various plants have been advantageously substituted for this purpose. The principal of these are the flowers of the yellow ladies' bedstraw (Galium verum), used in England, and the cardoon (Cynara cardunculus), in Spain. A strong infusion is made of the down of the latter vegetable in the evening, and on the succeeding morning a pint is poured among 14 gallons of new milk, which is thus effectually coagulated, and in consequence produces a delicious cheese. See CHEESE and CHEESE RENN ET.

RENT (Reddita; from redendo). The sum of money or other consideration issuing yearly out of lands and tenements paid by the occupier to the owner. This, in Britain, has generally been the usual mode of payment, whether in money, from a very different original tenantry; for, in former days, the land was generally held of the superior lord, by certain services rendered, of either a military or servile nature, such as carrying out the lord's manure on to his land; certain days of ploughing, digging, or cutting the corn, &c. of the landlord; the general adoption of a fixed rent or money payment in lieu of these arbitrary and vexatious tenures, was an advance of modern days.

RESERVOIR. A conservatory of water. The husbanding of water is now becoming a subject of peculiar importance to agriculturists. This arises from its scarcity in many districts, in consequence of the improved drainage of the land, and from the many uses to which machinery may be applied in farming operations by the agency of water power. The construction of reservoirs must resolve itself into the following heads:

First, where a sufficient quantity of water can be diverted directly from the channel of a stream or river.

Second, where the supply is to be obtained from drainage, which maintains a stream during part of the year, but to which stream falls during the summer months.

Third, where there are grounds affording a favourable situation for the construction of a reservoir, but through which there is no natural stream passing. See PONDS and TANKS.

RESINS. Peculiar vegetable substances of allied properties, composed of carbon, hydrogen, and oxygen; the most common of which is the rosin of commerce, or residue after the distillation of turpentine, in order to obtain the volatile oil. When no water is used in this process, an empyreumatic, brownish-yellow, semi-transparent substance remains, namely, colophony or felter's rosin; when water is used, the residue is the opaque yellow substance called yellow rosin. When every particle of water is evaporated from the last, and it is kept in a state of fusion at a moderate temperature, and then allowed to cool slowly, the best resin is procured. It is translucent, brittle, fusible at a moderate heat, inflammable, and soluble in spirits of wine, volatile oils, and
also fixed oils and fat, when aided by heat. The mineral acids convert it into artificial tannin; the alkalies into soap. Resin in combination with wax, a little oil of turpentine and wax, forms a good polish for furniture. Resin contains oxygen 13-337, carbon 75-944, hydrogen 10-719. The chief of the other resinous substances are elemi, copal, mastic, sandarac, lac, labdanum, amber, &c. They are almost all soluble in alcohol.

REST-HARROW. (Ononis, from onos, an ass, and ononi to delight; some of the species are said to be grateful to asses). All the plants belonging to this genus are of easy cultivation and several of them are rather handsome when in flower. The common rest-harrow or cammock (O. arvensis), is a native plant, with a woody, tough, and strong root, resisting the harrow's prongs, whence the English name. The stems are annual, though often considerably woody or shrubby, various in length, hairy. Leaves generally simple, entire towards their base. Flowers mostly solitary, large, and handsome, of a brilliant rose colour. See Pl. x. a.

RHIZOMA (Lat. Risza, a root). A term applied to roots which spread under ground, like those of the iris.

RHODODENDRON (From rhodo, a rose, and dendron, a tree, because of the appearance of the terminal bunches of flowers). The rhododendron is decidedly one of the finest of all known genera, containing some of the most handsome, elegant, and showy shrubs; all of which are admirably adapted either for ornamenting the green-house or shrubbery, or for planting singly on lawns. Peat soil is most suitable to these plants, but they may also be grown in very sandy or vegetable mould. They are propagated by layers or seeds. The small-wooded kinds may be also increased very freely by young cuttings, planted in sand, under a glass.

The species found in the United States are, the Rhododendron nudiflorum, or naked-flowered rhododendron, commonly called the wild honey-suckle, a beautiful American shrub found in the Middle States, frequent in woodlands and thickets, where it blooms from April to May. The flowers are of various shades, from very pale to bright purple. There are apparently several varieties of this beautiful flowering shrub. The leaves are subject to large green excrescences, produced by the puncture of insects. See Azalea.

Rhododendron viscosum, clammy rhododendron, or sweet white honeysuckle, a fragrant, pretty species, with very clammy white flowers, found in rocky woodlands in the Middle States, flowering in June. The stems grow to the height of 4 or 6 feet, with numerous short and crooked branches. See Azalea.

The Rhododendron maximum, or dwarf rose bay, forms a magnificent ornament of the American mountain forests. It generally presents itself in the form of a shrub, of less than 10 feet in height, although it occasionally attains an elevation of 20 to 25 feet, with a diameter of 4 or 5 inches.

RHUBARB (Rheum rhaponticum, from iow, to spread, and Rheum hybridum). A hardy perennial plant, a native of Asia. The leaves are very broad, and 9 feet long. Their petioles or stamks are large, and these only are used. They are agreeably acid and vinous, very wholesome, and much admired, whether stewed alone with sugar for tarts, and puddings, and pies, or combined with other fruits. Its use with us is fast increasing, and although its introduction to the London market did not take place, it is said, till 1815, yet now, we are told, a thousand cart-loads are there annually sold. The soil best suited to these plants is one that is light, rich, deep, and moderately moist. A poor heavy or shallow soil never produces them in perfection.

It may be propagated by cuttings, but the mode almost universally practised in England is by seed. This should be sown soon after it is ripe in September or October, for if kept out of the ground until the spring, it will often continue dormant for twelve months; if the danger of this, however, is risked, it must be inserted early in February or March. The seeds are best inserted in drills 3 feet apart and an inch deep, the plants to remain where raised; for although they will bear removing, yet it always checks and somewhat lessens their growth. When they make their appearance in the spring, and have been thoroughly cleared of weeds, they may be thinned to 6 or 8 inches asunder, and the surface of the ground about them loosened with the hoe. Towards the conclusion of summer, when it can be determined which are the strongest plants, they must be finally thinned to 3 or 4 feet, or the hybrid to 6. They must be continually kept clear of weeds. In autumn, when the leaves decay, they are removed, and the bed being gently turned over, a little well-purified stable-dung added, and some of the earth applied over the stools. In the spring, the bed may be again dug, previous to the plants making their appearance; and as the stools, when blanched, are much less harsh in taste, require less sugar to be rendered palatable, and are greatly improved in appearance, at this period a trench may be dug between the rows, and the earth from it laid about a foot thick over the stool. This covering must be removed when the cutting ceases, and the plants allowed to grow at liberty. As the earth in wet seasons is apt to induce decay, the covering may be advantageously formed of coal-ashes or drift-sand, which are much less retentive of moisture. Those plants produce the seed in greatest perfection that are gathered from, but on no account must they be subjected to the process of blanching. Two year old plants often produce seed, but in the third year always. It must be gathered as soon as ripe, and great care taken that none is scattered over the beds, for the plants then produced often spring up and greatly injure the old plants by growing unobserved amongst them.

Varieties.—1. Buck's new early Scarlet Rhubarb.—A new and beautiful variety, and very early. The stalks and the juice are of a beautiful red colour, and quite as high-coloured as the juice of red currants, and of excellent flavour. Fit for use, in our climate, in April.

2. Tobolsk.—A new and very superior variety; the earliest of all the early, not excepting, perhaps, Buck's Early Scarlet. The stalks
RICE.

are of a beautiful pink colour, and of excellent flavour. Originated in England by Mr. Youle, and fit for use here in April.

3. Dulley's Goliah.—A new variety, which grows to a very large size.

4. Dulley's Admiral.—A variety of a still more recent date, and remarkably large.

5. Elfort Rhubarb (Var. Undulata).

6. Giant Rhubarb.—A new and large species.

7. Widnet's Early Red.—Early and fine, with red stalks.

8. Mynta's Victoria.—A magnificent production, with leaves and stalks of enormous size, exceeding, in this respect, all other varieties: New, and of excellent quality.

9. Australian Rhubarb (Rheum Australe).—A new variety and valuable acquisition; later in its vegetation than any other kind; it also continues to grow vigorously, and to furnish a supply of leaves long after all other varieties are gone, or till hard frosts. By protection and a frame, it lasts till January. The flavour of Rheum Australe resembles apples; and, though thought by some to be more medicinal in its effects than other sorts, yet those who have used it for years have never found it prove injurious.

Young seedling plants only need to be protected the first winter by soil. Rhubarb may be forced very early, by being covered with boxes or barrels, surrounded by horse-manure at the top and sides. The rhubarb is highly deserving of cultivation by every family.

Rhubarb Wine.—The leaf-stalks of green-coloured rhubarb, being cut in pieces as for tarts, and bruised with a mallet to extract the juice, will make a delicious wine, quite equal to green gooseberry wine, and very closely resembling Champagne. Of the red rhubarb a fine red wine is made.

Rhubarb Jam and Jelly.—A superior jam or jelly is thus made from the tender leaf-stalks of rhubarb, equal or superior to that from currants, and of excellent flavour. To one pound of the stalks, cut as for tarts, add one pound of leaf or brown sugar; boil till the ingredients acquire a proper consistence. Unground ginger and lemon peel added to the jelly have been found a decided improvement. Buck's early scarlet rhubarb has a preference in point of colour, which is beautiful red; it is also of fine flavour, though not, perhaps, superior in this respect to other varieties. Rhubarb will answer for jelly three months before the currant is ripe. An excellent preserve is also made of rhubarb. For this purpose the stalks are cut into inch pieces, and preserved in the usual way with sugar. (Kerriick.)

RHUS (Derived from ross, in Greek, which is from rhudd, a Celtic word, signifying red; alluding to the colour of the fruit and leaves of some species in autumn). The hardy kinds are rather ornamental, and well fitted for shrubbery; some are propagated by cuttings of the roots, and others by cuttings and layers. The juice of R. radicans, poison or swamp sumach, and R. toxicadron, poison vine or poison oak, is milky, stains black, and is extremely poisonous. R. coriaria is powerfully astringent, and is used in tanning Turkey or Morocco leather.

RIB-GRASS. See Plantain.

RIBBON-GRASS (Phalaris). The variety of the genus Phalaris called picta, from its striped leaves, is found in gardens and yards as an ornamental plant. From its tendency to strike deep roots and spread, it often becomes troublesome to eradicate. The species called reed-like or American Phalaris, is common in swampy places in the Middle and Northern States. When, says Dr. Darlington, the panicles of this plant first appear, they have some resemblance to those of orchard grass; but it thinks it far inferior to the orchard grass, and is not so much of an aquatic for regular culture. Another species, the Phalaris canariensis, or wild canary grass, is particularly naturalized in some of the Northern and Eastern States, where it produces crops of the greatest luxuriance. It is perennial, spreads rapidly, and may be easily propagated by transplantation.

RICE (Oryza, from the Arabic word ēruz, the Greeks coined their word ὡριζ, and the various modern nations of Europe their riz, rīz, risko, &c.). O. sativa, the common rice, has the culm from 1 to 6 feet in length, annual, erect, simple, round, jointed. Leaves subulate-linear, reflex, embracing, not fleshy. Flowers in a terminating panicle. Calycine leaflets lanceolate. Valves of the carolla equal in length; the inner valve even, awnless; the outer twice as wide, four-grooved, hispid, awned. Style single, two-parted.

O. nucifera, the dry or mountain rice, cultivated in Ceylon, and of late in Hungary, has the culm 3 feet high, and more slender. Fruit longish, with awas the longest of all. It is sown on mountains and in dry soils; roots with a long inundation, and perishes with sea-water. The varieties of rice, as of other cultivated grain, are as numerous as the different soils, climates, and other physical circumstances, in which it is cultivated: besides the dry rice, the chief sorts, by some considered species, are the O. procera, or early rice, and the O. glutinosa, or clammy rice, both cultivated in irrigated lands.

The native place of rice, like that of the other sorts of grain in common use, is unknown; it is cultivated in great abundance all over India, where the country will admit of being flooded; in the southern provinces of China, in Cochin China, Cambodia, Siam, Japan, &c. In Japan it is very white, and of the best quality. It has also been introduced into cultivation in the southern kingdoms of Europe, Italy, Spain, the south of France, and within a few years into Hungary and Westphalia. In Carolina it has long been a staple commodity. Houghton's account of its introduction there is, that Ashby was encouraged to send a hundred pound bagful of rice to that province, from which, in 1698, 60 tons were imported into England. Dalrymple says, that rice in Carolina is the result of a small bag of paddy, given as a present from Duham, treasurer of the East India Company, to a Carolina trader. A Dutch vessel also, from Madagascar, brought rice into the same province; and this is attributed having their having two kinds.

In the hilly parts of Java, and in many of the Eastern islands, the mountain rice is planted 4 L 949.
upon the sides of hills, where no water but rain can come; it is, however, planted in the beginning of the rainy season, and reaped in the beginning of the dry season. The natives call it *Paddy Gumng*, which signifies mountain rice. It is entirely unknown in the western parts of India, but it is well known in Cochin China, where it thrives in dry, light soils, mostly on the sides of hills, not requiring more moisture than the usual rains and dews supply, neither of which are frequent at the season of its vegetation.

There is a kind of hill rice which is hardy enough to grow on the edge of the Himalayan snows. This, it may be expected, will, at some future time, prove an acquisition of value to the European and American cultivators.

Rice is extensively cultivated in the East Indies and China, chiefly on low grounds near large rivers, which are liable to be annually inundated, and enriched by the deposition of mud. According to Sir George Staunton's account, the Chinese obtain two crops of rice in a year from the same ground, and cultivate it in this way from generation to generation on the same soil, and without any other manure than the mud deposited by the water of the river used in overflowing it. After the waters of the inundation have withdrawn, a few days are allowed for the mud to get partially dry; then a small spot is enclosed by a bank of clay slightly ploughed and harrowed, and the grain, previously steeped in dung, diluted with animal water, is then sown very thickly on it. A thin sheet of water is immediately brought over it, either by a led stream, or the chain-pump. Thus a seed-bed or nursery is prepared, and, in the mean time, the remainder of the tract is preparing for being planted. When the plants are 6 or 7 inches high, they are transplanted in furrows made by the plough, so as to stand about a foot apart every way; water is then brought over them, and kept on till the crop begins to ripen, when it is withheld; so that when harvest arrives the field is quite dry. It is reaped with a sickle, threshed with a flail or the treading of cattle, and the husk taken off by beating it in a stone mortar, or passing it between two flat stones, as in a common meal mill. The first crop being cut in May, a second is immediately prepared for by burning the stubble, and this second crop ripens in October or November. After removal, the stubble is ploughed in, which is the only vegetable manure such lands can be said to receive from man. In Japan, Ceylon, and Java, according to Thunberg, Davis, and Raffles, aquatic rice is cultivated nearly in the same manner. Mountain-rice is grown much in the same way as barley.

In Lombardy and Savoy rice is sown on rich lands, the sower often wading to the knees in water: one crop a year only is obtained; but four crops are often taken in succession. In America a similar practice obtains.

In Westphalia, and some other parts of the south of Germany, rice has long been cultivated; there it is sown on lands that admit of irrigation; but the water is not admitted till the seed has germinated, and it is withdrawn, as in Italy, when the crop comes into flower. From long culture, in a comparatively cold country, the German rice has acquired a remarkable degree of hardness and adaptation to the climate; a circumstance which has frequently been alluded to as an encouragement to the acclimating of exotics. It is found, Dr. Walker remarks (*Essays on Nat. Hist.*), that rice seeds direct from India will not ripen in Germany at all, and even that Italian or Spanish seeds are much less early and hardy than those ripened on the spot.

In Hungary rice has not been long cultivated: the mountain sort has chiefly been tried, and that in the manner of our barley or summer-wheat.

In England a crop of rice has been obtained near Windsor, on the banks of the Thames. By far the best imported rice is that from Carolina: it is larger and better tasted than that of India, which is small, meager, and the grains frequently broken. As an article of diet, rice has been extolled as superior almost to any other vegetable: but whatever it may be in warmer climates, where it is a common, and to many persons almost their only food, it does not appear so well calculated for European constitutions as the potato; for we find that the poor constantly reject the use of rice when potatoes are to be had; and whilst these can be obtained, we may venture to predict, that rice will always be considered, in Britain, rather as a dainty, to be eaten with sweet com diments, spices, fruit, &c., than as ordinary food. *London's Ency. of Plants.*

The mountain rice has been raised in Maryland by Mr. Bordley, on dry sandy land. The following comprehensive directions respecting the water culture of rice, were furnished by one of the most successful cultivators in South Carolina:

Begin to plant about the 25th March, trench shallow and wide, and scatter the seed in the row; make 72 or 75 rows in a task, and sow 2 bushels to an acre.

1. Hoe about the end of April or beginning of May, when the rice is in the fourth leaf; then flood, and clear the field of trash. If the planting be late, and you are likely to be in grass, flood before hoeing; but hoeing first is preferable. The best depth of flood is 3 or 4 inches. It is a good mark to see the tops of the rice just out of the water; the deep places are not to be regarded; the rice will grow through in 3 or 4 days. Observe to make a notch on the frame of the trunk, when the water is at a proper depth: if the rains raise the water above the notch, or it leaks out, add, or let off accordingly. This is done by putting a small stick in the door of the trunk, about an inch in diameter: if seum or froth appear in 8 or 10 days, freshen the water, take off the trunk doors, run off the water with one cbb, and take in the next flood; then regulate as before. Keep the water on about 15 or 17 days, according to the state of the weather; that is, if a hot sun, 15 days; if cool and cloudy, 17 days, counting from the day the field is flooded; then leak off with a small stick for 2 days, then run off the whole, and keep the field dry. In 4 or 5 days after, hoe the second time, stir the ground, whether clean or not, and comb up the fallen
Rice, Wild. Rollers.

Rice with the fingers. Keep dry and hoe through the field. Hoe the third time and pick clean. This will be about the beginning of July. Then flood as you hoe. Let the water be the same depth as before. If any grass has escaped, it must be picked in the water after it shoots out. This is called the fourth hoeing, but the hoe is never used except for high places or to clean the damps. If the rice is flabby and likely to lodge, flood deep to support it, and keep it on until fit to harvest. (Domestic Encyclopaedia.)

If land is well drained and in good order, it is calculated that 5 acres of rice and 1 or 1½ of provisions may easily be cultivated to the hand.

Rice was formerly almost altogether exported in the form of clean rice, but at present the largest amount of that taken to England is in the husk or rough state, called dry or cargo rice. The rice crop for 1842 has been estimated by Mr. Ellsworth at 94,007,484 pounds.

The following statement shows the annual quantities and value of rice exported from the United States at different periods:

(Hunt's Merchants' Magazine, July, 1842.)

RICE WEEVIL. See Grain Weevil.

RICE, WILD (Zizania). Nutall mentions three species of aquatic grasses, called wild rice, found in the United States, viz.: the Zizania aquatica (Pl. 4, 4); Z. millicola; and the Z. fluitans. This last is very small and easily confused with other aquatic grasses. He found it around Savannah in Georgia.

The Z. aquatica is found in almost every part of the Northern and Middle States, where it goes by the names of water oats, Indian rice, and reed. The seeds resemble those of Polish millet. It is exceedingly prolific. The root is perennial. It grows in swampy places, and in deep water at the edges of ponds and sluggish streams. Stock of all descriptions are food of the plant when green, or cured as hay. It resembles, at a distance, slender shoots of Indian corn. The stems are jointed, and as large as the little finger. The panicle or head is a foot or more in length, and the seeds blackish, smooth, narrow, cylindrical, about three-quarters of an inch long, white and farinaceous within. Gillette's Ohio and Mississippi Pilot contains the following interesting details relative to wild rice: "Among the vegetable productions of the Western Territory north of Illinois and west of Green Bay, on the Ohio and Mississippi, and Fox rivers, the wild rice, called Folio cavo, by the French, and Monowen by the Indians, claims particular attention. It grows in inexhaustible abundance, through all parts of the territory, in almost every one of the innumerable lakes, ponds, bays, rivers, and creeks. It is said to be as palatable and as nourishing as common rice, and if so, it will be incomparably more valuable. It grows where the water is from 4 to 6 feet deep, and where the bottom is not hard or sandy. It rises above the surface of the water from 4 to 8 feet, and is often so thick as to prevent canoes from passing through or among it. The stalk is soft like the bulrush, but grows in joints like reed-cane, which it much resembles. It is usual for the Indians to force their canoes through it, just before it ripens, and tie it in large bunches for the purpose of preventing the wild ducks and geese from breaking it down and destroying it. When fully ripe, they pass through it again, and, spreading their blankets in the inside of their canoes, they bend the branches of the wild rice over them, and thresh off the grain with sticks; an operation which requires little time, and is generally performed by the women. After drying it in the sun, they put it into skins, for future use. Every autumn and spring the wild ducks and geese resort to the wild rice lakes in flocks incredibly numerous. It is thought by many that the Zizania aquatica will some day be an object of culture, which may afford a means of bringing into use large tracts of inundated land."

RICK. A pile of corn, hay, straw, &c., regularly heaped up in the open air, and sheltered from wet by thatch. See STACK.

RIDDLE. A sort of sieve used to separate dust and the seeds of plants from corn. They are made of various sizes for different uses.

RIGGIL. An imperfect male sheep, having only one or no testicle in the scrotum.

RIME. A hoary or white frosty appearance, sometimes on the ground in the autumnal, winter, and early spring mornings. See Dew and Frost.

RING-BONE. In farriery, a callus growing in the hollow circle of the little pastern of a horse, just above the coronet. It has its name from the resemblance to a ring.

RINGS, FAIRY. See Fairy Ring.

RIPPLE GRASS. A popular name of the English plantain (P. lanceolata).

ROADS. See Highways.

ROARING. In farriery, a disease well known to jockeys and horse-dealers, which usually accompanies or precedes bruising wind. It is generally divided into two sorts, the result of long-continued or violent exercises. It is connected with dilatation of the air-cells of the lungs, and is incurable. See Broken Wind.

ROCHAMBOLE. See Garlic.

ROCK CRESS. See Cress, Wall.

ROLLERS. An implement of simple construction, like the roller, the main object of which is to render smooth the surface of arable lands, would not seem to admit apparently of much variety in its construction. Nevertheless, it is an implement in which greater diversity of form is found to exist than in most other agricultural machines. Rollers are of all sizes, weights, and lengths; and the material of which they are made is occasionally iron, sometimes stone, but most commonly wood. Of these, the first is undoubtedly the best, and particularly for the jointed roller, by which the operation of turning at the ends of the ridges is materially facilitated, and the slading of the earth which would otherwise take place on the head-lands, not only to their great detriment, but to the no small increase of labour to the horses, is thereby prevented.

An ingenious gentleman, the late George
Booth, Esq., of Allerton, near Liverpool, who to a great love of farming added a very tolerable share of mechanical skill, and to both ample means to carry out his various devices, constructed a roller, or rather a nest of rollers, on the lever principle. He contended for a very small diameter as the most effective in crushing the clods, and throwing the greatest possible weight on the surface of the ground. We regret being only able to give an idea of his invention from memory, but do not think his roller was more than a foot in diameter at the outside. It consisted of five cylinders or rollers, arranged in such manner that three hind ones, separated from each other, have the two spaces overlapped by two cylinders placed in front.

Drill rollers.—These are made of rings adapted to a shaft. They are not by any means of modern invention, having been well known to the English farmers of Norfolk and Suffolk for the greater part of a century. The only improvement they have undergone has been to render each ring independent of its neighbour, so that the process of turning at the end of the field is facilitated, as in the case of the jointed roller. The modern drill rollers in other respects have not improved, if the doctrine of Mr. Booth, already noticed, be correct, that a small diameter is better than a large one. The drill roller is used for the double purpose of crushing clods on rough lands, and making grooves ready to receive the seed of wheat or other grain sown broadcast on light soils. It is a capital tool for either purpose. In the first case it is followed by a harrow, of sufficient weight to lighten up the surface; in the other, the fine, short-toothed harrow, or even a mere bush-harrow, will be found sufficient. The less such land is disturbed after sowing the better, and the more distinct will be the several rows or grooves of corn.

Heavy rollers.—The heavy roller is a very effective implement. It is formed of 3 separate cylinders, about 2 feet in diameter, and of the same length; the axis of each being independent of the other. On turning, they consequently revolve in different directions, and thus “sliding” at the land’s end is avoided.

The double-jointed barley roller is a very useful implement. It is so constructed that the two sides, being separate rolls or distinct frames, may revolve at opposite angles; and, when required, one may be placed behind the other. A plan has for many years been in use in Norfolk, of constructing them with twisted joints, so that the under end of one roll shall work behind the end of the other, thus leaving no seam between the roller.

Crosskills’ clover-crusher is, under many circumstances, a valuable implement. It is composed of a series of iron rings, with notched edges, set apart from each other about 3 or 4 inches. Small cross-bars or knives are placed at frequent intervals on the faces of these, and near their outer notched rims, so as to intersect every portion of land over which it passes. Its construction, combined with its great weight, renders it very effective for the purpose which its name denotes. Indeed, as an old farming bailiff once aptly remarked, it is a roll and a harrow combined. The roller is an implement which requires some judgment as to the time of its use, and this remark applies with increased force to the one under consideration.

Seam or land-presser.—If a drill is so effective an implement, far more so is the seam or land-presser, inasmuch as its whole force and weight is directed to each individual furrow, as it is turned over by the common plough. The seam-presser is in fact an abstract of a drill roller, consisting of but two cylinders of cast-iron, which, following in the furrow, press and roll down the newly turned-up earth, and it is more particularly useful when applied to clover stubbles intended for wheat. (Ransome on Agr. Imp.)

In the United States the roller is constructed of wood, stone, or cast-iron, according to convenience or the purposes for which it is used. In American husbandry we have yet no reason to expect, or perhaps desire, any but those made of wood, and such as any farmer, who has a moderate degree of mechanical skill, and the carpenter’s tools which every farmer ought to keep, may readily construct himself. A good, sound, oak log, with the frame and shafts appended, makes a good roller. They are made of different lengths and sizes, varying from 15 to 30 inches in diameter. The lighter kinds are made in one piece, but the larger and heavier kinds are advantageously made in two pieces, with an iron rod passing through the centre of both, and upon which they revolve. English farmers construct the frame so as to rise above the rollers, upon which a box is fixed, either to contain stones to add to the pressure of the roller, or to receive small stones and rubbish, collected on the field while at work, which are to be carried off. Their shafts, when at work, are generally horizontal. We think the roller is more easily drawn when the draught is on a right line from the collar or yoke of the team to the point of resistance. This may be done, and the advantages of the box retained.

The uses and advantages of the roller are many and important, and no farmer should be without one. They are particularly important in the seeding process, to break down the clods, pulverize and smooth the surface, and to press the earth to the smaller seeds, which otherwise often fail to germinate for lack of moisture. This is particularly the case with oats, barley, and the grass seeds. In autumn the roller is sometimes passed over winter grain, with a view to counteract the effects of frost the following winter. In spring it is advantageously passed over winter grain, as soon as the ground is so solid and dry that the feet of the cattle will not poach the surface. It renders light ground more compact; presses the soil to the roots of the grain, and thus promotes their growth; and upon all soils closes the innumerable cracks and fissures which abound on the appearance of dry weather in spring, and, by partially burying the crown, causes grain to tiller better, that is, send up more seed-stalks. Finally, the roller is of great advantage to grass lands in the spring, by reducing the in-
ROLLING.  

ROSE-CHAFER.  

ROSE BAY, or MOUNTAIN LAUREL.  

ROSE-CHAFER, or ROSE BUG, is a diurnal or day-dyning beetle of the Melolontha genus. Dr. Harris states that this insect, which is common in the vicinity of Boston, is, or was a few years ago, unknown in the northern and western parts of Massachusetts, New Hampshire, and Maine. The natural history of the rosebug, one of the greatest scourges with which American gardens and nurseries are afflicted, was for a long time involved in mystery, but is at present fully cleared up.

For some time after they were noticed, says Dr. Harris, rose-bugs appeared to be confined to their favourites, the blossoms of the rose; but within 30 years they have prodigiously increased in number, have attacked at random various kinds of plants in swarms, and have become notorious for their extensive and deplorable ravages. The grape-vine, in particular, the cherry, plum, and apple trees, have annually suffered by their depredations; many other fruit trees and shrubs, garden vegetables and corn, and even the trees of the forest and the grass of the fields, have been laid under contribution by these indiscriminate feeders, by whom leaves, flowers, and fruits are alike consumed. The unexpected arrival of these tremendous insects in swarms at their first coming, and their sudden disappearance at the close of their career, are remarkable facts in their history. They come forth from the ground during the second week in June, or about the time of the blossoming of the damask rose, and remain from 30 to 40 days. At the end of this period the males become exhausted, fall to the ground, and perish, while the females enter the earth, lay their eggs, return to the surface, and, after lingering a few days, die also. The eggs laid by each female are about 30 in number, and are deposited from 1 to 4 inches beneath the surface of the soil; they are nearly globular, whitish, and have at one-dimension a diameter of about 1/10 of an inch, and are hatched 20 days after they are laid. The young larvae begin to feed on such tender roots as are within their reach. Like other grubs of the Scarabeians, when not eating, they lie upon the side, with the body curved so that the head and tail are nearly in contact; they move with difficulty on a level surface, and are continually falling over on one side or the other. They attain their full size in the autumn, being then nearly three-quarters of an inch long, and about an eighth of an inch in diameter. They are of a yellowish-white colour, with a tinge of blue towards the hinder extremity, which is thick and obtuse or rounded; a few short hairs are scattered on the surface of the body; there are six short legs, namely, a pair to each of the first three rings behind the head; and the latter is covered with a horny shell of a pale rust colour. In October they descend below the reach of frost, and pass the winter in a torpid state. In the spring they approach towards the surface, and each one forms for itself a little cell of an oval shape, by turning round a great many times, so as to compress the earth, and render the inside of the ca-
Our insect-eating birds undoubtedly devour many of these insects; and deserve to be cherished and protected for their services. Rose-bugs are also eaten greedily by domesticated fowls; and when they become exhausted and fall to the ground, or when they are about to lay their eggs, they are destroyed by moles, insects, and other animals, which lie in wait to seize them. Dr. Green informs us that a species of dragon-fly, or devil’s needle, devours them. He also says that an insect, which he calls the enemy of the cut-worm, probably the larva of a Carabus, or predaceous ground-beetle, preys on the grubs of the common dog-bug. In France the golden ground-beetle (Carabus auratus) devours the female dor or chafer at the moment when she is about to deposit her eggs. I have taken one specimen of this fine ground-beetle in Massachusetts, and we have several other kinds, equally predaceous, which probably contribute to check the increase of our native Melolonthians. (Harria.)

ROSE-LICE. See Aphis.

ROSEMARY (Rosmarinus officinalis; from Rome and Armenia, of the sea, on account of its maritime habitat. Poetically implying “the dew of the ocean”). There are 3 varieties—the green, golden-striped, and silver-striped. The first is the one in general cultivation.

ROSE-SLUG. SeeSlug.

ROSIN. See Resin.

ROT. In farriery, a disease in sheep and other animals, in which both the liver and lungs are affected, and there is commonly a dropsical tendency. Its ravages are chiefly, however, confined to sheep, and it is most commonly closely connected with excess of moist food, or placing these animals in low, wet situations, every way foreign to their natural habits; for sheep, in a state of freedom, seek the most elevated, dry, and healthy situations—an instinct which long imprisonment and domestication has not yet eradicated: every farmer is aware with what tenacity his sheep adhere to the very highest portions of a field. It is only when we force them to inhabit low grounds, and situations foreign to their habits, that they thus become diseased. In a state of nature, too, they browse upon the heath plants, and seek with avidity at certain periods salt springs and salt exudations, facts which have not entirely escaped the notice of modern flockmasters. Thus the argali or wild sheep of Siberia, which are the presumed origin of all our domestic sheep, are found about the size of the fallow deer, on the immense chain of mountains reaching through the middle of Asia to the Eastern Ocean. They are found in small flocks, ranging over the highest elevations. As the winter approaches, they move downwards into the plains, and exchange their food from the mountain plants to grass and other vegetables. They are so partial to salt, that they scrape away the earth in considerable quantities in the neighbourhood of saline places in order to procure it. All animals in fact seek salt with the greatest avidity. In Flanders, sheep owners deem its use an effectual prevention of the rot, and there is very considerable reason to believe that by the use of this valuable con-
diment, the ravages of this dreadful disease might either be very materially modified, or perhaps entirely prevented.

Many years since, Ellis, in his Practical Husbandry, recommended the use of salt, mixed with wort, in which had been boiled sage, pennyroyal, wormwood, shepherd's purse, comfrey, &c., as a prevention of the rot; 7 or 8 spoonfuls was the dose, once a week after April, whenever the weather was wet.

More than three centuries since, Fitzherbert, the earliest of the English agricultural writers, alluded to this dreadful disorder in his Boke of Husbandry, and in his section entitled What thynges rotteth Shepe, he says, "It is necessary that a shepheard shoule knowe what thyng rotteth shepe, that he myghte kepe theym the better. There is a grasse called sperewort, and hath a longe narrow leafe lyke a sper head, and it wyll growe a fote hyghe, and bearth a yellowe floure in lowe places where the water is used to stande in wynter. An other grasse is called bellawe, and groweth lowe by the erthe in a marshe grounde, and hath a leafe as brode as a penye or two pence, and neuer beareth floure. All manner of grasse, that the lande floundle runneth oner, is very eyvilla for shepe, bycause of the sande and fylthe that stydheth uppon it. All moorish grounde and marsche grounde is yll for shepe. The grasse that groweth upon falowes is not good for shepe, for there moche of it wade, and ofte tymes it commeth uppe by the rote, and that bryngeth erthe with it, and they eate both, &c. Myylawe grasse is not good for shepe, and that yeart, whenever the weather is wettest, on the trees in the moringe, and specially of okes; take the leaves and putte thy tongue to them, and thon shall felle like hony uppon them. And also there will be many kelles uppon the grasse, and that causeth the myylawe, wherefore theyng may not well be left out of the folde, tyll the sonne have domination to drye them awaye. Also hunger rote is the worst rote that can be, for there is neither goodo fleshe nor goode skynne, and that cometh for lacke of meate, and so for hunger they eate suche as they can fynde, and so will not pasture shepe, for they seldom rot but wythe myylawe, and than wyll they have much fylthe and fleshe, and a good skyne. Also white snailes beyll for shepe in pastures, and in falowes there is an other rote which is called pette rote, and that commeth of grettate wete, speciallye in woode countrieys where they cannot drye."

The symptoms of the rot, and of some of its most decided remedies, have been thus described by Dr. Brown, of Boston (Mag. of Nat. Hist. vol. v. p. 98), "It cannot, I conceive, be demonstrated that in this disease the bile is thrown back upon the system, and mingles with the circulating fluid; for in the early stages there is no obstruction to the bile; and in the latter, what little is secreted is inter- cepted by the flukes on the hepatic side of the gall-bladder. The eye, which some persons take to be an index to the bilious condition of the system, has really not that 'tinge of yellow and jaundiced-like appearance' at the commencement of the disease. On the contrary, the peculiar whiteness of the eyes is the first symptom which guides the shepherd to the unwelcome truth. If the bile ducts be carefully examined in the earliest stage of the complaint, there will be found a few flukes in the duct which conveys the bile from the gall-bladder to the intestine, but none in the gall-bladder, and none beyond it, a sound liver, no 'tubercles,' no 'absceses,' and withal a fine, fat, healthy-looking carcass. If it be in the latest stage when the examination is made, the gall-bladder will be found filled with flukes instead of bile: and the animals will be seen making their way up those channels which convey the bile from the liver to the gall-bladder, arresting it in its course, and pressing forward and enlarging the biliary tubes. Thus, when but few of these animals have possession of this viscus, its function is not materially impaired; the parenchyma, or substance of the liver, is unaltered in appearance; the mucous channels, which convey the bile to the gall-bladder, and from the gall-bladder to the intestines, have not yet felt pressure, and the bile itself is secreted apparently unaltered in quality or quantity: but here, as they live in a medium of perpetual nourishment, they multiply to an extent incredible, and impede the natural action of the liver and subordinate organs of the body. They at length completely block up the conduits of the bile, devouring the bile as fast as it is secreted; spreading irritation and disease from the vessels in which they live to the whole mass of the liver itself; and in some instances they carve their way through the membrane which encircles them, and escape by myriads into the cavity of the abdomen; thus completing the destruction of an important organ, and with it the life of the animal. These extreme states are generally associated with dropsy and a total degeneracy of the muscular tissue; the blood is deficient in quantity, very serous, and almost destitute of fibrin. A correspondent inquires the class and family of the fluke, in hopes of finding a remedy for a disease so fatal. He will find it in the class Vérmes, and order Intestina, and it is the Fasciola hepatica. Contemplating it, as it is, as a variety of exotic worm, it occurred to me that verminages, destructive to other species, might be employed with advantage against this. But in instituting experiments on the living animals, I discarded those popular remedies which have only a mechanical action, and which could never reach the liver, for those which operate by a wider range of influence. What I have observed is, that there are in this class of remedies those which have little or no effect when brought in contact with the living fluke; and there are others which destroy the animal immediately. To the first of those which are inert, belong solutions of vegetable bitters, spirits of tar, and several others, which need not be enumerated. To the second, or to those which destroy the animal, belong solutions of mercury and the spirits of turpentine. For example: a little calomel suspended in water, and dropped upon the animal, quickly deprives it of life; and a drop of the spirits of turpentine kills it in a few seconds. The oil of tur- pentine is a deadly poison to the fluke. The next consideration is, how far it may be safe.
to administer this medicine to the living sheep, and what probability there is of its disturbing an animal inhabiting the liver. With regard to the first exception, there can arise no difficulty. The spirit of turpentine is borne readily by children, and has been given to adults in doses of a quarter of a pint; it is likewise applied externally to blistered surfaces, and as a styptic to the bleeding mouths of ruptured blood-vessels. There can be as little doubt with regard to the second exception, when we consider the penetrating nature of this drug; when we know that the mere immersion of the hand in it is sufficient to impregnate the ureinary secretion; nor can we doubt that its influence will be acknowledged by an organ approximating and communicating with the stomach, and by the worm inhabiting that organ."

The outward symptoms of this disease were many years since well described by Dr. Harrison of Boston, Lincolnshire, when he said, "If in warm, sultry, and rainy weather, sheep that are grazing on low and moist lands feed rapidly, and some of them die suddenly, there is reason to fear that they have contracted the rot; this suspicion will be further increased, if, in a few weeks afterwards the sheep begin to shrink, and become daccid in their loins. By pressure about the hips at this time, a cracking is sometimes perceptible. Now or soon afterwards the countenance looks pale, and upon parting the fleece, the skin is found to have parted its vermillion tints for a pale-red, and the wool is easily separated from the pelt; as the disorder advances, the skin becomes dappled with yellow or black spots. About this time the eye loses its lustre, and becomes white and pearly, from the red vessels of the tunic a oduata and eyelids being contracted or entirely obliterated. To this succeeds debility and emaciation, which increase continually till the sheep die, or else ascites or perhaps general dropsy supervene before the fatal termination."

Such are the symptoms and the most powerful known remedies for this disease; an equally important research is its origin, its predisposing circumstances, or immediate cause. In this, however, in common with most other diseases of animal and vegetable life, difficulties occur at every turn, of a nature almost entirely inexplicable. We have in our content to do little more than merely trace its symptoms and the course in which it commonly runs. No flockmasters are perhaps more anxiously alive to the disease, or more often its victims, than the owners of the noble water-meadows of the south of England, such as those of the valleys of the Kennett, the Itchen, and the Wiltshire Avon.

These excellent farmers have noticed, that the first crop of spring water-meadow grass never imparts the rot to sheep; but that the second crop, which they therefore make into hay, is almost certain to rot the sheep; that gravelly-bottomed water-meadows, like those between Marlborough and Hungerford, never rot the sheep fed on them, in any season or period of the year. This would appear to confirm the very common suspicion that it is not the grass which rots the sheep, but the gaseous or aqueous vapours which emanate from such places, more copiously as the weather becomes warmer in the summer; but, then, against such a conclusion we have the fact, well known to owners of the water meads, that when sheep are soiled even upon fine dry elevated soils (such as never render sheep rotten), with the second crop of grass from water-meads—that then the sheep become as equally rotten as if they had been pastured on the very meadows from whence the grass was carried. It would seem, therefore, that there are more watery matters, or other sources of disease in the second crop than in the first. That the grass of the second crop varies very materially in its chemical composition from that of the first, has been clearly shown by the analysis of the late Mr. George Sinclair. He found that rye-grass (Lolium perenne) at the time of flowering, with the second crop of grass that had been fed off with sheep till the end of April, afforded of nutritive matter 72 grains. The same grass from the meadow that had not been depastured in the spring, afforded 100 grains. The same weight of this grass, taken from a rich old pasture that had been shut up for hay about the same time, afforded of nutritive matter 95 grains. That from the rich pasture that had not been depastured, afforded 120 grains. (Hort. Gram. Web. p. 384.) And in the great majority of instances, the aftermath of the upland grasses is considerably less rich in nutritive matters than that of their first or spring crop.

Such, then, are the supposed causes, symptoms, and treatment recommended for the cure of this disease. For the cure, both turpentine and common salt seem to have sometimes been successfully used. But the effect of salt seems to be much more decided when employed as a prevention, rather than a cure. As a preventative, too, the use of aromatic vegetable substances seems to be excellent. It is the kind of prevention also which might be supposed to be efficacious from following the order of nature, and observing the habits of the sheep in their wild state, browsing as they invariably do upon the aromatic plants, and the shoots of mountain shrubs; and never descending to live upon the rank and watery grasses of the valleys, until compelled by the severity of the weather. Every farmer is aware with what avidity they consume such domestic herbs—the parsley, for instance—as abound in essential oils. An attempt has indeed been recently made to cultivate this herb in the fields as feed for sheep; and I have little doubt that if some attention were paid to the cultivation of such plants (if the parsley will not bear the browsing of the sheep, they might be occasionally soiled with it), by way of condiment or change; if the flock were allowed, at all times and seasons, access to common salt (and this might be mixed, if necessary, with aromatic substances
ROT IN TIMBER.

that wood saturated with common salt is never subject to this disease. Mr. Bethel has proposed a plan for its prevention, by saturating the wood with brine. The same purpose is served by a solution of corrosive sublimate (muriate of mercury). Sir W. Burnet employs a solution of muriate of lime. See Dry-Rot.

ROTATION OF CROPS. The order in which different crops are made to succeed each other. It was only towards the middle of the last century, that the importance of a scientific rotation of crops began even to attract the farmer's attention. Previous to that period we search in vain in the works of agricultural authors for the slightest notice of such a theme. The writers of those days, as Arthur Young noticed, recited courses of husbandry, good, bad, and execrable, exactly in the same tone as matters not open to praise or censure, and unconnected with any principles that could throw any light on the arrangement of the farm, or its more successful cultivation. And yet it is on this difficult part of the farmer's business being scientifically pursued, that much of the profits and advantages which he is to derive from his land for a course of years must depend. Arthur Young, the most popular and the most rapid of observers, saw the importance of this difficult inquiry in its true light: he correctly enough told the farmers of his day, that whenever good or very good husbandry is found on arable land, it is more the result of a right or wrong arrangement of crops than of any other circumstance; that no district is well cultivated under bad rotations, while it is extremely rare to find any badly cultivated under such as are good. More accurate and more generally diffused observations have long since, however, led the present race of cultivators to assign to the inquiry its proper value.

The importance in the fact of the investigation no modern farmer will for a moment doubt. It may not be a useless mode of conducting the research, if we inquire, as we proceeded in our proposed examination, into the few yet valuable lights which chemical and entomological investigations have shed upon this important, yet, from the endless variety of soils and situations, somewhat intricate and laborsious theme.

In regard to the general principles, as it has been well observed, on which the proper cropping of land depends, it is now perfectly understood, that some kind of crops deteriorate or exhaust the land to a much greater degree than others; that some by their capability of being consumed on the farm (though they do exhaust the soil) return, in such condition, better stock, as much or perhaps rather more to the soil than they draw from it, during the period of their growth. And again, that other crops, by admitting of profitable tillage and cleansing the land during their growth, aid very much in

the essential destruction of weeds, insects, &c., and in ameliorating the land for the succeeding crop; while, on the other hand, different crops, by not permitting such cultivation, and being great exhausters when following in immediate and rapid succession, not only deteriorate the soil, but fill it with weeds and grubs. Hence it follows in practice, that by suitable arrangements of these different crops in rotation, most kinds of land may, without lying idle, be constantly preserved in a clean and productive condition. In the management of rotations, however, much careful attention and skill is requisite to the cultivator, to profitably adapt them to the nature of the soil, and the other circumstances under which he is placed. Above all, the farmer must remember, that as different kinds of plants require different kinds and proportions of nutritious materials to be drawn from the earth for their increase and perfect growth, so also they need different situations and conditions of soil for their most profitable development.

The farmer, too, is well aware that certain crops never prosper well two or more seasons together in the same land. This is in fact commonly exhaust or "tear" the soil to such an extent, that every lawyer's clerk is aware of and notices it in some restraining covenant of "the lease."

Even the gardener, aided as he is by the most copious supplies of enriching composts, always avoids as much as possible planting a tree where one of the same species has preceded it.

Now it is of primary importance that we should endeavour to understand, if possible, the cause of this phenomenon. This question, therefore, has long engaged not only the attention of the most sagacious farmers, but of many distinguished chemical philosophers. By these it has been regarded in chiefly two points of view. First, it has been contended, that as each plant has peculiar excretory matters, which it constantly deposits in the soil in which it is placed—matters which are found to be particularly noxious to other plants of its own species—that in consequence, until these are decomposed and removed from the earth by other plants, or by the gradual effects of decomposition, the same crop cannot advantageously prosper in the soil. And in support of this doctrine it is adduced the well-known fact, that the excretory matters deposited or diffused through the water in which bulbs or other roots have been cultivated, will not well support other bulbs; yet still that such impure water is found to be more grateful than clear water to vegetables of another species.

And, again, that certain plants and trees are well known to be excellent and mutually fertilizing neighbours,—a knowledge indeed as old as the days of Rome under her emperors; for at those periods the Italian farmers commonly planted the elm as the companion, or "husband," as they called it, of the vine: and every farmer's farm, amongst other facts of a similar nature, that the corn-flower can be found only amongst his corn-crops—it is in vain to search for it elsewhere. The gardener also well knows, that it is almost useless to
replant old orchards with the same trees, or to replace old quick-hedges with young quick plants, yet an old orchard or the site of an old hedge-row are proverbial for their fertility, when planted with other crops. There is considerable importance I think to be attached to this mode of accounting for the facts of the case, but it is by no means so complete an explanation as is desirable. There are some soils, for instance, which would seem (if this were the sole cause of the phenomenon) to defy all the excretory powers of the plant. Some of the newly-enclosed lands of the United States of America, for instance, have produced excellent wheat crops for even 20 years without interruption. Some of the alluvial soils of the lower portion of the valley of the Thames have yielded alternate crops of wheat and beans from time immemorial; and by the addition of manure, the potato grounds near London yield abundant crops for a series of years. There are other observations too, of a similar kind, which will readily be remembered by the intelligent farmer, which do not seem to assimilate entirely with this mode of removing the difficulties of the case.

The other way of explaining the reluctance with which a crop follows another of the same description is, by supposing that each kind of plant has some peculiar and essential ingredient which it absorbs from, and in a great degree exhausts the soil, and that it is, therefore, only after a lapse of some time, when that ingredient or these ingredients are restored by the application of manure, or by other modes, that the same plants can be again profitably cultivated. To a great extent this theory is not only a very plausible but a very probable and reasonable explanation of the difficulty. Thus the farmer is well aware that certain soils on which red clover formerly grew very successfully once in 4 years, will now only yield any profitable degree of produce of the same plant once in 8 or once in 12 years. The excretory powers of the plant in this instance, therefore, are useless in explanation of the difficulty; for another theory, the excretory matter, which long were successfully dissipated or absorbed by other plants in the course of 4 years, should do so in our age just as well as in a former period. But if we admit what has been not only sometimes, but very often clearly proved to be the case, that the soils which are thus reluctant to produce red clover, are now totally exhausted of sulphate of lime (gypsum)—that, moreover, every fair average crop of this valuable grass contains from 100 to 200 pounds weight per acre of this salt—and that by dressing the land with this manure, in almost exactly the same proportion and quantity as that which is contained in the clover, that then the land will again grow the very same crop once in 4 years; when these and other similar facts are proved, the very strong probable conclusion to which we must arrive is apparent, viz., that the clover had gradually exhausted the land of an essential ingredient which only needed to be restored to it, to enable the clover again to flourish with its wonted vigour. And this is not a solitary instance: thus, marine plants will only grow successfully in inland situations, where common salt is added to the soil. The sun-flower and the nettle need in an equal degree the assistance of salt-petre. The presence in the soil of phosphate of lime (the earthy salt of bones) is equally essential to the vigorous growth of almost all the crops.

Then, again, there are other facts of a different nature well known to the farmer, which appear to lead us to the same conclusion; for instance, every cultivator is aware that by cutting his crops green, his land is not nearly so much exhausted as when the same crops are allowed to ripen their seeds. And if, in explanation of this observation, it can be shown that the plant, when ripe, contains a larger proportion of any peculiar saline or earthy ingredient than it does when in a growing, unripe state, this will further tend to establish the truth of the last-named theory—that it is the abstraction from the soil by the plant of some peculiar substance, which thus exhausts and indisposes it to support the same crop. Now this, according to chemical investigations, seems, at least in many instances, to be the case. Thus, M. Saussure, in his chemical researches, has shown by the results of his analysis, that the ashes of the plants of peas (Pisum sativum), when green and in flower, contain only 17-25 per cent. of phosphate of lime, but that, when ripe, they yield 22 per cent. And, again, that the ashes of plants of vetches (Vicia faba), which yielded only 13-5 per cent. of this same salt when in flower, contain 17-75 per cent. when they are ripe. The same result was obtained from other plants: the Solidago vulgaris, for instance, which yielded 8-5 per cent. of phosphate of lime when first in flower, contained 11 per cent. when ripe. The turnsole (Helianthus annuus), which afforded only 6 per cent. when flowering, contained 22-5 per cent. when ripe. The wheat plant, which held 10-75 per cent. in flower, contained 11-75 when ripe. The ashes of the straw of wheat were found to yield only 6-2 per cent. of this essentially present salt, but it was found that of the same kind of flouring of it. M. Vanquelin obtained a result somewhat similar in his examination of the ashes of the oat plant; the seeds affording him 39-3 per cent. of phosphate of lime, but when he burnt the whole plant, seed and stalk together, he then found only 15 per cent.

The evidence, therefore, in favour of the absorbent theory, is certainly rather stronger than that in support of the excretory mode of explaining the phenomenon. Yet, in all probability, both causes may contribute to produce the effect. Davy, the chief of modern chemists, adopted the former mode of explaining the reluctance with which a crop grows for 2 years successively on the same land. (Lectures, p. 357.) Changes of all kind seem, in truth, ever to be grateful to vegetation—change of soil, of seed, of the course of cropping, of manure, &c. "Peas and beans," said Davy, "in all instances, seem well adapted to prepare the ground for wheat; and in some rich lands, as in the alluvial soil of the Parret, and at the foot of the South Downs, in Sussex, they are raised in alternate crops for years together. Peas and beans contain a small quantity of a
ROTATION OF CROPS.

matter analogous to albumen (hard white of egg); but it seems that the nitrogen which forms a constituent part of this matter is derived from the atmosphere. The dry bean leaf, when burnt, yields a smell approaching to that of decomposing animal matter; and in its decay in the soil may furnish principles capable of becoming a part of the gluten in wheat.

"Though the general composition of plants is very analogous, yet the specific difference in the products of many of them, and other well ascertained facts, prove that they must derive different materials from the soil; and though the leaves of a potato, containing the finest system of leaves, will proportionately most exhaust the soil of common nutritive matter, yet particular vegetables, when their produce is carried off, will require peculiar principles to be supplied to the land in which they grow. Strawberries and potatoes at first produce luxuriantly in virgin mould, recently turned up from pasture, but in a few years they degenerate and require a fresh soil; and the organization of these plants is such as to be constantly producing the migration of their layers. Thus, the strawberry, by its long shoots, is continually exhausting the surface soil, and the fibrous radicles of the potato produce bulbs at a considerable distance from the parent plant. The most remarkable instance of the powers of the plant to exhaust the soil of certain principles necessary to its growth, is found in certain fungi. Mushrooms are said never to rise in two successive seasons on the same spot; and the production of the phenomena called fairy rings, has been ascribed by Dr. Wollaston to the power of the peculiar fungus which forms it, to exhaust the soil of the nutrient necessary for the growth of the species. The consequence is that the ring annually extends, for no seeds will grow where their parents grew before them, and the interior part of the circle has been exhausted by preceding crops; but where the fungus has died, nourishment is supplied for grass, which usually rises within the circle, coarse, and of a dark-green colour." "When cattle," adds Davy, "are fed upon land not benefited by their manure, the effect is always an exhaustion of the soil: this is particularly the case where carrying-horses are kept on estates; they consume the pasture during the night, and drop the greatest part of their manure during their labour in the daytime. Thus, they rest upon the country from a country, unless some articles capable of being manured, if introduced in compensation, must ultimately tend to exhaust the soil. Some of the spots, now desert sands in northern Africa and Asia Minor, were anciently fertile; Sicily was the granary of Italy, and the quantity of corn carried off from it by the Romans is probably a chief cause of its present sterility." The same theory is also supported by M. Liebig: in his excellent work on Organic Chemistry, p. 158, he remarks, "It is evident that two plants growing beside each other will mutually injure one another, if they withdraw the same materials from the soil. Hence, it is surprising that the Matricaria chamomilla and Spartium junceum impede the growth of grain, when it is considered that both yield from 7 to 743 per cent. of ashes, which contain six-tenths of carbonate of potash. The darnel and the Erigeron acer blossom and bear fruit at the same time as the wheat; so that, when growing mingled with it, they will partake of the component parts of the soil, and, in proportion to the vigour of their growth, that of the corn must decrease; for what one receives the others are deprived of. Plants will, on the contrary, thrive beside each other, either when the substances necessary for their growth, which they extract from the soil, are of different kinds, or when they themselves claim the smallest of the plant's supplies of development at the same time. On a soil, for example, which contains potash, both wheat and tobacco may be reared in succession, because the latter plant does not require phosphates, salts which are invariably present in wheat, but requires only alkalies and food containing nitrogen. According to the analysis of Posselt and Reimann, 1000 parts of the leaves of the tobacco plant contain 16 parts of phosphate of lime, 88 parts of silica, and no magnesia; whilst an equal quantity of wheat-straw contains 473 parts; and the same quantity of the grain, 9945 parts of phosphates."

The late George Sinclair turned to a view of the cause of the exhaustion of soils. "If," he says, "a plant impoverishes a soil in proportion to the weight of vegetable matter it produces on a given space of ground, the following will be the order in which the under-mentioned plants exhaust the ground, being the proportion they bear to each other with respect to weight of produce:

<table>

</table>

But when we take the weight of nutritive matter which a plant affords from a given space of ground, the results are very different, and will be found to agree with the daily experience in the garden and the farm.

The following table represents the proportion in which they stand to each other with respect to the weight of nutritive matter per acre, and in exhausting the land:—

Change of crops also prevents very materially the increase of the predatory grub and insects which also more or less prey upon the farmer's crops. The parent of the English wire-worm, for instance, which is the larva of a small beetle, the Elater segetis, may be seen in the summer months depositing its eggs on lays or meadows abounding with the cereal grasses; for instinct teaches it to place its eggs where the young wire-worm will meet with its natural food, which are the cereal grasses. Change of crops; therefore, not only checks the deposit of the eggs, but, by removing the natural food of the young vermin, it materially pre-
ROTATION OF CROPS.

vents increase, or even their continuance; which otherwise, as is the case, for instance, with the wire-worm, might for 4 or 5 years be a pest to the soil. See Beetle.

The ordinary course or rotation of crops under which the light lands of England are commonly cultivated, is either on what is denominated the four-course or shift system, or the five-course or shift.

The four-shift system commonly consists of fallow, manured; 1, turnips, fed off; 2, oats or barley; 3, grass seed; 4, wheat.

The five-shift system, which in many situations a much more advantageous course of husbandry, is commonly fallow: 1, turnips; 2, oats, or barley; 3, clover; 4, peas; 5, wheat.

On clays the course varies: on some kinds of heavy clays it is usually fallow, with manure; wheat; beans; wheat, manured; clover; oats, or wheat.

On other clays the system pursued is fallow, with manure; wheat, or oats; clover; beans; wheat.

The variations, however, are of necessity exceedingly various. Thus, on some of the inferior adhesive clays of the midland counties, they adopt the four-course system.

Another system of moderately heavy soil husbandry is:—

There are endless variations, however, of this system, varying in their course from that practised in some of the heavy, rich Essex soils, of a two-shift system; viz., 1, wheat; 2, beans; 3, wheat; 1, clover, with an occasional fallow. And that more extensively used in the hundreds of that great agricultural county, of a five-shift system of fallow: 1, oats; 2, clover, dunged; 3, wheat; 4, beans; 5, wheat. To the nine-shift system of husbandry, sometimes practised, which is about the longest course with which I am acquainted, viz.:

The following course, which takes in every valuable crop, without in any instance violating the rules that science directs, seems to me the best, and is recommended by a Norfolk farmer for most clays not too wet. Say for a farm of 350 acres—100 acres of green crops, such as cabbages, turnips, rape, and tares, adapting the green crops to the nature of the land; 50 acres of peas or beans; 50 acres of barley or oats, laid down with clover; and 100 acres of wheat.

You will by this course have every year 200 acres of wheat and other corn, 50 of clover, and 100 of green crops, thus saving your land from exhaustion by too frequent repetition of crops of the same genus. And white crops will in no instance succeed each other. The wheat stubbles are in this way sown with green crops, to be followed by 50 of barley and 50 of beans or peas; the barley sown with clover and followed by wheat, 50 acres on clover, and 50 on the bean or pea stubble, taking care that the 50 acres of green crops, followed by beans or peas, when next coming in course for green crops, shall be sown with barley and clover, as by this means the clover comes only once in 7 years.

In whatever point of view, therefore, the farmer examines the rotation of crops best adapted to his land, the more highly interesting does the investigation appear. Long observation and the practice of ages have convinced the best English cultivators that sooner or later the soil is tired of or exhausted of something essential to its luxuriant produce by a repetition of the same crops; that the richest meadows gradually decrease in their produce; other soils become "clover-sick;" and it is now even pretty generally suspected that the land is in many districts gradually getting tired of turnips. To the examination, therefore, of this great question, let every farmer contribute his mite of practical observations: it is a theme whose investigation has long yielded a rich harvest to English agriculture; for amongst its fruits must be numbered the introduction of turnips, of mangel-wurzel, and other green crops; its examination led to the adoption of the four-shift system, and the banishment of that which for ages rested on the miserable plan of one crop and a fallow. It is idle, therefore, to contend that nothing more is to be effected by change of crops; for the experience of all periods is against so indolent and so erroneous an assumption. Let the farmer only remember what has been accomplished by the mere introduction of the turnip plant; what thousands of acres have been brought into cultivation by its means, and how many millions are fed by the increase of the fertility of the land produced by the adoption of that four-shift system of rotation of which it is the first crop. Let him bring to mind what superior crops are now produced by the adoption of new seeds and novel courses, to those which a century since tenanted the lands of merry England; and he will then see abundant reason for hope, and for an energetic perseverance in a course of discovery, which has already rendered such an abundant harvest to the excellent cultivators of our soil. See M. Bousingault on the "Rotation of Crops," Quar. Journ. Agr. vol. x. p. 251; Liebig's Organ. Chem. of Agr. &c.

To prevent the depreciation of soil and improve its productive capacity, a proper rotation of crops is indispensable. The same general principles upon which these objects may be most judiciously accomplished will apply to all countries, but the manner of carrying out these principles must vary with localities and peculiarities of climate and soil.

It was once thought that, after culture, it was necessary to allow the land to remain for one or more years at rest and idle, or fallow and
rotation of crops.

Unused, in order that the soil might thus have its strength renovated. It has, however, been found that with judicious management land need never be suffered to lie idle, but cultivated every year in one or more crops with profit, and even with improvement of the soil. In other words, the system carried out on a small scale in gardens may be extended to farms. A large portion of Europe is at present cultivated without naked fallows, which are unknown in the vast productive agricultural operations of China.

In the United States, the rotations of crops vary considerably in different sections. In Massachusetts, one of the oldest settled portions of the Union, and the usages of which may perhaps represent those prevailing throughout the New England States, it would appear from Mr. Colman, that little of what may be called systematic husbandry prevails, the succession of crops being dictated rather by accident or convenience than by foresight. The following details from his 4th Report on Agriculture, will show how things are managed in different parts of Massachusetts.

The rotation of crops in Franklin county is very limited, as the crops cultivated are few. In Buckland, the first year the land is cultivated, corn is planted and manured: the second year, oats are sowed without manure, and the land ploughed to grass. It is continued in grass five years and then broken up, and the same course repeated. The first year of grass the produce is about two tons per acre, and when it is under mowing for a hay crop it yields 5000 lbs. It is considered proper to break it up again. In Shelburne, on one of the best farms in the state, the course is, first year, Indian corn on green sward, manured; second year, spring wheat, and laid down to grass; the grass-seed sown with the wheat; one peck of herd’s grass and one of red-top to the acre. The land remains in grass ordinarily five years. The average yield of grass is estimated at three tons to the acre,—which must be an over-estimate,—and the cost of getting the hay at $2 per ton. For spring wheat, in the second year of the course, is sometimes substituted for rye, or oats, or oats and peas, or oats and wheat.

In Whatley, first year, Indian corn; second year, oats, and laid down with herd’s grass (timothy) and clover, and remains in grass three years.

On much of the meadow land in Deerfield, the first year the land is in corn; the succeeding year peas and oats, and so on continually. The corn is manured in the hill. The land, after the corn is gathered, is sometimes sown with winter rye.

In some parts of Deerfield, the usual rotation is, first year, corn, usually manured in the hill; the second year, spring wheat; or, when wheat and oats, or peas and oats, or rye with southern clover; third year, clover; and then ploughed again. The best farmers universally advise to sow the southern or June clover with grain, to be ploughed in with the stubble where the land is not to remain in grass, with a view to enrich the land. If the grain is winter grain, the clover is usually sown in the spring before the snow has left the ground, at the rate of a bushel of clover chaff or clover-seed not cleaned, or else at the rate of 6 or 7 lbs. of cleaned seed.

One of the most experienced farmers in the town has been accustomed to sow rye and clover together on the same land for a succession of years; in which case the clover and stubble are always ploughed in together for the purpose of enriching the land for the succeeding crop, and in this process he states that the condition of the land was continually growing better. The crops, however, at best were not large.

I think proper here to mention the statement of another farmer, a man of much intelligence and experience, in confirmation of the experience of two other farmers referred to in a former report, that it is much better that the clover should be withered or dead when it is ploughed in, rather than in a green or succulent state.

In some instances, as in Sunderland, for example, broom-corn is repeated several years in succession on the same land, and, as it is stated, without a diminution of produce. In these cases, the crop is manured in the hill every year; and the corn-stalks, after the brush is gathered, are burnt upon the land.

In the oldest cultivated sections of Pennsylvania, the rotations seem to have been conducted with much good judgment, as is evinced by very successful results generally obtained. These, as well as the system highly approved by many of the most judicious farmers, are set forth in the following communication in the Farmers’ Cabinet (vol. v. p. 94).

The example to which I refer, says the correspondent, is that of an old, practical, hard-working farmer, who commenced in the world as a day-labourer, and who is now worth at least $100,000, not taking in the account many heavy pecuniary losses he has, at various times, sustained. This man, when 30 years of age, by the avails of his industry, added to a small legacy, was enabled to purchase and pay, in part, for a farm of 130 acres of land, 100 of which was under cultivation, but in a very low state. This farm is altogether good land, with a soil composed of lime, clay, and sand, in the chief of which the latter preponderates, the former being least considerable. When he commenced farming, he adopted a particular system of rotation, to which he has implicitly adhered from that time to the present, which is 40 years, and his success is the best comment on the worth of his experiment. His mode was as follows: having divided his farm into eight fields of equal size, as nearly as possible, three of these fields are sown with wheat each year, one with rye, one planted with corn, two in clover, and one an open fallow, on which corn had been raised the year previous. One of the two clover-fields is kept for mowing, the other for pasture, both of which are ploughed as soon after harvest as possible, and prepared for wheat in the fall. All the manure which is made on the farm for one year is hauled, in the spring, on the field intended for open fallow, which is then ploughed, and after one or two
cross-ploughings through the summer, is also sown with wheat in the fall. The field on which rye is sown, is that from which a crop of wheat had been taken the same year, and which had yielded three crops of wheat, alternating with crops of clover. Corn is planted on the field from which rye had been gathered the year previous, the stubbles of which are ploughed down in the fall. Clover-seed is sown early in the spring on two of the wheat fields, those which have been most recently manured. By this method, each field yields three crops of wheat, two of clover, one of rye, and one of corn, every eight years. Each field, in the mean time, has lain an open fallow, and received a heavy dressing of manure, perhaps at an average of 15 four-horse loads per acre. His crop of wheat is seldom less than 1500 bushels, but often much more. His average rye crop is about 450 bushels, and his corn crop, annually, about 500 bushels—all which grain, at the present low prices, would amount to more than $2000 annually, and at former prices to double that amount; and his farm is withal very highly improved.

This system corresponds very nearly with that of which a tabular statement is presented in the same volume, by Mr. W. P. Kinizer, of Pequea, Lancaster county, Pennsylvania, as successfully practised by himself. It is as follows:

<table>
<thead>
<tr>
<th>1st Year</th>

In the county of Montgomery, where agriculture is in a very flourishing state,—the crops consisting of the ordinary grains and hay-grasses,—a five-shift rotation, from the division of the farm into five fields, is very much pursued. Commencing with Indian corn, the sod, which has been top-dressed with lime the previous season, is ploughed in the fall or spring. The corn is followed by oats, which being harvested, the stubble is turned under, manure spread upon the ground and wheat sown, with timothy-seed in the fall and red clover in the spring. The wheat has thus the important advantage of immediately succeeding two cleaning crops, and the ground, after harvesting the wheat, is left in fine condition for the hay grasses. The first year after the wheat is harvested, the grass is mown, the second year pastured, after which the sod is again turned under for corn, and the rotation recommences.

What is known in Pennsylvania as the Old York and Lancaster system, corresponds with the one last described, so far as the succession of grain crops and sowing of the grass-seeds are concerned, but differs in allowing the hay grasses to occupy the field five years. The first two years are most productive in red clover, which, being a biennial and the root dying out, leaves the ground in possession of the timothy and other perennial grasses.

The following interesting view of the former and present Virginia modes of conducting rotations, and the improvements introduced and suggested, is from the able editor of the Farmers' Register (vol. vii.).

The first and most humble attempt at a rotation in this country, and the one which formerly was general on the greater part of most farms, and is even now in extensive use, is the two-shift; which, however, short as it is, had various grades of bad quality. This usually followed the continual cultivation of the land, in its newer condition, in tobacco, while rich enough for the crop, and afterwards in corn, every year.

The two-shift was most usually this:

<table>
<thead>
<tr>
<th>1st year, corn</th>
<th>2d year, corn</th>
</tr>
</thead>
<tbody>
<tr>
<td>1st,</td>
<td>2d</td>
</tr>
<tr>
<td>wheat—or oats, if on land too light or too poor for wheat—</td>
<td>wheat—or oats, if on land too light or too poor for wheat—</td>
</tr>
<tr>
<td>after harvest, grazed closely until next spring, when ploughed for corn again.</td>
<td>after harvest, grazed closely until next spring, when ploughed for corn again.</td>
</tr>
</tbody>
</table>

The celebrated Eastern Shore rotation is of two shifts or fields, but of three crops in the two years. This is—

<table>
<thead>
<tr>
<th>1st year, corn</th>
<th>2d year, corn</th>
</tr>
</thead>
<tbody>
<tr>
<td>1st</td>
<td>2d</td>
</tr>
<tr>
<td>first crop,</td>
<td>natural cover of weeds, grazed.</td>
</tr>
<tr>
<td>corn</td>
<td>When not grazed the second year, as was sometimes the case, for want of separate feeding, or some other cause, this rotation made a nearer approach to alternate and improving husbandry. It was then—</td>
</tr>
<tr>
<td>2d</td>
<td>1st year, corn</td>
</tr>
<tr>
<td>weeds not grazed, and which (if not burnt off, as was done most usually) formed a very poor manuring crop.</td>
<td>When not grazed the second year, as was sometimes the case, for want of separate feeding, or some other cause, this rotation made a nearer approach to alternate and improving husbandry. It was then—</td>
</tr>
</tbody>
</table>

The second crop, Magoby hay bean—a spontaneous and close cover immediately succeeding the oats, and which remains mostly or entirely untouched by the grazing stock, and is ploughed under for the next crop of corn. The interposition, by nature, and not by the design or industry of the cultivators, of this leguminous and manuring crop, is a most valuable feature in a rotation which otherwise would be altogether exhausting and destructive. The moisture of the air, no less than the sandiness of the soil, and the cleanliness from other plants, give vigour to this bean, and make one-third of the whole course a melioration of two-thirds of exhausting crops. The same moisture also nourishes the oats, and prevents that crop exhausting so much, as in dryer regions—and also by its greater bulk of straw, furnishing more materials for manure. These circumstances render this rotation, severe and barbarous as it is, less exhaust-
ing (or more improving, if much attention is paid to manuring) than the ordinary three-shift rotation. Except in the chance-made addition of the spontaneous bean crop, this rotation offends against every principle and rule which ought to govern.

The three-shift rotation was the next step in the supposed march of agricultural improvement, and even yet is that which many remaining two-shift or no-shift cultivators aspire to reach, as the limit of their farming and improving can not, and their ne plus ultra of mild cultivation. This was

1st year, corn—
2d " wheat, and afterwards the spontaneous grass and weeds grazed—
3d " pasture, closely grazed—

The severity of the second year was generally moderated on the poorer parts, by the wheat being there necessarily omitted, which of course gave to those parts two years rest from tillage, in three; and, while the wheat was growing, a cessation from grazing also. With very few exceptions, every one of the generally cultivated farms in lower Virginia, when Taylor wrote; and it is on this kind of three-shift rotation that his denunciations were so deservedly cast. This rotation violates every sound principle and rule, and certainly deserved to be treated without mercy; but many have continued to denounce the three-shift rotation, even when rendered comparatively mild, as if the evil was in the number three, and not in circumstances more important than the mere number of shifts.

But, taken in the aspect above described, and which was the best then that was exhibited, the three-shift rotation had no merit whatever. It had no other than fibrous-rooted plants; no other than narrow-leaved crops; no root, leguminous, or even grass crop; for the close grazing merely served to prevent the scanty weeds and grass from growing; and while every year's crop was exhausting, the system furnished but small resources and materials for manure. For the grazing animals were as many as the land could keep alive, and scarcely any were fattened (by grazing alone) for home consumption or market; and their support served to diminish, instead of adding to, the fattening or manuring of the land. At that time it would have been difficult for a reading farmer to comprehend this undoubtedly sound maxim of English writers, "the more cattle kept, the more grain and other crops produced."

But the English farmer keeps no animal except for the profit it will yield; and all that are so kept, give their rich and abundant products of manure, as an additional profit to the soil. But when a stock of cattle, sheep, and hogs, can barely make out to keep alive through the year, and never fatten, except by stall and grain feeding, then keeping them certainly yields no clear profit to their owner, and their clearing the land, and in any way more of fertilizing materials than their dung can possibly replace. An English or French farmer would be no less at a loss to comprehend the object (or even to believe in such a general practice) of keeping a large stock of animals from which no net profit was obtained, or even hoped for; and he would justly think that it would not be more absurd for a farmer to tend a crop of grain, and then leave it to rot on the field, than to give all his grass through summer to animals, and then lose the flesh so acquired, by starvation through the winter. Indeed, the general cattle management of this country would scarcely be believed in any good grazing or farming region. On the farms under the usual three-shift rotation, say of 400 acres of arable land, there would be from head of grazing cattle, which furnished annually to the owner, at most, about as much milk and butter as two well-kept cows might supply, one or two passable beeves, with the aid of grain feeding, a few poor calves for veal, and a pretty large supply of hides from deaths by starvation in the spring. There were hogs enough to furnish the year's supply of bacon; but only by means of grain feeding, which alone was admitted to cost nearly or quite as much as the market price of the meat. A flock of poor sheep were on some farms also, of which, besides the wool, the fore short and back half the meat of many was hanging on the briers, and the remaining fleeces filled with burs. This sort of grazing system accompanied the old three-shift rotation; and, inveterate as were old habits, and patient as we are of long-borne grievances, this evil was so great, that none could deny but that the mere expense of the dividing fences, necessary to keep the cattle from the fields of grain, cost more than all the returns from the grazing animals.

The four-shift rotation, recommended and practised by Col. Taylor, was—
1st year, corn—
2d " wheat, and clover sown—or if too poor for wheat, left at rest, and not grazed—
3d " clover (or weeds), not mown or grazed—
4th " clover, not mown or grazed.

This rotation, as before stated, was the first introduction of manuring fields by their own vegetable cover, and this practice, and the admission of the opinions on which the new practice was founded, was a prodigious step towards agricultural improvement. It is true that even this rotation is opposed to the rules of good husbandry in most respects. But the giving of two and a half years out of four for vegetables to grow, that were to die and decay on, and be finally ploughed into the land, was a feature that compensated for every fault, and made the rotation decidedly flattering, if on land capable of being enriched by the mere application of vegetable matters.

In the first of these numbers, it was stated incidentally to other matters why this rotation became of less benefit and more objectionable, in proportion to the time, and to the effect with which it operated; and if it improved the productive power of any land, that it also greatly increased the labours of tillage, and the destruction of products, by increasing weeds and noxious insects. In consequence of this objection, very few disciples of the great introducer of and advocate for this rotation, have continued long to pursue it strictly.

The four-shift and clover fallow rotation differs

963
widely from that of Col. Taylor. This has been, and I believe still is pursued with great success by Hill Carter, of Shirley, John A. Selden, of Westover, and has been on some other of the best lands on James River, where it has since, in other hands, been either neglected or abandoned, for some modification of the three-shift rotation. This four-shift system is:

1st year, corn—
2d " wheat, and clover sown, and not grazed—
3d " clover, not grazed, and ploughed in deeply in August and September, and the field sown in wheat—
4th " wheat, to be followed by corn, in recommencing the rotation next year.

A sufficient standing pasture was kept on other land. Mr. Carter, for a considerable length of time, substituted oats for corn in the first year.

The farmers above named (whose accounts of their systems and their products were reported at length in vol. i., Far. Reg.), and others also, undoubtedly made great crops, and great improvement of land, under this very severe rotation. But those results were due more to the excellence of their general management than to their rotation. None but admirable executive farmers can possibly overcome the great difficulties which accompany this rotation. He who, in our dry climate, on a stiff or even medium soil, can plough every August and September one-fourth of all his arable surface, to the depth of 8 or 10 inches, and turn in and cover effectually a heavy coat of clover—this without failing in any year—shows thereby alone his ability to execute the most arduous undertakings, and to do well every thing which he may make a part of his general plan of operations. This rotation, in such hands as have directed it, has some admirable features; but it must be executed in the most perfect manner, or these best features are lost, and there will remain only the great evil of three fibrous-rooted, narrow-leaved, and exhausting grain crops, in succession.

The great merit of the four-shift rotation, in general, and considering it as embracing both of these various differences, is its easy adaptation to more mild or more severe cultivation, without any different arrangement or number of fields. Thus, Taylor's rotation may be rendered still milder (as is needed on the poorest lands) by omitting the wheat crop; and in the rotation thus modified, the richer spots may be thrown under the more severe cultivation of the other four-shift system, as practised by Mr. Carter or Mr. Selden. But, in any form, the rotation still remains objectionable, for the succession of grain crops (if there are even two in the course), as well as for other things, in one or the other variety, which have been already stated.

Every rotation yet known in Virginia is more or less objectionable, upon one or more of the following grounds:

The adoption of certain usual crops, without regard to the various qualities and the wants of the soils, or even to the demand of the market. Thus, every farmer is sure to make corn and wheat (or oats) his principal, if not his only crops. Thus, the fields are deprived universally of the most improving culture of roots, which dip into and draw from the soil deeply: and of pea crops, which feed on the air; and give the product to the soil as manure; and of all annual green manure crops, which would cleanse the soil by their getting in, their growth, and ploughing under, as well as manure it; and the store cattle and hogs suffer for the want of roots and other succulent food, and those which are necessarily well fed consume grain almost exclusively. Besides these and other objections, which any good practical farmer, or sound theorist, would make, I would further object to the great defect of the preparatory crop not serving to destroy the weeds which will obstruct, and the insects which will prey on the succeeding crop. Two great exceptions to this last general fault are presented when wheat follows clover, or tobacco, both of which are plants of the broad-leaved kind, unlike in all respects to the succeeding crop, and of such unlike conditions also, that it may be presumed that the growth of either has served well to destroy many of both the weeds and insect depredators, which are injurious to wheat. Accordingly, these two crops are the best forerunners of the manure crops, of which all other vegetable crops may be an excellent crop for the land and the season.

Every well-informed farmer will agree to the importance of there being more meliorating crops introduced in our rotations—more grass, peas, roots, and broad-leaved vine crops. But the objection always is to making crops for which there is no sale or market demand. But suppose there is no direct sale and money profit made from hay or roots, they will yield as much profit by being used to feed and fatten (not merely to keep alive) the necessary farm-stock, and thus allow to be sold the corn and other grain which would be otherwise consumed by the animals, with less labor and less expense.

While roots are totally wanting in our rotations, one important office is left unfilled, that is, the deep piercing of the soil and thorough opening of it by tap-rooted and tuberous-rooted plants. Another thing wanting, is the ploughing under of pea or other annual green crops, to cleanse, as well as to manure the soil. These properly introduced, and the grain crops separated by green crops, would produce rotations far more improving to the land than any yet known, and probably as much better for early annual income as for improvement of the land, the farmer's best and least benefited acres.

ROWAN TREE (Prbara aucuparia). The quicken tree, or mountain ash, as it is sometimes called, is a handsome tree, of slow growth, with a tough, cross-grained, not very hard wood, indigenous to our mountains, woods, and hedges. The leaves are pinnate: scarcely a span long, composed of leaflets, uni form, serrated, smooth. The fruit is globose, scarlet, very juicy, sour, and bitter. They are eagerly devoured by birds of the thrush kind. The fruit, also, when the bitter is extracted by soaking it in water, may be made into a preserve.

RUBBING-POST. A stone pillar or post set up in a field for cattle, hogs, or other animals.
R U D D L E.

RUE (Ruta graveolens). Rue thrives best in a poor brick earth, in which a portion of calcareous rubbish has been mixed. It will not endure the application of dung or a rich soil, for although this causes a luxuriant growth in summer, death is as certainly produced by severe frosts. It is propagated by slips and cuttings as well as from seeds; the first two modes being usually practised as being the most easy. It may be planted or sown any time during the spring.

RUNCINATE. A botanical term, applied to the lobes of leaves: a leaf is said to be runcinate when it is irregularly lobed, the lobes gradually diminishing to the base, and hooked backwards. The leaf of the dandelion (Taraxacum officinale) is an example of the runcinate leaf.

R U N T. A name given to a small kind of black cattle brought from Wales and Scotland. See Cattle. It is also a term applied to the weak and stunted pigs of a litter; also several species of pigeons; as the Leghorn, Spanish, and Friesland runt.

R U S H (Juncus). Linnaeus derived the name from janggo, to join; in allusion to the first ropes being made from rushes). This is an extensive genus of coarse plants, many of them aquatic, which are common on most wet lands. Rushes always intamate a deep, rich soil, and thrive best in land which is too cold and wet for other plants. The growth of these plants may be easily prevented by under or surface draining, which will prevent the stagnation of water on the soil; and by the application of saline or calcareous top-dressings, such as sand, lime ashes, and road-scrapings. All the species of rush do best cultivated in a moist situation, some of them entirely in water, and others in a peat soil; they may be increased by seeds, or dividing the roots. In Japan they cultivate the soft rush (J. effusus) for making floor-mats.

Sir J. E. Smith, in his English Flora, enumerates 23 indigenous species of rush. (Paxton's Bot. Dict.; Smith's Eng. Flora.) Of the scirpus genus of plants, which includes the rushes, about 40 species have been found by botanists in the United States. Among these are the club-rush, or marsh scirpus; the bull-rush, which is also called tall club-rush or lake scirpus, which grows so luxuriantly along the shores of the Delaware; and the brown cotton-grass, or wool-bearing scirpus.

The species of club-rush commonly met with in the United States are the Scirpus palustris, S. olivaceus, S. tenius, which, with the common bull-rush, S. Lacustris, are all worthless occupants of low, wet grounds. (Flora Cericica.)

R U S T. See Mildew.

R U T A. BAGA. See Turnips.

R Y E (Secale cereale; Germ. roggen dui rog). This species of grain is much more hardy, but incaulculably less valuable in every respect than wheat. It has been cultivated from time immemorial, and is supposed to be a native of the Caspian Caucasian desert. In England it is very little used as an article of food compared with wheat and oats, though in the north of Europe, and in Flanders, it forms a principal article of human subsistence, but generally mixed with wheat, and sometimes also with barley. The grains consist of 45-5 of meal, 24-5 of husk, and 10-2 of water. The preparation and culture of rye are exactly the same as for wheat; but the same quality of soil is not equally suited to each. Rye grows most luxuriantly for feeding when sown on hazel mould, but any poor, dry, sandy soil is fit for its production. It is sown either broadcast or in drills, in the autumn or spring; but the spring variety is that most hardy and most generally cultivated. The proportion of seed is about two or three bushels per acre when required for a crop, and three bushels and a half when it is intended to be fed off. The meal of rye is considered second only to that of wheat; when it is not mixed with a proportion of wheat flour to make bread and gingerbread. In those unaccustomed to its use, it is apt to cause an aceseant state of stomach and diarrhoea. Rye is liable to a disease called ergot, which depends on a fungus, which attacks and alters the character of the grain. It becomes long, of a deep violet hue externally, and pinkish-white within. The odor of the ergotted grain is fishy and fetid, the taste slightly aerid. Ergotted or spurred rye is poisonous, when it is baked into bread. It causes febrile symptoms, great debility, often paralysis, tremors, abscesses, gangrene, and death. Some of the epidemics which have occasionally nearly depopulated the north of Europe, have been traced to the use of the spurred rye. As green food for sheep, rye is not only valuable for its early produce, but as producing a flow of milk in the ewes. The straw is highly esteemed for Dunstable work, for thatching and litter; and is also used to stuff horse-collars. See Ergot.

R Y E-GRASS or RAY-GRASS (Lolium perenne), pl. 5, a. There has been much difference of opinion respecting the merits and comparative value of rye-grass. It produces an abundance of seed, which is easily collected and readily vegetates on most kinds of soil under circumstances of different management; it soon arrives at perfection, and produces in its first year of growth a good supply of early herbage, which is much liked by cattle. These merits have no doubt upheld it till the present day in practice, and will probably for some time to come continue it a favourite grass with many farmers. But the latter-math of rye-grass is very inconsiderable, and the plant impoverishes the soil in a high degree, if the culms, which are invariably left untouched by cattle, are not cut before the seeds advance. The spike of the Lolium perenne is ainsless; calyx shorter than the spikelets; floret lanceolate. The varieties of this species are very numerous, such as the slender rye-grass (var. tenue); compound or broad-spiked rye-grass (var. compressum); Pacey's rye-grass (var. ramosum); Russell's grass 4 x 2.
SACCHARINE.

(Russellianum); Whitworth's grass (Whitworthiensis); Stickney's grass (Sticknei-cennis); pani-cled rye-grass (paniculatum); double-flowered rye-grass (monstrosum); viviparous rye-grass (viviparum): all the varieties have a strong tendency to vary their form when sown on different soils. The annual species are common only to land under cultivation, under the alternate husbandry.

Rye-grass appears to have been cultivated previous to the year 1677 (Woldridge's Husbandry, 1st ed.), besides which, red clover, spurrey, trefoil, and nonsuch were the only plants then cultivated as grasses, or termed such; and it is only of late years that any other species of the natural grasses has been tried as a substitute for it in forming artificial pastures. One peck of rye-grass, with fourteen pounds of clover, per acre, is generally considered sufficient for sowing artificial pastures. Rye-grass, when not more than three years old, flowers in the second week of June, and ripens the seed in about 25 days after: as the plants become older they flower much later, sometimes so late as the beginning of August. See Grasses.

A variety called the Italian rye-grass was some time since brought prominently into notice, and is well spoken of. One species of rye-grass, the bearded darnel (Lotium temulentum) is poisonous. Pl. 7. c. It is an annual, and flowers in July. The root is downy and fibrous; the culm leafy, smooth, about two feet high, with leaves of a bright-green, rough in the under disk. The spike is a span long, and roughish. The calyx of the flowers linear, flattish, many-ribbed, rising above the spikelets. The florets are six, with the outer valve of the corolla elliptical, concave, with a dorsal awn. The seeds are elliptical, flattened, and furnished with a furrow along its upper side. See Dandel.

SAFFRON. A term applied to such substances as contain sugar. The plants in which this substance is abundant are in general highly nutritious and useful in the fattening of animals. See Molasses and Sugar.

SACKS. The term sack, in the sense of a bag, is found in all the European and many Asiatic languages.

SAFFRON (Crocus sativus). The stigmata of this purple crocus are of a deep orange colour, and when in quantity have a peculiar and very characteristic odour; they are used in medicine, chiefly as a rich yellow or orange-colouring matter. Saffron is now chiefly imported from the south of Europe, especially Spain; it was formerly much cultivated in England in the vicinity of Saffron Walden, in Cambridgeshire.

Saffron is often largely adulterated with the petals of other plants, especially with those of the marigold. The English saffron is superior to that brought from Spain. It should never be compressed into cakes, but the stigmata left in a dry, shrivelled state, or, as it is termed, hay saffron. Where the stigmata are pale, the saffron is bad. Saffron, as a medicine, is of little value. See Carthamus and Crocus.

SAFFRON, THE MEADOW. See Colchic.

SAGE, GARDEN (Salvia officinalis; from salve, to be safe, on account of the sanative properties with which it was supposed to be fraught). Sage is now used principally in culinary preparations. There are several varieties, as, 1. The common green. 2. Wormwood. 3. Green, with variegated leaves. 4. Red, with variegated leaves. 5. Painted, or parti-coloured. 6. Spanish, or lavender-leaved. 7. Red. A dry, moderately fertile soil, is best suited to its growth, in a rather sheltered situation. If the soil is rich, or super-abounding in moisture, they grow luxuriantly, but are apt to perish in winter. Sage is propagated by cuttings of the young shoots from the sides of the branches, sometimes also by rooted offsets, and likewise by seed. See Clary.

SAGE, THE WOOD. See Germander.

SAGO (Malay and Jav. sugu). A species of secula or starch obtained from the cellular substance of a palm tree—the Sagus farinifera, Gaertn.; Sagus Ramphii, Wild. In the early writers it is called suga, suga, and zoga. In Java the term signifies bamboo. The sago which is procured from the above palm, and six other species of the same family, is the pith of the trunk. When the tree is of sufficient age it is cut down, split, and the pith extracted and reduced to powder, which is mixed with water and strained through a sieve. The sago is deposited from the fluid, and after two or three washings it is fit for use, and is called in this state, when dried, sago-meal. For the European market it is made into a paste and granulated, and is known in the trade under the name of pearl sago. The consumption of sago has undergone an almost incredible increase within the last twenty years, which is wholly ascribable to the reduction in the interval of the oppressive duties by which the article was formerly loaded. Sago has latterly been brought prominently into notice as food for domestic animals usually reared upon the farm, particularly horses and calves. Experience having decided in favour of its wholesomeness and economy, it will no doubt very soon become a general and staple article of food on all farms that rear young stock. From its emollient and nutritive properties, it appears to be admirably adapted for calves while suckling corn milk; fattened, sometimes before and after calving; for young horses in winter, instead of much dry corn, or none at all, as is too frequently practised; and for young pet lambs, whose mothers have either died or forsaken them, in which events a serious encroachment is apt to be made on the milk intended for the calves. Sago seems peculiarly well adapted for horses for fast work, and for sporting dogs, since it is found to leave the wind unaffected; and with regard to fowls, the whole class of them might be rendered by it much more white in flesh and delicate for the table, than the food usually fed them on farms. Sago is most commonly used in a gelatinous state, and it is easily reduced to that state by boiling water.
SALTO.

As a drink for horses, after a severe run or burst in the field, sago gruel, consisting of about a pound of the mucilage or jelly, completely dissolved in two or three gallons of warm water, is found to be superior to any other kind of drink. For cows, the jelly should also be given in the shape of drink. Sago jelly mixed with new milk forms an excellent food for calves. Dogs should have the jelly poured over biscuit, bread, or potatoes. To pigs sago should be administered in the shape of drink, from 2 to 3 pounds being given to each pig once a day; and the jelly for fowls should be in warm balls, mixed up with barley meal. Sago has been sometimes used as an ingredient of household bread, in the proportion of 1 part of sago to 3 of wheaten flour. It forms an excellent pudding for the convalescents from acute diseases. It is only moderately nutritious, consisting chiefly of starch; yet it is the bread, and may be termed the staff of life of the natives of the Molucca Islands.

SAINTOIN or SAINTOIN (Holysarum onobyckis). The Bourgogne or Esparette of the French. Pl. 8. Having been first introduced to the farmer from France, this plant brought its French name of saint-oïn along with it; and cock's-head, by which it was before known as a native of England, is become obsolete. The stems of sainfoin are recumbent, 2 or 3 feet in length; leaves pinnate, nearly smooth; flower-stalks axillary, ascending, longer than the leaves, each bearing a dense tapering spike of handsome variegated crimson flowers. The flowers have a legume, erect, single-seed, toothed at the top, long and ribbed. Sainfoin is a well-known object of cultivation as fodder for cattle, on dry, barren, especially chalky or marly ground, in open situations. From its not thriving well except the soil or subsoil be calcareous, sainfoin is not generally met with in England; it is most extensively cultivated on the Cotswold Hills, and on the chalk soils of Surrey, &c. Its nature, qualities, and treatment are similar to those of Lucerne, which see.

SAINT JOHN'S-WORT. See John's-Wort.

SAINT PETER'S-WORT. See John's-Wort.

SALAD, CORN. See Corn Salad.

SALAL BERRY. A new fruit from the valley of the Columbia river. It is about the size of a common grape, of a dark purple colour, and possesses a sweet and pleasant flavour.

SALLOW. The common name of several species of Salix, which, unlike those known under the name of osiers, are not flexible, but form large trees or rough bushes, which grow in moist, marshy woods and hedges, in various parts of England. Sallows generally yield the best kind of charcoal for the manufacture of gunpowder, though all the species of salix are burnt for the preparation of this substance. Sir J. E. Smith particularizes, in England, nearly a dozen different native species of sallow. See Osier and Willow.

SALLOW-THORN (Hipophyse, from hippos, a horse, and phoo, to destroy; in reference to the supposed poisonous qualities of the seeds). The species are mostly ornamental trees or shrubs, growing in any common soil, and may be readily increased by layers or cuttings of the roots. The common sallow-thorn or seabuckthorn (H. rhamnoideas) is a bushy, rigid shrub, 5 feet or more in height, with hard wood, and straight, spreading, leafy branches, each terminating in a thorn. The shrub is a native, being found growing wild on sandy cliffs on the eastern coast of England. The leaves are linear-lanceolate, scattered, deciduous, 1½ inch long, on short stalks, dark-green on the upper side, minutely dotted, beautifully silvery as well as scaly beneath.

SALSIFY (Tragopogon porrifolius). An ornamental plant, which, when grown in the kitchen garden, succeeds in any common soil. It is sown and treated in the same manner as carrots; the flavour of the root is mild and sweetish. When properly cooked, it has a flavour much resembling that of oysters, from which it often goes by the name of oyster plant.

SALSILAA (Edible altheareria). A very herbageous plant, a native of Peru. Its roots are eaten like the potato. It is cultivated in the West Indies, and may answer well in many parts of the United States. (Kentrick).

SALT, COMMON, as a manure (Germ. salz; lit. sale). This salt is a compound of chlorine and a metal, the base of soda, called sodium; or, in chemical language, salt is a chloride of sodium. It is too well known to require description; but it may be proper to state that it dissolves equally well in cold and in hot water. It would be, perhaps, difficult to name any other substance in the catalogue of modern fertilizers, which, however, has been so warmly disputed as common salt; and for this controversy many reasons may be assigned. It has been generally employed with little scientific accuracy, and in far too loose a manner for any reliance to be placed upon the majority of the reports which have been furnished to us; and for many years a prohibitory duty in England rendered it inaccessible to the farmer—an impost which has not very long been removed, and which yet was the occasion of a great variety of blundering trials, miscarried experiments. The duty on salt was, indeed, one of long continuance. It was raised as a war tax, in the ninth year of the reign of William III., and was not removed until after many an arduous debate, in the end of that of George III. The price of salt, in consequence of the duty, was raised from 6d. a bushel to more than 20s.; and was, therefore, during the continuance of the tax, too expensive a fertilizer to be employed by the English farmer; and it was only after being for a century and a half lost to agriculture, that it was again presented, in 1823, unshackled with duties, to the notice of the agriculturist. During that long interval, salt, as a manure, was known only in the traditions of the English farmers. Through these they learned that it was formerly used to kill worms, and to destroy weeds; that it cleansed fallows, increased the produce of light, arable soils, and was good to sweeten grass. These reported advantages were rendered more probable by certain facts that had been forced, as it were, upon their attention. The gardener was well aware that the brine of the pickling tubs, when poured over his heaps of weeds, not
SALT, COMMON.

only killed every weed, every seed, and every grub, but that these heaps were then converted into so many parcels of the most fertilizing manure; the good effects of which, especially upon potatoes and carrots, were very decided. It was well known, too, that a single grain of salt placed upon an earthworm speedily destroyed it; that if brine were poured upon the lawn, all the earthworms were immediately ejected from that spot; and that if it were sprinkled about over a portion of the grass, to this salted portion all the deer, sheep, or the horses of the park constantly repaired, in preference to any other part of the field. Salt evidently, therefore, destroyed weeds and worms, and rendered grass more palatable to livestock; and, upon consulting the old agricultural writers, it was found that the notices of salt as a manure were many and important; and that salt had been employed in various agricultural operations from a very early period. Thus it is referred to in St. Luke, xiv. 34. Virgil reprobaches a salt soil. Cat. 150 years b.c., commends it for cattle, hay, straw, &c.; as does Virgil, lib. 9, v. 294. The early German farmers knew of its value, and for the same purpose, in Spain, it has been employed from the earliest ages. In 1570, Conrad Heresbach commends it as being a certain prevention of the "murrain or rotte." In 1653, Sir Hugh Platt speaks of salt as a fertilizer in his usual visionary manner, and details the result of a very successful experiment on a "patch of ground" at Olipham; from which some late writers upon the uses of salt have led their readers into great blunders, by stating that this experiment was performed on an acre of land.

The use of salt by the cultivator, since the repeal of the duties in 1823, has been considerable, however, in many districts of England, in spite of these blundering instructions, ill-contrived experiments, and ignorant conclusions. If to this be added the natural difficulty of obtaining correct results in any experiments in which vegetable life is concerned, we need no longer be surprised that many contradictory statements have been made with regard, not only to salt, but to all other fertilizers.

Common salt is composed of 35.42 parts of chlorine, and 64.58 of sodium. This is not the place to enlarge upon its almost universal presence in almost all waters, soils, and situations, nor of the masses with which our country is endowed. Its fertilizing properties, when applied to land, may be described as five in number.

1. In small proportions, it promotes the decomposition of animal and vegetable substances—a fact first ascertained by Sir James Pringle and Dr. Macbride. Salt, therefore, promotes the rapid dissolution of the animal and vegetable remains contained in all cultivated soils. The recent discoveries of M. Macaire, with regard to the excretions of vegetables, impart considerable information as to the use of common salt in promoting the putrefaction of vegetable substances in the soil; since it has been shown by this gentleman that the brown excretory matter of a plant is extremely noxious to those of its own species; the salt, therefore, by its presence in the soil, promoting the putrefaction of the excretion, naturally assists in removing the offending matter; and, in so doing, the excretion, as it decomposes, certainly affords nourishment to the plant which produced it. We are fully aware that this hypothesis may be disputed: we therefore offer it merely as an hypothesis. But it is true that salt, properly used, enables land which has been deteriorated by one crop to bear another with advantage.

2. It destroys vermin and kills weeds, which are thus converted into manure. 3. It is a direct constituent or food of some plants; and it has been clearly ascertained, that if salt is applied to a soil, the vegetables afterwards growing on that land are found to contain an increased proportion of common salt. (Mr. George Sinclair, Prize Essay on Salt as a Manure.) All marine plants contain it in considerable proportions. 4. Salt acts on vegetable substances as a stimulant. Dr. Priestley tried various experiments, all supporting this supposition. He added to phials, containing an equal proportion of water and salt, which had been exposed to the rays of common salt, from 1 to 12 grains, and in the solutions placed various sprigs of mint and other vegetables. In those solutions which contained more than 12 grains, the plants died immediately, and the rest died in their order, except that which contained 3 grains of salt, which seemed to grow as well as plants growing in simple water. It was remarkable, however, that this plant, as well as all those that died in the stronger solutions, seemed to flourish at first more than those which were growing in simple water, and that that which had 3 grains of salt, and that which had 1 grain only, continued to live after the plants in simple water were dead. (Nat. Philos. vol. i. p. 106.) That vegetable substances are capable of being stimulated by chemical solutions, is well known. A solution of chlorine in water will make certain seeds vegetate which would otherwise rot in the earth; and a mixture of camphor, &c., has been found to be very beneficial in restoring vitality to cuttings of various exotics too long delayed on their passage.

5. Salt preserves vegetables from injury by sudden transitions in the temperature of the atmosphere. That salted soils do not freeze so readily as usual when salt is supplied to them, is well known; and salt preserves crops of turumps, cabbages, &c., from injury by the frost, is equally well established. (Johnson's Essay on Salt, pp. 66-68.)

6. Salt renders earth more capable of absorbing the moisture of the atmosphere—a property of the first importance, since those soils which absorb the greatest proportion of moisture from the atmosphere are always the most valuable to the cultivator. "It affords," said the illustrious Davy, "one method of judging of the productiveness of land." (Agr. Chem. vol. i. p. 9.)

The impure picking of sealings of the salt-makers is usually to be obtained by the farmer at a very low rate, and from its being a mixture of common salt and gypsum (sulphate of lime), it is excellently adapted as a manure for the
grasses, such as clover, lucern, sainfoin, &c.; and, as such, I will give the chemical analysis, for the information of the cultivator, of the refuse of the marine and fossil salt-makers. The pan scale of the Lymington marine salt-makers consists, according to the analysis of Dr. Henry, of—

- Marisate of magnesia - - - 29
- Deseated sulphate of magnesia - - - 18
- Carbonate of lime and magnesia - - - 197
- Sulphate of lime - - - 216
- Marisate of soda (sea-salt) - - - 610

Of the pan scale of the fossil salt-refiners of Norwich, two specimens were examined by Dr. Henry; the first was composed of—

- Common salt - - - 950
- Carbonate of lime - - - 40
- Sulphate of lime - - - 40

The second variety was composed of—

- Common salt - - - 110
- Carbonate of lime - - - 390
- Sulphate of lime - - - 790

Salt, it should be remembered, rarely causes the wheat plant to grow larger or taller, but it fills up the ear better, and brings the weaker plants forward. Mr. Sinclair informs us, that "salt appears to lessen the produce of straw, and increase the weight of grain." I have never been able in my experiments, nor in any I have witnessed (with salt alone), to observe any increased quantity of straw, even in cases where there was an increased produce, by means of salt, of 6 bushels of wheat per acre. The salt should be applied some time before sowing the seed, not less than 10, and not more than 20 bushels per acre. In my own experiments upon a light gravelly soil, at Great Toatham, in Essex, the use of this quantity of salt per acre (in 1819) produced an increase of 5½ bushels per acre. The following statement of the result of some trials in 1820, on a light and gravelly soil, will show how important may be the result to the country at large by its judicious application. I regret that incessant employment of a very different nature has hitherto prevented my continuing these experiments.

No. 1. Soil without any manure for 4 years - - - 13
No. 2. Soil manured with stable dung to the previous crop (potatoes) - - - 26 52
No. 3. Soil with 5 bushels of salt per acre, and no other manure for 4 years - - - 26 12

The testimony of a plain Essex farmer corroborates these results. "The soil," says Mr. James Challis, of Panfield, "that I described to you to be of rather a loose, hollow description, had a dressing of salt in November, after the wheat was sown, about 14 or 15 bushels per acre; it produced at the rate of 6 bushels per acre more than that which was not dressed, and it may be stated to be 1½ per load of 40 bushels better in quality." (Essay on Salt, p. 45.) It is a custom in most counties of England, to apply salt and water as a sweep to prevent the ravages of the disease in wheat, called smut; the value of this is known to almost every farmer. Recent experiments have suggested that it may even be of use, when employed in larger quantities, as a preventive of mildew; the most dreadful of the numerous diseases to which the cultivated grasses are exposed. The experiments of the late Rev. E. Cartwright strongly evidence, that when salt and water are sprinkled with a brush upon diseased plants, it affects a complete cure, even in apparently the most desperate cases. (My Essay, p. 49.) "The proportion, one pound to a gallon of water, laid on with a plasterer's brush, the operator making his casts as when sowing corn, is instant death to the fungus." The time and expense are trifling. It appeared, in the course of some inquiries made by the Board of Agriculture, that a Cornish farmer, Mr. Sickler, and also the Rev. R. Hobbin, were accustomed to employ refuse salt as a manure, and that their crops were never infected with the rust or blight. See Mildew.

Experiments demonstrate the efficacy of salt on barley and oats. In 1820, on a good alluvial soil, at Heybridge, in Essex, in a field of barley, the results of two experiments were—

1. Soil dressed with 6 bushels of salt per acre, and 20 loads of earth and stable dung, at turnip-time, produced per acre - 65
2. Soil dressed with 20 loads of dung and earth - - - 60

In the same year, at Sproughton, in Suffolk, on a sandy, barley soil, belonging to Mr. Ransome—

1. Soil without any manure produced, per acre - - - 20
2. Soil dressed with 16 bushels of salt per acre in March - - - 51

The following table contains the results of fourteen experiments, made in 1819, by the late Mr. George Sinclair, at Woburn, on the uses of salt to the barley crop. The soil had, the previous year, carried a crop of turnips, and was composed of three-fourths silicious sand:

In these experiments upon oats, the quantity of salt applied was evidently too great. Mr. Legrand states, that in his experiments upon barley, "it gradually advanced in its effects 16 bushels, and gradually diminished to 6 bushels, when vegetation was stopped."
The following table contains the results of the experiments made at Woburn, 1818–19, by the late Mr. George Sinclair, with his usual scientific accuracy. I would direct the farmer’s attention to this table, as containing a mass of valuable information.

As a Manure for Grass Land, Meadows, &c., salt has been used in all parts of England, with varying success. It always, however, sweetens the herbage. It has been employed at the rate of 6 to 16 bushels per acre, and where the primary object has been the destruction of the old turf, even 30 to 40 bushels have been successfully employed on the same extent of land. It has the effect of completely preventing wormcast on lawns, &c.

In a letter with which I was favoured from Mr. Collyns, of Kenton, Devonshire, 1826, he says:—"One of my neighbours writes me, ‘In using salt as a manure on grass land, I have found salt manure portions, which are likely to be affected by severe frosty nights, when every blade of grass on the unsalted portions has been in a frozen state. I observe, too, that it is destructive to every kind of grub and worm; and I am convinced, where it has been used with judgment, that it has not failed.’ Another intelligent neighbour," continues Mr. Collyns, "whose farm is almost entirely a light black sand, writes, ‘I have found salt answer my most sanguine expectations for barley, oats, potatoes, and turnips, both as to the increased quantity and improved quality of the crops, of which I can now give ocular demonstration: my barley and oats, which used to yield me only 15 to 20 bushels per acre, now yield from 40 to 45. My wheat is certainly much improved in quality, but I expected more in quantity. I have had 35 bushels of wheat from an acre dressed with 10 bushels of salt; and from the same field last year, after the same quantity of salt, 140 bags of potatoes per acre. This year again, dressed with 10 bushels of salt, I have not more than 20 bushels of wheat per acre, but the quality very superior indeed, and the root of clover in it very fine and luxuriant. In every field I have salted, I find the grass very much superior to any produced before the use of salt.’ I have since," adds Mr. Collyns, "gone over his farm, and am astonished at the verdant pasturage, in what used to be coarse and rushy meadows. In this arable land, he never got more than 10 bushels of wheat per acre until he used salt; so that this is also a decided improvement.”

In Suffolk, according to a statement furnished to me by Mr. Broke, of Capel, near Ipswich, "In the month of April, 1821, 6 bushels of salt manure were applied to half an acre of red clover; the soil good turnip land, not sharp; extent of the field 10 acres. The salted clover at first looked very yellow, and apparently injured, but it soon began to recover, and when mown, the increased produce was, at the very least, 10 cwt. per acre; and the aftermath proportionally good; the cattle eating it down closer, and in preference to any other part of the field.”

---

**SALT, COMMON.**

The soil on which these experiments were made was sandy, and the plots each contained 36 square feet; the Talavera wheat was drilled into the soil November 5th, and reaped August 2d, 1818.

**Footnote:**

970
With potatoes.—There have been various experiments made with salt as a manure for potatoes. The author of this work, in 1817, on a gravelly soil, at Great Totham, in Essex, made the following trials:

1. Soil simple, produce per acre
2. Soil with 20 bushels of salt in September
3. Soil with stable manure, 20 loads in the spring of the year
4. Soil with 20 loads of manure and 20 bushels of salt
5. Soil with 40 bushels of salt alone
6. Soil with 40 bushels of salt and 20 loads of manure

The Rev. Edmund Cartwright, of Hollenden House, in Kent, in 1804, made various important trials of soil as a manure for potatoes. The soil on which the experiments were made consisted of three-fourths sand. See Potatoes.

"Of ten different manures," said this agriculturist, "salt, a manure hitherto of an ambiguous character, is (one only excepted) superior to them all. The effect of the mixture of salt and soot is remarkable." The writer of this witnessed the same result on carrots, at the rate of 16 bushels of each per acre.

Vermin.—With regard to the destruction of vermin by means of salt, we may safely assert, that there is, perhaps, no agricultural use of common salt more undoubted. The effect, too, is direct, and the result immediately apparent. For this purpose, from 5 to 10 bushels per acre are sufficient. The agriculturist need be under no apprehension that the salt will destroy his crop, for 20 bushels of salt per acre may be applied to young wheat with perfect safety: I have seen even 25 bushels used with advantage. See Insects.

In reference to Weeds.—Salt has been of late years used at the rate of from 20 to 40 bushels per acre, to kill weeds and to cleanse fallows, with great advantage; it also, in the large proportion we have named, will destroy coarse, sour grass, &c.; and though, for a time, all vegetation is destroyed, yet, in a short period, a multitude of useful herbs is produced. If the cultivator can collect weeds, parings of turf, ditches, banks, &c., of the most foul description, and spread evenly on the surface of the heap half a bushel of salt to every ton of the collection, he will find every weed, in the course of a few weeks, killed and dissolved away. This plan I have long followed myself, on a light, gravelly soil; and upon spreading this salted mixture, at the rate of 14 or 15 loads per acre, its beneficial effects can be traced to an inch. I have principally used it as a dressing for turnips and oats.

In the Garden.—Salt has been employed by the gardener for many purposes; most commonly on lawns, at the rate of 10 bushels per acre, to prevent worm-casts; and on gravel walks in a larger proportion, to kill weeds; it may be employed, however, as a fertilizer in gardens with decided advantage. I have witnessed the results of the following experiments made by my brother, Mr. George Johnson, at Great Totham; and I more readily give them a place here, from knowing with what care they were made:—

The soil was composed of—

| Stones and gravel | Port. | 27 |
| Vegetable fibre | 1 | 5 |
| Soluble matter | 2 | 3 |
| Carbonates of lime and magnesia | 18 | 18 |
| Oxide of iron | 4 | 4 |
| Animal and vegetable matter | 1 | 1 |
| Alumina | 4 | 4 |
| Silica | 40 | 40 |
| Loss | 1 | 1 |

Windsor beans were sown on it—

In preventing clubbing in the roots of some of the brassica tribe, Mr. Johnson found salt highly useful; he states, in some observations on this disease read to the Horticultural Society of London, October 16, 1821:—"Some cauliflowers were planted upon a light silicious soil, which had previously been manured with well-patfreed stable manure, and over one-third of the allotted space was covered with salt, at the rate of 20 bushels per acre, immediately before planting, in July, 1821. The previous crop had been broccoli. Fifty-four plants were set on the two-thirds unsalted, and 26 on the one-third salted; the result has been, that of the 54 unsalted, 15 have been diseased and unproductive, but of the 26 salted only 2." There is little doubt, but that salt might be much more extensively employed by florist than at present. A very small quantity of salt added to the water in which flowers are placed, adds considerably to their duration. There are many bulbous-rooted flowers which flourish best in the immediate vicinity of the sea. Mr. Edwin Greville remarked, in 1824, that some common salt applied at the rate of 16 bushels per acre to a portion of a bed of stocks, in his garden at Wyaston, in Derbyshire, made them grow much more decided stronger and finer, and bloom much more perfectly than those growing in the same bed unsalted. "There was no possibility of error or doubt on the subject," said my intelligent informant. I have given the experiments of Dr. Priestley upon various plants vegetating in salt and water. He found
SALT, COMMON.

that the use of salt materially protracted the existence of the plant. It is a common custom with the importers of exotic plants, to dip cuttings in salt-water. Before the adoption of this plan, they were almost invariably perished in the passage.

Among the many excellent communications with which I have been favoured on the use of salt in the cultivation of plants, was one from an eminent florist, near Paddington, Mr. Thos. Hogg. "From the few experiments," he observes, "that I have tried with salt as a garden manure, I am fully prepared to bear testimony to its usefulness. In a treatise upon flowers, published about 6 years since, I remarked, that the application of salt, and its utility as a manure, was yet imperfectly understood. It is a matter of uncertainty, whether it acts directly as a manure, or only as a kind of spice or seasoning, thereby rendering the soil a more palatable food for plants. The idea that first suggested itself to my mind arose from contemplating the successful culture of hyacinths in Holland. This root, though not indigenous to the country, may be said to be completely naturalized in the neighbourhood of Haerlem, where it grows luxuriantly in a deep, sandy, alluvial soil; yet one great cause of its free growth, I considered, was owing to the saline atmosphere: this induced me to mix salt in the compost, and thus I found that no hyacinths will grow well at a distance from the sea, without it. I am also of opinion, that the numerous bulbous tribes of amaryllideae, especially those from the Cape of Good Hope, ixias, aliums, which include onions, garlic, shallots, &c., anemones, various species of the lily, antholyza, colchicum, crinum, cyclamen, narcissus, iris, gladiosus, ranunculus, seilla, and many others, should either have salt or sea-sand in the mould used for them. I invariably use salt as an ingredient in my compost for carnations; a plant which, like wheat, requires substantial soil, and all the brine and salt that no hyacinths would be content to thrive in perfection; and I believe I might say, without boasting, that few excel me in blooming that flower."

In the inundations of the sea, as in Friesland, for instance, in 1825, various curious effects were produced by the salt-water. The oak, the mulberry, pear, peach, and others with deep roots, did not suffer; neither did the asparagus, onions, celery, &c., for they were never finer, or more luxuriant. But the vines and gooseberries contracted a salt taste; and the apricots, apples, cherries, elms, poplars, beech, willows, &c., could not bear the brine and salt; so that these plants perished out a few leaves, but speedily perished. (Turner's Sacred Hist. p. 117.) Similar results were noticed, after an inundation of the sea, in the garden of the late Richard Gower, Esq., near Ipswich, in Suffolk; in November, 1824. In this instance a portion of the garden remained 24 hours under the seawater. The asparagus beds were materially improved in their produce. The cherry trees, in the following year, produced a numerous crop of cherries, which tasted, however, so very salt that they could not be eaten, although very fine in appearance. These trees all died in the following year, 1826. (Johnson on the Fertilizers, p. 374.)

SALT, with other MANURES.—Salt and Lime. With a mixture of salt and lime, a manure is gradually formed of a most powerful description. It promises now, through the successful example of Mr. Bennett and Sir C. Burrell, to be very generally adopted. It is difficult to account for the neglect of this manure, on any other ground than the difficulties which were so long thrown in the farmer's way, by the long-continued tax upon salt. That it is not a novel plan for enriching the land is quite certain. Glauer, a celebrated German chemist, one of the last of the alchemists, described it in the jargon of his craft nearly two centuries since, when he said: "The Sol mirabilis (common salt), as it is of itself, is, by reason of its corroding virtues, which it as yet retains, plainly unfit for the multiplication of vegetable, for that being so used would prove more hurtful than profitable. Upon this account it is necessary that to one part of it be added two parts by weight of the best calyx vine (lime), which being moistened with water and made into balls, are to be well heated red-hot for an hour, that so all the corrosivity being introverted, the Sol mirabilis may be alkaliized, and used to vegetables for an universal medicine: for it conserves its attracting force, and loiseth it not in the heating red-hot." (Glaufer's Works, by Packe, pp. 2, 47.)

Christopher Packe, who, in 1688, published in English Glaufer's folio volume, dwells at considerable length in his preface upon this mixture of salt and lime; "for the enriching of poor and barren land, it is the cheapest of all mixtures, and is most easy to be done; for any ploughman having but once seen it done may be presently able to manage it."

Salt and lime was used as a manure by Mr. Mitchell, of Ayr, many years since, and he, not knowing what others had done with this fertility, and that he was the discoverer, he therefore described his process:—Take 32 bushels of lime, and slack it with sea-water, previously boiled to the saturated state. This quantity is sufficient for an acre of ground, and may be either thrown out of the carts with a shovel over the land in the above state, or made into compost with 40 loads of moss or earth, in which state it will be found to pay fully for the additional labour, and is sufficient for an acre of fallow ground, though ever so reduced before. Its component parts are muriate and sulphate of lime, mineral acid and sea-water; and also muriate and carbonate of soda. All the experiments have done well with it, but especially wheat and beans; and it has not been behind any manure with which it has been compared. There is one instance in which it was tried in comparison with 72 cart-loads of soaper's waste and dung; and although this was an extraordinary dressing, yet that with this salt and lime manure was fully above the average of the field. Mr. Mitchell calculates that 3000 gallons of sea-water, boiled down to about 600 gallons, will slack 64 bushels of shell lime. (These 3000 gallons of sea-water will contain about 973}
The mixture of salt with soot produces the most remarkable effects, especially when trenched into ground prepared for carrots. Mr. G. Sinclair found that when the soil, unnatured, produced twenty-three tons of carrots per acre, the same soil, fertilized with a mixture of only six bushels and a half of salt, and six and a half of soot, yielded forty tons per acre. Mr. Belfield describes the mixture as equally beneficial for wheat. And Mr. Cartwright found, that when the soil, without any addition, yielded per acre 157 bushels of potatoes, that, dressing the same land with a mixture of three bushels of soot and eight bushels of salt, made it produce per acre 240 bushels. (Johnson on Fertilizers.)

SALTS, their uses to vegetation. That peculiar saline substances exist in almost all vegetables, was an early observation made by the natural philosopher. The saline and alkaline taste perceivable in the ashes obtained by the combustion of these substances, very plainly indicated the fact. And although the skill of the chemist did not at first enable him to accurately discriminate between the salts, the alkalies, or even the earths contained in plants, with even tolerable accuracy, yet the progress of science has long accumulated a mass of difficulties, and has detected a strange variety of salts in plants. A salt, be it remembered, is a substance produced by the combination of an acid with a base, that is, with an earth, an alkali, or a metallic oxide: the class of salts, therefore, is exceedingly numerous (they have been estimated at about 2000), and includes many substances which at first sight do not appear entitled to such a name; thus the union of the carbonic acid with the earth lime, which is an oxide of a metal, forms the salt carbonate of lime, or chalk, marble, &c. Sulphuric acid and lime form the salt sulphate of lime (gypsum); and many other earthy salts look to the mechanical eye as little like salts as these.

The farmer must avoid, in entering into this examination, the common error of supposing that the saline substances found in plants are not their essential constituents or food, but are merely there by chance; that their presence is unattended with benefit, and their absence totally unproductive of injury; for such is a most erroneous conclusion. Not only are certain salts, the phosphates and sulphate of lime, and the carbonate of potash, for instance, invariably present in certain plants, but those salts are present in the soil in which they grow, they will not maintain a healthy vegetation. Under the head EARTHS, GASES, WATER, I have endeavoured to show how essential those substances are to vegetation, and what a great part they perform in the support of the farmer’s crops; but still it will be found, that when a soil is carefully composed of all the pure earths discovered in plants, watered in abundance with pure water, and supplied with all the gases of putrefaction and of the atmosphere, that still these are not sufficient by themselves to support a single cultivated crop; but then it is found that where such a soil is supplied with various saline sub-
stances (for instance, with the various saline matters draining from a dunghill), that then every difficulty is removed. Neither must the cultivator suppose, that when saline substances are mixed with the soil, that the plant growing upon it absorbs those salts as a matter of necessity, united with the moisture contained in that soil, without having the power of rejecting or separating it from its solution; for such an assumption has been proved to be contrary to the fact by several very accurate experiments. M. Sausserne, for instance, found that plants had the power, when placed in saline solution foreign to their habits, of separating them from the water in which they were dissolved. These are researches fraught with instruction to the cultivator. He dissolved the following salts in water, in such proportions that each solution contained \( \frac{1}{10} \) part of its weight of the salt—muriate of potash, muriate of soda (common salt), nitrate of lime, sulphate of soda (Glauber salt), muriate of ammonia (sal ammoniac), acetate of lime, sulphate of copper (blue vitriol). In each of these solutions he put plants of Polygonum Persica, or of Bidentis cannabin, furnished with their roots with the Polyg. The Polyg. grew for five weeks in the solution of muriate of potash, nitrate of lime, muriate of soda, and sulphate of soda, and its roots increased in them as usual. It languished in the solution of sal ammoniac, and the roots made no progress. It died in 8 or 9 days in the solution of acetate of lime, and in less than 3 days in the solution of sulphate of copper. When such a number of plants of Polygonum were put into the solutions as to absorb one-half of each in 2 days, the remaining half was found to have lost very different proportions of the salt which it had originally contained. Supposing the portion of salt at first in solution to be 100, the following table exhibits the quantity of each which had disappeared when one-half of the liquid was absorbed—

<table>
<thead>

<td>Sulphate of copper</td>
<td>7</td>
</tr>
</tbody>
</table>

The Bidentes absorbed pretty nearly the same proportions, but in general did not vegetate so long as the Polygonum.

When various salts were dissolved at once in the same solution, and plants made to vegetate in them, it was found that different proportions of the salts were absorbed. The following table exhibits the results of these trials, supposing, as before, the original weight of each salt to have been 100, each solution contained \( \frac{1}{10} \) part of its weight of each salt—

</tbody>
</table>

These experiments succeeded nearly equally with other plants, as the Mentha pipetita and the Sedum. When the solutions were once removed, the plants absorbed all solutions indiscriminately; on examining the plants, the salts absorbed were found in them unaltered. It being thus clearly established that plants possess a discriminating power, and that they do not absorb saline solutions merely because they happen to be dissolved in the soil, it next becomes an object of interest, as an illustration and guide for the operations of agriculture, to ascertain what salts are found by the researches of the chemist in commonly cultivated plants. And if, at the conclusion of our examination, we find that certain salts are found in abundance only in certain plants, and that these saline substances exist in them invariably in all soils and situations, and that without their presence the plant languishes and merely supports a sickly existence, we shall be almost driven to the conclusion, that these are as essentially the food of plants, as any of the other substances with which they abound.

For a lengthened period, the vegetable alkaline salt, carbonate of potash, has been obtained from plants. Procured at first by their combustion, in iron pots, it hence obtained its name. Dr. Thomson has given a table of the quantity of potash obtained from 100 parts of various trees and plants. See Alkali.

In general, says Dr. Thomson, three times as much ashes are obtained from shrubs as from trees. An equal weight of the branches of trees produce more ashes than the trunk, and the leaves more than the branches. Herbs arrived at maturity produce more ashes than at any other time. Green vegetables produce more ashes than dry. The salt which is obtained by the combustion of plants, although chiefly composed, does not consist wholly of potash: there are many salts mixed with it; these are a muriate of soda, sulphate of potash, muriate of potash, sulphate of lime, phosphate of lime, &c., but these bear in general but a small proportion to the potash.

Perhaps the most copious table of the alkaline and other salts obtained by the combustion of various plants has been given by M. Sausserne in his chemical researches on vegetation. He obtained from 100 parts of the ashes of the—

M. Vauquelin found 20 per cent. of potash in the ashes of the oak; and from his experiments it is probable that potash exists in plants in combination with the acetic and carbonic acids.

The mineral alkali soda, or carbonate of soda, is found in almost all the plants which are found growing in the sea, or on the shore, within reach of its influence. The amount of alkali which these produce, is considerably greater, in proportion to that produced by plants natives of inland places. Thus, 100 parts of the sal soda yield 19,921 parts of ashes, and these contain 1,992 parts of soda and common salt. Many plants, the vegetable marrow and the vine, for instance, derive great benefit from the application of soda to their roots. Soap-suds are used as an excellent liquid manure by many gardeners.

Sea-weed, kelp-soda, barley, and the common washing-soda of the shops, have all been used for the same purposes, and are the well-known fertilizing mixture of salt and lime, after it has remained undisturbed for some time, contains chloride of lime and soda in abundance. Sea-weeds abound with a strange mixture of alkaline salts, and there is no green manure more powerful in its effects than this, especially when it is ploughed in as fresh as possible. Mr. Gaultier de Claibury found in the Fucus saccharinus and in the Fucus digitatus (which is much used in Scotland as a manure) the following substances—saccharine matter, mucilage, vegetable albumen, oxalate of potash, malate of potash, sulphate of potash, sulphate of soda, sulphate of magnesia, muriate of soda, muriate of potash, muriate of magnesia, carbonate of potash, carbonate of soda, hydriodate of potash, silica, phosphate of lime, phosphate of magnesia, oxide of iron, oxalate of lime. In the islands of Guernsey and Jersey they employ the ashes of the sea-weeds, which they call vrat. Half a bushel stirred over a perch of ground in winter, or the beginning of spring, is sufficient. It gives a full ear to the corn, and prevents it from being laid.

Phosphate of lime, which is composed, according to the experiments of M. Berzelius, of phosphoric acid 100 parts, and lime 84-63, abounds in vegetable substances. It forms the basis of bone, from which, for the purposes of experiment, it is commonly procured. Obtained in this way it is always in the form of a white powder, without either taste or smell; it is insoluble in water, and unaltered by exposure to the atmosphere. Phosphate of magnesia is composed of phosphoric acid and magnesia; is a salt soluble in 15 times its weight of water. These two salts have been found in a variety of vegetable substances by MM. Vauquelin, Saussure, and other able chemists. See Bones.

There is little doubt but that these salts are absorbed from the soil by the plants. Almost all cultivated soils contain them in some form or other; and of the value of their addition to the soil in almost every form, there is considerable evidence. Thus, phosphate of lime abounds in all the richest animal manures, such as in bone-dust and the richest excrements of animals; and, again, it is found by the Cheshire graziers, that the earthy salts of bones obtained from the size-makers, after most of the oily matters are removed by the action of steam, and hardly anything but the salts of lime remain, are quite as fertilizing to their pastures as when used in their fresh state, abounding with animal matters.

Sulphate of lime, or gypsum, is another salt, which is invariably found in and promotes the growth of certain plants.

It must, I think, be regarded as one of those salts which constitute the food or constituents of plants. It is always present in the clover, lucern, and sainfoin, and in smaller proportions in the potato and the turnip. See plaster of Paris.

That it was a food for plants, was the opinion of Sir Humphry Davy. He remarked, when speaking of gypsum and the alkalies, "It has been generally supposed that these materials act in the vegetable economy in the same manner as condiments or stimulants in the animal economy; and that they render the common food more nutritious. It is true, however, a much more probable idea, that they are actually a part of the true food of plants, and that they supply that kind of matter to the vegetable fibre, which is analogous to the bony matter in animal structures. Thus, those plants which are most benefited by the application of gypsum, are those which always afford it on analysis. Clover and most of the artificial grasses contain it, but it exists in very minute quantity only in barley, wheat, and turnips." (Ag. Chem. p. 19) And it is noticeable, that most of these remarks apply to the phosphate of lime (which can hardly be regarded as a stimulant), since it is not even soluble in water; it is also worthy of observation, that the same salts of lime (the phosphate and the carbonate) which Davy thus supposes to be placed in plants to add to their strength and solidity, are precisely those salts which for that very purpose are placed in the bones of animals. They thus, as it were, mutually nourish each other. The very phosphate of lime, which in the dissolving bone-dust is absorbed by the plant, again becomes, in the food of animals, a material for the formation of other bones.
The carbonate of lime, in some of its forms of chalk, limestone, marl, &c., is the most universally present of all the salts contained in vegetables. It is, in minute proportions, soluble in water, and more so if the water is saturated with carbonic acid gas, hence it is readily absorbed by the roots of plants. It exists in vegetables in very varying proportions; thus, the ashes of the perfect oat plant, strung together, were proved by M. Vanquelin to contain more than 5 per cent. of this earth. (Ann. de Chem. vol. xxix. p. 19.) In 32 ounces of seeds of wheat, M. Schraeder found 12 grains of carbonate of lime; and in the same quantity of seeds of rye 13-4 grains; 24-5 grains in seeds of barley; 33-75 in those of the oat; and 46-2 in the same weight of the straw of rye. It is most commonly, although not always, found in vegetables with carbonate of magnesia. These were found together by M. Sauassure in the ashes of the following different substances. He obtained from 100 parts of the ashes of the—

Carbonate of lime has also been detected in the sap and white matter of the ulcer of the elm by M. Vanquelin; in the ashes of wormwood (more than 50 parts in 100), by Kuns-muller; in the flowers of the arnica, by M. Chevalier; in the potato, by M. Einhof; in the red bark of St. Domingo, in Peruvian bark, and in the root of the quinquania, by M. Fourcroy. Existing, therefore, so universally in plants, there can be no doubt of the fact that this salt is fulfilling, then, some wise and salutary purpose; not fortuitously, but with design; not by chance, but by the regulation and arrangement of their Divine Architect.

The action of saltpetre or nitrate of potash upon vegetation is not so easily explicable as that of many other salts; and the same remark applies to that of cubic petre or nitrate of soda.

Nitrate of potash, which is composed of nitric acid 54-34 parts, and potash 45-66 parts, enters into the composition of a few plants, it is true, but in the greater number, even in those of the farmer's crops, on which some its application produces such luxuriant effects, its presence cannot be detected, even in minute proportions. Some plants, however, do contain it in considerable quantities. Thus it has been found in the common nettles, the horse-radish, and the sunflower. M. Chevrel found it in the Chenopodium album; M. Vanquelin in the leaves of the deadly nightshade; M. Chevreul in woad; Dr. John in the Mesebrayanthemum crystallinum. M. Bouillon Le-grange made various plants, such as the sunflower, vegetate in soils which did not contain any saltpetre: upon examining them, no traces of saltpetre were discernible, but upon watering them with a weak solution, it made its appearance in them as usual. (See Nitrates.)

The presence of cubic petre (nitrate of soda), which is composed of nitric acid 62-1, and soda 37-9, is still more rare in plants; it has only been detected in barley.

The salts formed with the vegetable acids existing in the juices of plants are rather numerous. Oxalate of potash, for instance, exists in the Oxalis acetocella, and several others; oxalate of lime in rhubarb, parsley, fennel, squills, tormentilla, deadly nightshade, and spinach. Nitrate of lime is contained in the onion; malate of lime in the houseleek, wake-robin, mignonette; and malate of potash in rue, the garden purslane, nasturtians, lilac, madder, &c.

There is, perhaps, no saline substance that exists to so great an extent in marine plants, and which has been used for so long a period and to such an extent for those growing in inland situations, as common salt. (See Salt.) A substance which not only abounds in all plants growing on the sea-shore, but always exists in smaller proportions in many of those growing in upland districts. Thus, Mr. G. Sinclair obtained from 1450 grains of wheat-chaff from Bedfordshire, ashes 50; common salt 2.4; from 1450 parts of the seed, ashes 10; common salt 1.4. But from the same crop, which had been dressed with 44 bushels of common salt per acre, he obtained from 1450 parts of the chaff, ashes 40; common salt 4; and from 1450 parts of the seed, ashes 10; common salt 4.

Common salt is found generally in minute proportions in most cultivated soils. Davy detected in 400 grains of a good silicious soil from a Tonbridge hop-garden, nearly 8 parts of common salt.

Besides being in small proportions a direct food for plants, common salt also seems to perform several other services to vegetation, and the same remark probably applies to other salts; for instance, when applied to the soil in small proportions, it certainly promotes the putrefaction of its organic matters. See Salt.

And again, salt, in common with several others, appears to excite or stimulate the plant, when applied to it in proportions not too excessive; a fact first noticed by Dr. Priestley.

Another use of common and other salts to vegetation is, the preservation of the plant from injury by sudden transitions in the temperature of the atmosphere: salted soils only
SALTS.

He from it richest of rock-salt, produced deliquescent, Mr. Bennett, dressed hours, dried when experiments calcium, all property, moisture been found of such calcium, Magnesia, cubic pete, or nitrate of soda, &c., which, in consequence, when they are used as fertilizers, they increase this property, so valuable and so essential to all cultivated soils. Thus I found by some experiments upon a rich soil near Maldon, in Essex, worth 42s. per acre, that 1000 parts, dried at a temperature of 212°, absorbed in 18 hours, by exposure to air saturated with moisture at a temperature of 62°, 25 parts. But 1000 parts of the same field, which had been dressed with 12 bushels of marine salt per acre, under the same circumstances, gained 27 parts; and 1000 parts of the same soil, which had been dressed with 6 bushels per acre, gained 26 parts. The attraction of some saline substances for the moisture of the atmosphere is very considerable. I found that 1000 parts of refuse salt manure, dried at 212°, absorbed in 3 hours, by exposure to air saturated with moisture at 60°, 194 parts. 1000 parts of the sediment or pan-scratch of the salt-makers, gained 10 parts; 1000 parts of Cheshire crushed rock-salt, 10 parts; 1000 parts of gypsum, 9 parts; 2000 parts of calcium, is so powerful deliquescent, that it absorbs sufficient moisture from the air to dissolve in it and form a solution.

Dr. Marcell found that 288 grains in 124 days absorbed 684 grains of water. 288 grains of nitrate of lime, a salt found in some of the richest alluvial soils of the East, absorbs in 147 days 448 grains. Carbonate of potash, another saline fertilizer, also absorbs moisture. Now, it is worthy of the farmers' notice, that chloride of calcium is the very salt which is produced in such abundance by the decomposition of common salt by lime, in the way so satisfactorily recommended by the able German chemist Glauber, by Mr. Hollingshead, Mr. Bennett, and Sir Charles Burrell (See Salt and Lime); for, by the slow action carried on for three months by these substances on each other, this salt and soda are produced by the decomposition; and it is not improbable that when these salts are present in the juices of plants, that by this means the attractive powers of their leaves and roots for aqueous vapour may be increased. Davy alludes to these essential, yet too little understood powers of absorption possessed by vegetables, when he says (Lectures, p. 207), "In very intense heats, and when the soil is dry, the life of plants seems to be preserved by the absorbent power of their leaves; and it is a beautiful circumstance in the economy of nature, that aqueous vapour is most abundant in the atmosphere when it is most needed for the purposes of life, and that when other sources of its supply are cut off, this is most copious."

Of the salts of ammonia, as I have in another place remarked, carbonate of ammonia has been detected in the Chenopodium album by Messrs. Chevalier and Lasseigne; and it probably exists in other plants which are distinguished for their powerful disagreeable odour. Muriate of ammonia has been found in wood by M. Chevreul. The salts of ammonia are in general exceedingly fertilizing in their effects upon vegetation. Soot owes part of its efficacy to the ammoniacal salts it contains. The liquor produced by the distillation of coal contains carbonate and acetate of ammonia, and this liquid of the gas-makers is a very good manure. "In 1808," says Davy, "I found the growth of wheat in a field at Roehampton assisted by a very weak solution of acetate of ammonia." The experiments of Mr. Robertson with soot clearly show the fertilizing effects of the soluble portion of it. He mixed together, in order to form a liquid manure, six quarts of soot in a hogshead of water. "Asparagus, peas, and a variety of other vegetables," says this intelligent horticulturist, "I have tried with this mixture, with as much effect as if I had used solid dung." Care must be taken, however, in using this and all other liquid fertilizers, not to make the solutions too strong: it is an error into which all cultivators are apt to fall in their early experiments. Even Davy was not an exception, since, from making his liquids too concentrated, he obtained results which widely differed from his later experiments. There is no doubt but that the salts of ammonia, and all the compound manures which contain them, have a very considerable forcing or stimulating, or, perhaps, nourishing effect upon vegetation. In the experiments of Dr. Belcher upon the common garden cress, by watering them with a solution of phosphoric of ammonia, the plants were 15 days forwarder than plants growing under similar circumstances, but watered with plain water; and he also describes the experiments of Mr. Gregory, who, by watering one-half of a grass field with urine, nearly doubled his crop of hay. Other testimonials in support of the fertilizing powers of the salts of ammonia are furnished by Mr. Handley. Of the most remarkable effects that ammonia operates upon plants, a late valuable work on organic chemistry, by M. Liebig, abounds with observations, with some of which I cheerfully and cordially agree. To understand these remarks, however, the farmer must remember that ammonia is composed, according to the analysis of Davy, of hydrogen 74 parts, and azote or nitrogen 26 parts. "The nitrogen of putrefied animals," he observes, "is contained in the atmosphere, as ammonia in the form of a gas, which is capable of entering into combination with carbonic acid, and forming a volatile salt. Ammonia in its gaseous form, as well as all its volatile compounds, are of extreme solubility in water. Ammonia, therefore, cannot remain long in the atmosphere, as every shower of rain must condense it, and convey it to the surface of the earth: thence, also, rain-water must at all times contain ammonia, though not always in equal quantity. It must be greater in summer than in spring or in winter, because the intervals of time between the showers are greater; and, where

123

4 x 2

977
several wet days occur, the rain of the first must contain more of it than the second. The rain of a thunder-storm, after a long-protracted drought, ought, for this reason, to contain the greatest quantity which is conveyed to the earth at one time. But all the analyses of atmospheric air hitherto made have failed to demonstrate the presence of ammonia, although, according to our view (says M. Liebig), it can never be absent. If a pound of rain-water contains only one-fourth of a grain of ammonia, then a field of 40,000 square feet must receive annually upwards of 80 lbs. of ammonia, or 65 lbs. of nitrogen; for, by the observations of Schubler, which were formerly alluded to, about 700,000 lbs. of rain fell over this surface in twenty months. This is much more nitrogen than is contained in the form of vegetable albumen and gluten in 2650 lbs. of wood, 2800 lbs. of hay, or 200 cwt. of beet-root, which are the yearly produce of such a field; but it is less than the straw, roots, and grain of corn which might grow on the same surface would contain. Experiments made in the laboratory of Giessen, with the greatest care and exactness, have placed (continues Liebig) the presence of ammonia in rain-water beyond all doubt. It had hitherto escaped observation, because no one thought of searching for it."

I cannot recommend the farmer to adopt the able conclusions of M. Liebig without considerable caution: hardly any thing retards the progress of science more than erroneous theories. Fortunately, however, the farmer can in all cases impatiently and successfully examine and apply the valuable facts of the skilful chemist without mystifying himself with not always intelligible doctrines. It is very probable that plants have the power of decomposing ammonia, and of assimilating the nitrogen which it contains, in the same way as there is little doubt that animals assimilate nitrogen by them; but we have no direct evidence of the facts, and the best course, therefore, will be to regard them not as absolute chemical truths, but merely as of the class of what may be perhaps denominated scientific probabilities.

Some of the other compounds of chlorine, the old class of chlorides of the chemist, have been tried as fertilizers, with very doubtful success; for although at first the seeds which had been steeped in them germinated with a considerably increased rapidity, yet they speedily seemed to suffer by this additional stimulus. Davy tried solutions of chlorine, and sulphate of iron (green vitriol): he says, "Though the plume was very vigorous for a time, yet it became at the end of a fortnight weak and sickly, and at that period less vigorous in its growth than the radish sprouts which had been naturally developed, so that there can be scarcely any useful application of these experiments. Too rapid growth and premature decay seem invariably connected in organized structures, and it is only by following the slow operations of natural causes that we are capable of making improvements." Oxynitrurate of lime, or, properly speaking, chloride of calcium, however, appears to be beneficial to vegetation: this was ascertained in 1796, by Ingenhoutz; and I have given in my work On Fertilizers, p. 367, the result of some trials by Mr. Fincham with this chloride that were highly successful: he says, "Half of some turnip-seed were steeped for 36 hours in a solution of chloride of calcium, composed of 1 part chloride of calcium, and 48 parts water; this was sown under precisely similar circumstances of soil and aspect with the other half unsteeped. The first came up much sooner, was never attacked by the fly, and the produce was half as much again, and the tops made more luxuriant. He attributes the failure of Davy to his having used the chlorine, uncombined with the base lime. Such then are the chief facts with which I am acquainted, relating to the uses of the saline bodies to vegetation. It is a research much more extensive and valuable than it at first may appear to the intelligent farmer. What we already know of the action and the effects of these saline bodies as the food or constituents of plants, he will find exceedingly important. It is more than probable, that the salts act upon vegetation in many beneficial ways, yet unknown to the philosopher. The material action upon some soils of saltpetre (nitrate of potash), for instance, is to us inexplicable by any chemical knowledge that we at present possess. The effect of cubic metres of nitrate of potash and other salts is often equally marvelous; but although there are difficulties of this kind, the scientific farmer, far from allowing such impediments to restrain either his ardour or his thirst for knowledge, will only see in these at present hidden truths additional reasons for a noble perseverance in the pursuit of knowledge; for he will feel that the discovery of the reasons of the at present many unknown phenomena of vegetable life will in all reasonable probability extend very materially the powers, and increase the sphere of usefulness of many succeeding generations of enlightened cultivators.

SALT-PETRE (Germ. and Fr., salpetre). See NITRATES and SALTS.

SALTWORT (Salsola, from salus, salt; in allusion to the saline properties of the species). A genus of plants which inhabits the sea-coast, especially abundant on the coast of the Mediterranean, where they are extensively gathered and burnt for the manufacture of barilla and soda. See KELP.

SALT-MARSH CATERPILLAR. See CATERPILLAR.

SALVING or SMearing sheep is resorted to in various districts, for the purpose of preserving the fleece from the effects of weather, destroying injurious insects, and preventing cutaneous diseases. A mixture of damaged butter, hog's lard, resin, and Gallipoli oil, is found to be the most efficacious salve. Tar stains and spoils the colour of the wool. See SHEEP.

SAMPLE. A small quantity, of a commodity exhibited at public or private sales, as a specimen. Wool, wine, corn, seeds, and indeed most species of agricultural produce and merchandise that can be conveyed in small bulk, are sold by sample. If an article be not at an average equal to the sample by which it is sold, the buyer may cancel the contract, but...
SAND. return the article to the seller. (McCulloch's Com. Dict.)

SAND (Germ.). Finely divided siliceous matter constitutes common river and sea-sand; particles of other substances are often blended with it, and sometimes it becomes calcareous from the prevalence of carbonate of lime.

Sand is often employed as a manure by the cultivator of the poor, hungry clays, especially if he can obtain calcareous sand. See Earths, Mixture of Soils.

SANDBURNT. See Chicken Weed. (Arcenaria, from sand; referring to the sandy situation in which most of the species are found.) This is an extensive genus of herbs, of humble growth, with numerous slender stems, opposite, mostly narrow, entire, undivided leaves, and small, white or reddish, inodorous flowers, with coloured anthers. This succulent vegetable bears a great resemblance to samphire, and considerable quantities of it are pickled and sold for that plant.

SANICLE (Sanicula, from sano, to heal.) The wood sanicle (S. Europaeus) is a mere perennial weed, growing in woods and meadows, from a foot high, flowering in May. The root is tufted, with fleshy fibres. The leaves are chiefly radical, simple, with deeply cleft lobes, veiny, and of a deep shining green. Flowers cream-coloured, in capitate umbels, in an irregular, twice compound, partly umbellate panicle. The herb is bitter, with an acrid, somewhat aromatic pungency. Its reputed vulnerary qualities are no longer believed.

SAP. In botany, the fluid which is absorbed by the roots from the earth, and undergoes the first action of the vital chemistry of the plant, is called sap. It is formed as the absorbed fluid ascends upwards into the stem. It is afterwards conveyed to the leaves, where it is exposed to the influence of light and air, loses a large portion of its water, undergoes a chemical change, and, being returned to the branches and stem, it is analogous to the blood in animals; all the secretions being formed from it. Changed in the leaf into proper juice, it is assimilated to the various parts of the plant. In its crude state it consists of little except water, holding earthy and gaseous matter in solution, especially carbonic acid; but as it rises through the tissue of the stem, it dissolves the secretions it meets with in its course, and thus acquires new properties, so that by the time it reaches the leaves it is entirely different from its state when it first entered the root. The course taken by the sap in its passage through the stem, is by the whole of the tissue included within the bark, provided it is all permeable; but as, in many plants, the central part of the stem becomes choked up with solid matter deposited in the tissue, it usually happens, especially in trees, that the course of the sap is confined to the outer part of the wood, hence called sapwood. It is not certainly known through what kind of tissue the upward motion of the sap takes place, but it is probable that it is carried onwards through all the tubes and vessels of the wood, and their intercellular passages. The dotted vessels of the wood seem more especially destined to fulfill this office when the sap is in rapid motion; but as they afterwards become empty, while the ascent of the sap continues, there can be no doubt that the woody tubes or pleurenchnya offer the most constant means by which the sap is conveyed. See Alburnum.

SAP-SAGO. A kind of cheese made in Switzerland, having a dark olive-green colour and agreeable flavour, derived chiefly, if not entirely, from the addition of melilot. See Cheese and Milch-Benzin.

SAVIN. See Juniper.

SAW-DUST. The refuse or waste powder obtained from saw-pits, after any wood or timber has been separated or cut asunder by the saw. If fresh oak saw-dust be scattered upon gravel walks it effectually prevents the growth of weeds, and when mixed with blood and quicklime it forms an excellent manure for the garden. This substance has lately been brought prominently into notice as an adjunct to other manures. There can be no doubt of its usefulness when made into compost with patrescent manures, sand and subtil substances. The compost of this kind, which has been well mixed and decomposed, and turned over with the spade at proper time, will produce an excellent crop of turnips.

SASSAFRAS (Laurus sassafras). This, on account of its sensible qualities, and real or supposed active medical virtues, was among the first American trees which became known to Europeans. In the United States, the neighbourhood of Portsmouth, New Hampshire, in latitude 43°, may be assumed as one of the extreme points at which it is found and is suited towards the northeast. But here it is only a tall shrub, rarely exceeding 15 or 20 feet in height, whilst in the Middle States it attains a height of 50 or 60 feet, being still more stately farther south. It is found in the Western and extreme Southern States, and in the low, maritime parts of Virginia, of the two Carolinas, and of Georgia. The sassafras is observed to grow of preference about plantations and in soils which have been exhausted by cultivation and abandoned. The old trees give birth to hundreds of shoots which spring from the earth at little distances, but which rarely rise higher than 6 or 8 feet. Though this tree is common on poor land, and blooms and matures its seed at the height of 15 or 20 feet, yet it is never of very ample dimensions except in fertile soils, such as form the declivities which skirt the swamps, and such as sustain the luxuriant forests of Kentucky and West Tennessee. About New York and Philadelphia the sassafras is in full bloom in the beginning of May, and six weeks earlier in South Carolina. The wood stripped of its bark is very durable, strong, and resists worms, &c. It forms excellent posts for gates. Bedsteads made of it are never infested with bugs. It is, however, only occasionally employed for any useful purpose and it is not found in the lumber-yards of large towns. The pith and dried leaves of the young branches of the sassafras contain much mucilage, resembling that of the okra plant, and are extensively used in New Orleans to thicken potage, and make the celebrated gumbo soup. In Virginia and other Southern States, the inhabitants make a 979
SAW-FLIES.

beef by boiling the young shoots of the sassafras in water, to which a certain quantity of molasses or sugar is added, the whole being left to ferment. The beer is regarded as a wholesome and pleasant drink during summer. So is an infusion of the bark of the roots, which is much drunk for the cure of cutaneous and other disorders.

SAW-FLIES. The names of above 60 species of saw-flies, natives of the United States, and found in Massachusetts, are given in Dr. Harris's Catalogue. Some of these are very interesting in their caterpillar state. One of the largest flies is called Cimbex Ulmi, because it inhabits the elm. The female of this species, at first sight, might be mistaken for the hornet. (The name Cimbex was originally given by the Greeks to certain insects resembling bees and wasps, but not producing honey.)

The elm saw-fly measures an inch in length, the wings expanding about 2 inches. It appears in the Eastern States from the last of May to the middle of June, during which the female lays her eggs upon the common American elm, the leaves of which serve as food for the young caterpillars hatched out. These come to their growth in August, and then measure from 1½ to 2 inches in length. Like all false caterpillars of the genus Cimbex, this insect, when handled or disturbed, betrays its fears or its displeasure by spitting out a watery fluid from certain little pores punctuated on the sides of its body just above its spiracles. The false caterpillars of other saw-flies prove very destructive to pines and other fir trees. They crawl down the trees and weave cocoons which are concealed in the leaves, &c. In the following spring the insects burst their chrysalids and come forth as winged flies.

No means, says Dr. Harris, for the destruction of the caterpillars of the fir saw-fly have been tried here, except showering them with soap-suds, and with solutions of whale-oil soap, which has been found effectual. They may be either shaken off or beaten from the trees, early in the morning, when they are torpid and easily fall, and may be collected in sheets, and be burned or given to swine. For other means to check their depredations the reader may consult the articles on the pine and fir saw-flies of Europe, contained in Kölliker's Treatise.

Dr. Harris has described a kind of saw-fly (Seländria vires), which attacks the grape-vine. It is of a jet-black colour, except the upper part of the thorax, which is red, the legs being a pale-yellow or whitish. The body is about 4 of an inch long. The false caterpillars progeny from the eggs of these flies may be found in swarms of various ages on the lower sides of the leaves, some very small and others fully grown. When fully grown they mesure about 6ths of an inch in length. The body is a light-green, the legs and tip of the tail being black. After the first molting they become almost entirely yellow, and then leave the vine to burrow in the ground. They come out again from their chrysalis state in about a fortnight, pair and lay eggs for a second brood. The young of the second brood are not transformed into flies until the succeeding spring, remain-
in throughout the winter, and appear, in the winged form, in the following spring and summer.

During several years past, these pernicious vermin have infested the rose bushes in the vicinity of Boston, and have proved so injurious to them, as to have excited the attention of the Massachusetts Horticultural Society, by whom a premium of $100, for the most successful mode of destroying these insects, was offered, in the summer of 1840. Showering or syringing the bushes with a liquor, made by mixing with water the juice expressed from tobacco by tobacconists, has been recommended; but some caution is necessary in making this mixture of a proper strength, for if too strong it is injurious to plants; and the experiment does not seem, as yet, to have been conducted with sufficient care to insure safety and success. Dusting lime over the plants when wet with dew has been tried, and found of some use; but this and all other remedies will probably yield in effeacy to Mr. Hagarston's mixture of whale-oil soap and water, in the proportion of two to the gallon of the tap to fifteen gallons of water. For particular directions to use this, see Aphides.

For a species of minute saw-fly, destructive to the turnip crops in England, see Fly in Turnips.

SAW-GRASS. See Boo-Rush.

SAXIFRAGE. (Saxifraga; from saxum, a stone, and frango, to break; in allusion to its reputed medical qualities in that disease). This is a very extensive genus of beautiful alpine plants, the greater part of which are particularly suitable for ornamenting rock-work, or growing on the sides of naked banks. They are all readily increased by seeds or divisions. These herbs are, for the most part, perennial, various in habit, often in some degree hairy and glutinous, with stalked, simple, undivided or lobed leaves. Flowers either panicked, rarely solitary, on a long naked stalk, or corymbose at the top of a round leafy stem; erect, white, yellow, or purple, frequently spotted, inodorous. Dr. Darlington describes two American species under the names of Virginia or Early Saxifrage, and Pennsylvania or Tall Saxifrage. Canada and Labrador have some species.

SAXIFRAGE, BURNET. See Burnet.

SAXIFRAGE, GOLDEN. See Golden Saxifrage.

SCAB. A contagious disease incident to sheep, which, like the mange in cattle, horses, and dogs, and the itch in the human subject, is the effect of certain minute insects belonging to the class Acari; at least these insects always are present in this disease. In the human subject the itch insect obtains its food from the pustules of the disease. The cure of scab, however, is supposed to be in the destruction of this insect. Washes, whether infusions of tobacco, belladonna, or arsenic, appear to be objectionable, and a scab; in more, the surgical method of curing the disease and benefiting the wool is the application of a mercurial ointment. The ointment should be made of two strengths. That for bad cases should consist of common mercurial or Trooper's ointment, rubbed down with three times its weight of lard. The other, for ordinary purposes, should contain five parts of lard to one of the mercurial ointment. (Vouatt on the Sheep, p. 536). See Sheep, Diseases of.

SCABIOUS (Scabiosa, from scabies, the itch; the common kind is said to cure that disorder). Some of these plants are well adapted for ornamenting the flower-border. The herbaceous species are readily increased by division at the root, or by seed. The seeds of the annual kinds merely produce stock in the open border. There are three indigenous species, all perennials; viz., the devil's-bit scabious (S. suscisa), which is common in grassy, rather moist pastures, flowering from August to October (see Devil's-Bit Scabious); the field scabious (S. arvensis), growing in corn-fields and pastures, with a bristly stem a yard high. The radical leaves are lanceolate, serrated, stalked, the rest pinnatifid and quite sessile. The flowers, which appear in July, are large and handsome, of a fine pale purple. Sheep and goats are said to eat this herb; but its bitter and nauseous flavour is not agreeable to domestic cattle. The small scabious (S. columnaria) is a less common species, attaining to the height of twelve or eighteen inches. The leaves and flowers are smaller and more delicate than the last.

SCALD CREAM. Provincially, cream raised by heat, or clotted cream. See Dairy, Milk, Butter, Lactometer, &c.

SCALLION. See Onion.

SCAPE. In botany, a stem rising from the roots, more frequently from a rhizome or underground stem, bearing nothing but the flowers. The iris is an example.

SCARIFIER. A tilage implement for stirring and loosening the soil, without bringing up a fresh surface. Under the same head may be included the grubber, the cultivator, and the sculler, all of which act on the combined principles of plough and harrow at the same time. Some of these implements have wheels, by the raising or lowering of which the tines or prongs may be made to sink more or less into the earth. See Harrow.

Amongst the earliest of the many varieties of this implement that I am acquainted with (says Mr. J. A. Ransome, in his work upon the Implements of Agriculture), is one which the late T. Cooke availed, attached to the framework of his drill, the coulters and apparatus of which, being removed, gave place to a bar, or head, suspended by joints to the axle, on which a row of strong tines was fixed. See Pl. 14, fig. 2.

On a similar plan to this, but working on a plough-carriage, another invention by Robert Fuller, a practical farmer of Ipswich, came into operation, and worked exceedingly well. Bidwell's Scarifier and Extirpator (Pl. 15, fig. 3) is held in deservedly high repute in Suffolk (where it originated) and the eastern and midland counties, where it is now in very general use. It is an implement of immense power, and well calculated to supersede the extensive use of the plough, otherwise indispensable in the cultivation of strong land, and we are inclined to believe with better effect. There can
be no question that in a general way a finer tith may be obtained with Biddell's scariifer than with any plough; and, for this reason, strong and tenacious clays and even many of the better loams, though dry at the surface and apparently in good order for ploughing, frequently turn up coarse and "loamy." In the early part of the spring, the combined action of frost and the atmosphere may probably in one-time effect what a scariifer would do at once, viz., reduce the clods to a comparatively fine mould, without which the hope of a good barley crop is but slender. There is no reason why the process of scariifying should not prove equally beneficial to the turnip or any other crop. Indeed, some are of opinion that what is usually called a stale furrow, in contradistinction to a newly ploughed one, is more favourable to the germination and after-growth of a plant like the turnip than a sowing on soil freshly turned up.

A great improvement on Fuller's extirpator, was Finlayson's Patent Self-cleaning Harrow. Pl. 15, fig. 5. This well-known implement may be called the parent of several of the same description, which, in improved forms, have subsequently come into use. It is formed of iron, and, according to the inventor, has the following advantages:—1. From the position in which the tines are fixed, their points (a a a a a) hanging nearly on a parallel to the surface of the land, it follows, that this implement is drawn with the least possible waste of power. 2. From the curved form of the tines, all stubble, such as corn, &c., that the tines may encounter in their progress through the soil, is brought to the surface, and rolled up to the face of the tines; when it loses its hold, and is thrown off (at b b b b b), always relieving itself from being choked, however wet or foul the land. 3. The mode by which this harrow can be so easily adjusted to work at any depth required, renders it of great value; this is done as quick as thought by moving the regulator (c) upwards or downwards between the lateral spring (d e); and by each movement upwards into the openings (f g h i k), the fore-tines (i i i i i) will be allowed to enter the soil about 1 3 inch deeper by the regulator (c) than the hind-tines (a a a); until the regulator is thrown up to (c), when the harrow is given its greatest power, and will then be working at the depth of 8 or 9 inches. Also the axle-tree of the hind-wheels is moved betwixt o and p, a space of 7 or 8 inches, by a screw through the axle-tree, which is turned by a small handle (g), so that the hind part of the harrow, by this simple mode, is also regulated to the depth at which it is found necessary to work. 4. When the harrow is drawn to the head or foot lands, the regulator is pressed down to d, and the fore-wheel (w) is then allowed to pass under the fore-bar (a), by which the nose of the harrow is lifted, and the points of the fore-tines (i i i i i) will then be taken 2 or 3 inches out of the soil, which affords the means of turning the harrow with the greatest facility. 5. Being made of malleable iron, its durability may be said to be endless; whereas, if made of wood, the prime cost would be entirely lost at the end of every 5 or 6 years. Lastly, the mode of working is so easy, that any boy of 10 or 12 years of age is perfectly qualified to manage it. Next to Wilkie's brake, we consider this the most valuable of propped implements, and think that, like Wilkie's implement, it might be substituted for the plough, after drilled green or root crops, on light soil generally. Some account of the astonishing powers of the implement, as exemplified in making up Hyde Park, London, in 1826, will be found in the Gardener's Magazine, vol. ii. p. 250.

Wilkie's Parallel Adjusting Brake is very nearly allied to the implement last mentioned; its chief improvement consists in the triangular adjustment of the teeth or prongs, and the facility with which they may be completely thrown out of work; whereas, with Finlayson's harrow this can only be partially done, the hind-teeth of the latter still retaining some hold of the ground, even though the first row be lifted up. This we are aware has been represented as an advantage, inasmuch as the slight hold retained by the back-row of tines prevents the implement from running on the horse's heels, when turning at the ends of the stretches on hilly ground. We see but little in this as an argument in favour of any implement of the kind. Indeed, we are rather disposed to give the preference to one like Wilkie's brake, which, by a parallel movement of the frame in which the tines are fixed, can, either at the turnings or while in action, be elevated or depressed en masse.

Kirkwood's Grabber in its operation somewhat resembles those last described, but is superior to them in working. The leverage that is obtained by pressing on the handles or stilts of the machine, whether in action or rest, is so simple, and yet so powerful in its effect, as to regulate the depth of the tines to the greatest nicety; or, in cases of obstruction, to throw them out of work altogether. It is an admirable implement, and well deserving the high commendation which has been bestowed on it.

SCORE. A term signifying 20 lbs. in speaking of the weight of cattle or swine.

SCORING. A provincial term signifying the glossing or making the furrow-slice in ploughing or turning land up, by the plough acting as a trowel. It is sometimes written scowering.

SCORPION-GRASS (Myositis, from myos, a mouse, and otes, an ear; fancied resemblance in the leaves.) All the perennial species of this genus are very beautiful, especially the well-known Forget-me-not (M. palustris). They grow best in moist places, or by the edges of ponds or ditches; they may also be grown in pots among alpine plants. The annual species, like a dry, sandy soil; most of the perennial kinds may be increased by divisions of the roots, and all by seeds. Sir J. E. Smith describes seven species of scorpion-grass indigenous to England, two of which are annuals, the rest perennials. Besides the M. palustris and M. arvensis, there are one or two other species found in the United States.

SCOTCH FIR. A common but improper name for the Scotch pine (Pinus sylvestris). See PINE and FIR.

SCOURING. See PURGING.
SCAPER. See Mouldbray.

SCUFFLER. An implement of somewhat the same kind as the scarer, but which is mostly lighter and employed in working after it. See Harrow.

SCULL-CAP (Scutellaria). There are several species of this plant found in the United States. The common hairy scull-cap (S. pilosa) has a perennial root, and stem 12 or 18 inches high, more or less hairy, and often purplish. The flower is a purple-blue colour, and opens from June to August. There are several varieties of this species. The large-flowered or entire-leaved scull-cap (S. integrifolia) is distinguished for its handsome, large, bluish flowers, which bloom in June. It is intensely bitter to the taste. The lateral-flowered scull-cap (S. lateriflora), has acquired the name of mad-dog scull-cap, from its having acquired much notoriety some years ago as a supposed remedy for hydrophobia. "Like its numerous predecessors of the same pretensions," says Dr. Darlington, "it had its day of importance among the credulous, and then sank into the oblivion which necessarily awaits all such species." Several other species of scull-cap are enumerated in the United States.

SCURVY-GRASS (Cochlearia). A genus of plants of little interest, with the exception of horse-radish (C. armoracia), and the common scurry-grass (C. officinalis). Besides these there are three other indigenous species: the Greenland scurry-grass, the English scurry-grass, and the Danish scurry-grass. They are either annual or biennial herbs, and were once celebrated as antiscorbutics, but have lost their reputation. The plants are mostly smooth and rather succulent, with branched, spreading stems, and simple leaves, the radical ones stalked and most entire. Flowers white, or pale-purplish.

The common scurry-grass is cultivated in gardens for its leaves. It flourishes best in a sandy, moist soil, but will succeed in almost any other, especially if abounding in moisture. The situation must always be as open as possible. It is propagated by seed, which should be sown as soon as it is ripe in July or June, for if kept from the ground until the spring, they will entirely lose their vegetative power, or produce plants weak and unproductive. The sowing is performed in drills 8 inches apart, and half an inch deep.

SCYTHE. This implement for moving grass has been latterly much used for cutting grain crops, and with great success, when it has been properly mounted with a rake or cradle, and put into expert hands.

Drummond's iron-handled scythe is considered in Scotland very effective. A good mower will cut down with it from an acre and a half to two acres in the day, and with this scythe he can either cut on't from the standing corn when upright, or cut in, as he may deem the better way at all times.

The common grass-scythe will cut oats and barley also very well when upright, but the mower will perceive his inability to lay down evenly and at right angles with the standing corn, for the convenience of the binders, a heavy crop of wheat with this scythe, even if furnished with a bow.

The Hainault or Flemish scythe, the favourite Belgian implement for severing corn, appears to be a very efficient instrument, but although all the trials made with it in Scotland and England report favourably of it, it has not come into use even partially; prejudice and the results of habit and custom rendering the old sickles, scythes, and reaping-hooks more popular. See Hay-Making, Reaping-Hook, Sickle.

SCYTHE AND CRADLE. The well-known American implement called the scythe and cradle used in the United States for harvesting wheat and all other kinds of small grain, is much preferable to the Hainault scythe. The cradle is made with 5 long teeth extending the full length of the scythe, and bent to the same shape. These teeth are generally made of the strong and pliant ash, shaved down so as to be as light as is consistent with the necessary strength. The handle is bent in such a manner as contributes greatly to the convenience of using the implement. It is slowly becoming introduced into England.

SEA-BUCKTHORN. See SalloW-Thorn.

SEA-HOLLY. See ERINGO.

SEA-KALE. See Kale.

SEA-LAVENDER. See Thrift.

SEA-MUD or OUSE. This rich saline deposition from salt-marshes and the sea-shores is found to possess very enriching properties, and to be a useful addition to the soil where it can be obtained in any quantity. See Alle-vium, Marsh-Mud, and Wapping.

SEAM. A provincial term applied to any fatty substance, as tallow, grease, or lard. A seam of corn is also a quarter or 8 bushels, and a seam of wood a horse-load, or about 3 cwt.

SEA-MILK-WORT (Gluza, from glaukos, gray, in allusion to the colour of the leaves). The common sea-milk-wort, or black salt-wort (G. maritima), is in England a pretty little indigenous perennial plant, growing abundantly in muddy salt-marshes.

SEA-SHELL. All marine shells, where they can be obtained in sufficient quantity, form a durable and lasting addition to the soil. See Oyster-Shells.

SEA-SHARE. A term frequently applied to the weeds thrown up by the sea in many situations, and which is collected and made use of as manure and for other purposes. It consists principally of the Quercus marina, and various species of Fuci, and has often the names of sea-wrack, ore-weed, sea-tangle, &c. See Kelp.

SECHIUM (Sechium edulis or Siegos edulis). A new vegetable from South America; in size and form resembling a very large bell-pear; the skin smooth, of a pale-green colour; the flesh solid. For the table it is prepared in a manner similar to the squash, and is stated to be of a more delicate flavour. It has but one single flat seed, which is larger than a Lima bean. A new vegetable, imported by Mr. Buist, of Philadelphia, and altogether unlike any thing before known or cultivated here.

SEDGE (Carex, from carro, to want, the upper

983
spikes being without seeds). This is a very extensive genus, the species of which are uninteresting; part of them are natives of marshy situations, while a few thrive on dry, sandy eminences; they seed freely, by which they are increased. The roots are, perhaps without exception, perennial, mostly creeping; sometimes fibrous and tufted only; herbage grassy; stem simple, generally with thin, finely serrated, and sharply-cutting angles, without knots or joints. Leaves linear, pointed, flat, roughish, with similarly cutting edges; their bases more or less tubular and sheathing, membranous at the summit, often auricled, the upper ones becoming bractes. Sir J. E. Smith enumerates and describes no less than 62 species of Carex indigenuous to Great Britain. There are a great many species of sedge found in the United States.

SEED is the reproductive part of a plant, resulting from a change effected in the ovules by the process of impregnation: it contains the embryo or rudiment of a future plant.

For the preservation of the seed from insects and decomposition, and for food for the embryo, seeds contain fecula, saccharine, gummy matter within their coverings, and sometimes acid, poisonous principles. In their coverings they also contain mucilage, oil, both fixed and volatile, and other principles which man makes subservient to his use, either as diet or condiments, or for other purposes. Seed is a form of reproductive matter peculiar to flowering plants, its equivalent in flowerless plants being the sporuli. It is commonly and very justly remarked, that, as the seed is the part intended by nature to multiply the races of plants, in this respect it resembles the egg, and, like it, long retains its vitality.

The choice of the seed intended to be sown is an object of greater importance than many farmers seem to imagine. It is not sufficient that the finest grain be chosen for this purpose, unless it be likewise clean from weeds. In procuring seed, it should be a rule with the farmer to purchase or reserve such as is the most full, plump, sound, and healthy, whatever the kind may be, as it is perhaps only in this way that crops of good corn can be insured. And this practice is still more obvious from the circumstance of its being in some measure the same with plants as with animals, that the produce is in a degree similar to that from which it originated. See Barley, Grasses, Oats, Temperature, Wheat, &c.

The usual quantity of seed applied per acre for the ordinary crops of the English farmer, when either broadcast, drilled, or dibbled, is as follows:

<table>

</table>

The quantities here given are those common throughout the island. But from the general custom in Flanders, and from the extensive practice which I have witnessed on the farms of Mr. Hewitt Davis and other excellent farmers, I am inclined to think that these quantities may be considerably reduced. As in most cases it is usual to have on the land many more seedling plants than the soil can properly mature, thinner sowing has the effect of producing stronger, healthier, and more prolific heads; and I am still inclined to this opinion in favour of thinner sowing, notwithstanding I am aware that such excellent agriculturists as Lords Leicester and Western practise, and strongly recommend, thick sowing.

As to the season for sowing, only general directions can be given. It is a highly important subject, much too little attended to in general. In the north of England they are frequently sowing weeks earlier than in the south.

SEED-LIP. A sort of basket in which the sower carries the seed he is about to scatter over the ground.

SEEL. A term provincially applied in England to time or season in respect to crops, as hay-seel, or hay-time, and barley-seel, or barley-seed time, bark-seel, barking-season, &c. It is sometimes written seal.

SENA, WILD (Cassia Marylandica). This plant, which is abundant in the Middle States, is quite ornamental, and often introduced into gardens. It has a perennial root and erect stem, growing to the height of 3 or 4 feet, and branching. The leaves resemble those of the imported senna (also a species of cassia), for which they are a good substitute, the medical properties being nearly similar. Its flowers are yellow and in clusters, followed by a seed-pod or legume 3 or 4 inches long.

SENSITIVE PLANT, WILD, commonly called Twinkling Cassia (Cassia micricotylans). This plant is found in the Middle States, on roadsides, &c. Its root is annual, and the stem grows 5 to 12 inches long, mostly oblique, slender, branching, and roughish-hairy. It produces yellow flowers in August, succeeded by seed-pods an inch to an inch and a half long, and two or three lines wide.
SEPTA. In botany, the partitions which divide the interior parts of a fruit.

SERRATE. A botanical term, implying notched, or cut like the teeth of a saw.

SERVICE TREE (Pyrus). There are in England two species of this tree, the wild service tree (P. torminalis), and the true service tree (P. domestica). Both are indigenous trees, often of considerable size, of extremely slow growth, and the wood is very hard. The service tree is still occasionally to be met with in the hedgerows in Kent, and in the wealds of Sussex, as also in the north of England and Wales. The leaves of the wild service tree are dark-green, deciduous, simple, somewhat heart-shaped, serrated, seven-lobed, on long stalks. Flowers white, numerous, in large, terminal, corymbose, downy panicles. The unblotted fruit, which is not larger than that of the hawthorn, becomes agreeably acid and wholesome after the frost has touched it, or when, like the medlar, it has undergone a kind of putrefactive fermentation. Ray prefers its flavour to the true service, which latter is now become obsolete. See June Berry.

SESSILE. A botanical term, applied to leaves without footstalks, which are seated close upon the stem.

SETACEOUS. In botany, implies shaped like bristles.

SETON. In farriery, a small cord constituted of a number of threads laid together and passed through the skin by a proper needle, for the purpose of keeping open an issue.

SHALOT or ESCALOT (Allium ascalonicum). Having a stronger taste than the onion, yet not leaving, as it is said, the strong odour on the palate which that species of Allium is accustomed to do, the shalot is often preferred, and employed instead, both in culinary preparations and for eating in its natural state. Each offset of the root will increase if planted in a similar manner to its parent. The planting may be performed during October or November, or early in the spring, as February, March, or beginning of April. The first is the best season, especially if the soil lies dry, as the bulbs become finer; but otherwise the spring is to be preferred, for excessive moisture destroys the sets. Mr. Henderson supports the practice of planting in autumn, and says, "if the smallest offsets are employed for planting, they never become mouldy in the ground, and are never injured by the most intense frosts." They are to be planted 6 inches asunder every way, in beds one yard to its fall, being usually inserted in drills, by the dibble, or with the finger and thumb.

SHAMROCK. The national emblem of Ireland. The term "shamrock" seems a general appellation for the trefoil, or three-leaved plants. There has been much dispute as to what is the true Irish shamrock; it has generally been considered to be the clover or Trifolium repens. A writer in the Journal of the Royal Inst. No. 3, advances abundant testimony in proof of the wood-sorrel (Oxalis acetosella) being the true shamrock.

SHARE OF A PLOUGH. That part which cuts or breaks the ground. See Plough.

SHAW. A country term applied to a wood that encompasses a close.

SHEARING OF SHEEP. The operation of cutting off the fleece or coat of wool with a pair of shears.

This is performed in different ways, but the best mode is that of the circular or round the sheep, instead of the longitudinal, which is now mostly in use in Britain. Shearing is usually performed about June or July, according to situation and season, but should not be done either too early or be too long protracted, as injury and inconvenience may attend either extreme. A good clipper is capable of clipping from 14 or 15 to 20 or 25 sheep in the day, and more are frequently done by very expert persons. Great care should be taken not to cut or prick the animals; but where this accident happens, in the northern parts of the kingdom, they touch the part with a little tar or sheep-salve; and in Sweden it is often done with train-oil and resin melted together. After shearing, the sheep should be turned into a warm, dry pasture. See Sheep.

SHEARING. The name given to a sheep that has been once shorn.

SHEARS. A name applied to some instruments employed in agriculture. The shears used for sheep-shearing are of very ancient origin: they were termed ferc by the Romans; and it appears that no improvement has been made on the instrument. In a collection of antique gems at Berlin, called the Stosch collection, is a gem bearing a representation of a newly shorn sheep, and the shears, which are exactly the same as those now used. Shears are also employed for clipping hedges.

SHEATH. In botany, the lower part of the leaf that surrounds the stem.

SHEEP (Ovis aries, nat. ord. Ruminantia). Of the original breed of this invaluable animal, which is in modern English farming almost equally important for furnishing the farmer with a dressing of manure, and the community at large with mutton, clothing, and other almost necessary of life, nothing certain is known. Several varieties of wild sheep have, by naturalists, been considered entitled to the distinction of being considered the parent stock. Of these are, 1. The musmon (O. Musimon), still found wild in the mountains of the larger islands of the Mediterranean and in European Turkey. 2. The argali (O. Ammon), or wild Asiatic sheep, which are the tenants of the highest mountains of central Asia, and the elevated plateaus of its northern portions. 3. The Rocky Mountain sheep (O. montana), which is found on the mountains of North America; and, 4. The bearded sheep of Africa (O. tragelaphus), found in the high lands of Egypt, and in Barbary. It is doubtful whether sheep are indigenous to Britain, but they are mentioned as existing there at very early periods. The Romans established a woollen manufactory at Winchester, at which city the first guild of fuller's was established.

The natural habits of the sheep attach it to the highest ground, to the upland slopes, where the heath and other aromatic plants with which Nature never intended this animal to occupy

40 985
the deep alluvial turnip lands of our rich arable farms, or to consume the succulent grasses of our water-meadows: every shepherd is aware that their natural instinct, after being for ages domesticated, still leads them invariably to the elevated portions of the field in which they are placed. All these facts tell the farmer in very intelligible language that it is change of food, of pasturage, and, if possible, the giving them occasionally aromatic food, that will best conduce to the prosperity of his flock. With this view parsley has been successfully cultivated. Then, again, the wild sheep are found to frequent all those places where saline exudations are to be found. In common with the deer and other ruminating animals, they lick the salt clay of some of the American uplands to such an extent, that these places are denominated **flicks**. Some of the most skilful of the English flock-masters never allow their sheep to be without salt. The female sheep goes with young twenty-one weeks, produces one, and rarely more than two at a birth; her milk yields a great abundance of strong-tasted cheese, but a very limited quantity of cream. The sheep, in temperate climates, is clothed with wool, which is annually renewed, but in warmer countries the animal is furnished with hair. In its wild state it has generally horns, but these have nearly disappeared in most of the breeds of domestic sheep. The domesticated sheep is known in England by different names, according to its age or sex. "The male," says Mr. Youatt, "is called a ram or tup. While with his mother he is denominated a tup, or ram lamb, a header, and in some parts of the west of England a hog. From the time of weaning until he is horned he has a variety of names; being called a hog, a hogget, a hoggerel, a lamb hog, a tup hog, or a teg; and, if castrated, a wether hog. After shearing, when probably he is a year and a half old, he is called a shearing, a shearing hog, a shear hog, a diamond, or dissident ram or tup, and a shearing wether when castrated. After the second shearing he is a two-shear ram or tup or wether; at the expiration of another year he is a three-shear ram, &c., the name always taking its date from the time of shearing. In many parts of the north the west of England and Scotland the tup hog is a tup lamb, after he is salved and until he is horned, and then a tup hog, and after that a tup, or if castrated, a dissident or wether. The female is a ewe or gimmer lamb until weaned, and then a gimmer hog or ewe hog, or teg, or sheeder ewe. After being shorn she is a shearing ewe or gimmer, sometimes a sheare or double-toothed ewe, or teg; and afterwards a two-shear or three-shear, or a four or six-tooth ewe or sheare. In some of the northern districts, ewes that have been weaned their lambs are called cild or yeld ewes." (Youatt on Sheep, p. 2.)

The teeth of the sheep are in number the same as those of the ox, viz., eight incisor or cutting-teeth in the lower jaw, and six molar teeth on each side, and in each jaw.

When the lamb is born he has either no incisor teeth or only two, but before he is a month old he has eight. The two central teeth of these are shed, and again at two years old at-tain their full growth: when between two and three years of age, the two next incisors are shed; at three years old, the four central teeth are fully grown; at four, he has six complete teeth. That the primitive breed of sheep were horned, we have direct evidence. (Gen. xxii. 13; Joshua vi. 6.) Immense flocks of this animal have in all ages of the world been kept by man, but more universally for their wool and skins than for their flesh: for that is yet to many nations by no means a favourite meal. The Calkms and Cossacks still prefer that of the horse and the camel; the Spaniard who can procure other flesh rarely eats that of the Merino; to many North Americans it is still an object of dislike. Englishmen, perhaps, consume more mutton than the people of any other country, but the taste for this is certainly of modern origin. It has rapidly extended, as better breeds and sweeter kinds of mutton have been produced.

My limits will not allow me to describe the great varieties of breed of sheep which belong to various countries; I shall, therefore, confine myself to a brief notice of those which tenant the British islands, referring those of my readers who need further information on the valuable work of Professor Youatt On the Sheep, and to Professor Low's Illustrations of the Breeds of Domestic Animals, from whence this article is chiefly taken; there is also an excellent essay upon the sheep by Mr. Ellman in Baxter's Library of Agricultural Knowledge.

**Class I.—Sheep without Horns.**

The new Leicester Sheep, says Mr. Youatt, which comprehends the most excellent of Bakewell's own breed, and of Culley's variety or improvement on it, is precisely the form for a sheep provided with plenty of good food, and without any great distance to travel or exertion to make in gathering it. It should have a head hornless, long, small, tapering towards the muzzle. Eyes prominent, with a quiet expression; ears thin, rather long, directed backwards; neck full and broad at its base, gradually tapering towards the head, particularly bare at the junction with the head; the neck seeming to project straight from the chest, so that when the neck is side of the head and the face, and the gullet and the throat, postion is added, one continued horizontal line from the rump to the pole. The breast broad and full; the shoulders broad and round, no uneven or angular formation, no rising of the withers, no hollow behind the situation of these bones. The arm fleshy throughout, even down to the knee. The bones of the leg small, standing wide apart, no looseness of skin about them, and comparatively bare of wool. The chest and barrel deep and round; the ribs forming a considerable arch from the spine; the barrel ribbed well home; the carcase gradually diminishing in width towards the rump; the quarters long and full; the legs of a moderate length; the pelt moderately thin, soft, and elastic, covered with a good quantity of white wool, not so long as in some breeds, but considerably finer. The principal recommendations of this breed are its beauty, and its fulness of form; in the same apparent dimensions greater weight than any other sheep; an early matu-
SHEEP.

...liness and a propensity to fatten, equalled by no other breed; a diminution in the proportion of offal, and the return of most money for the quantity of food consumed. (Colvill on Livestock; Marshall's Midland Counties; Youatt on Sheep, p. 111.)

For Bakewell's views, when engaged in improving sheep, see DISHLER BREED.

The Teeswater Sheep was bred originally on the banks of the Tees; it came from the stock of the old Lincolnshire, and, like them, is nearly extinct. It was a tall, clumsy animal, polled, and with white face and legs; they were crossed by the Dishley sheep, because a smaller and a better breed, and few traces are now to be found.

The Lincolnshire Sheep.—Colvill described the old breed of Lincolnshire sheep, half a century since, as having "no horns," white faces, long, thin, and weak carcasses; the ewes weighing from 14 to 20 lbs. per quarter, the three year old wethers from 20 to 30 lbs.; thick, rough, white legs, large bones, thick pelts, and long wool, from 10 to 18 inches, and weighing from 8 to 14 lbs. per fleece, and covering a slow-feeding, coarse-grained carcass of mutton. Colvill, however, ran into the opposite extreme; if the Lincolnshire farmers bred only for the wool, he regarded only the mutton. A cross between the two produced a very profitable and much improved animal.

The Cotswold Sheep have been long celebrated for the fineness of their wool. In 1647, a flock of these sheep were carried into Spain by license from Edward IV. Gervas Markham, in the time of Queen Elizabeth, describes them "as long-woolled and large-boned breed." Few of the original Cotswold breed, however, now remain; they have been gradually improved by crossing with the Leicester sheep, and it is this half-bred Cotswold and Leicester which now chiefly tenants the Gloucestershire and Worcestershire districts. The old Cotswold sheep are described by Mr. Youatt, as being taller and longer than the improved breed, comparatively flat-sided, deficient in the fore-quarter, but full in the hind-quarter, not fattening so early, but yielding a longer and heavier fleece. (Youatt on Sheep, p. 310.) The mutton of this breed is well described by Mr. Ellman, as fine-grained and full-sized, but capable of great improvement by proper crossing. "The Cotswold," he adds, "difier from the South Down in several particulars; the skin of the Cotswold is much thicker than the South Down; the head larger and the face not so thick, having no wool but a tuft on the poll; wool below the hock considered objectionable. On the Cotswold they never allow two rams to run together." He thinks twin ewes have much more to do with getting twins than twin rams; both, however, should be attended to, as well as a still more important particular, their keep. (Baxter's Lib. of Agr.)

The Dartmoor Sheep.—"The short or rather middle-woolled sheep of Devonshire," says Mr. Youatt, "a few of which are still seen in South Devon, and on the greater part of the hills in the northern district, but much diminished of late, in the forests of Dartmoor and Exmoor, are everywhere of nearly the same character, and betray on a smaller scale a great affinity with the Dorsets; have white faces and legs; some with and some without horns; small in the head and neck, and generally small-boned; carcase narrow and flat-sided, weighing when fat from 9 to 12 lbs. per quarter; the fleece 3 or 4 lbs. in weight in the yolk; wool short, with a coarse and hairy top."

The South Down Sheep.—The remarks of Mr. Ellman of Glynde, in Sussex, who has done more than any one to improve the race of South Down, are so practical and clear, that what he has done so well it is useless to give in any other language; he says, when speaking of this valuable breed, "the head should be neither too long nor too short, the lip thin, the neck neither too long nor too short; but thin next the head, and tapering towards the shoulders. South Down breeders object to a long, thin neck; it denotes delicacy. The breast should be wide and deep, projecting forward before the fore-legs; this indicates a good constitution, and disposition to feed. The shoulders should not be too wide between the plate-bones, but on a level with the chine; if the shoulder-blades are wide on the top, the animal generally drops behind the shoulders. The chine should be low and straight from the shoulders to the tail; the ribs should project horizontally from the chine, for to an animal will then lay its meat on the prime parts; the sides high and parallel; the rump long and broad; the tail set on high, and nearly on a level with the chine; the hips wide; the ribs circular, and barrel-shaped; the legs neither very long nor very short; the bones moderately fine." (Baxter's Lib. of Agr. p. 570.)

Romney Marsh Sheep.—Towards the beginning of this century, Mr. Price described the "pure Romney Marsh bred sheep as distinguished by thickness and length of head, a broad forehead with a tuft of wool upon it, a long, thick, and heavy neck; the head and neck sharp, the chine sharp, tolerably wide on the loins, breast narrow and not deep, and the fore-quarter not heavy nor full; the thigh full and broad, the belly large; the tail thick, long, and coarse, the legs thick, feet large, the muscle coarse, bone large. Wool long and not fine; have much internal fat, much hardihood; requiring no artificial food during the hardest winter, except a little hay." (Youatt on Sheep, p. 334.) With all these good properties, however, the old Romney Marsh sheep has been nearly obliterated by occasional crossings with the Leicester sheep, which, by judiciously intercrossed (taking care not to render the breed too tender by the introduction of too much of the Leicester), has produced a sheep possessing sufficient hardness for these bleak marshes, yet producing more symmetry of form, with earlier maturity, and greater propensity to fatten.

The Cheviot Sheep are a peculiar breed, which are kept on the extensive range of the Cheviot Hills. They are described as having the face and legs generally white; the eye lively and prominent; the countenance open and pleasing; the ear large, and with a long space from the ear to the eye; the hair long, and hence they are called 'long sheep,' in distinction from the black-faced breed. They are full...
behind the shoulder, have a long, straight back, are round in the rib, and well-proportioned in the quarters; the legs clean and small-boned, and the pelt thin, but thickly covered with fine, short wool: they possess very considerable fattening qualities, and can endure much hardship, both from starvation and cold. He is fit for the butcher at three years old, and at two when crossed with the Leicester." (Youatt on Sheep, p. 285; "On crossing the Mountain and Cheviot Sheep," by Mr. Hogg, Quart. Journ. Agr. vol. i. p. 176.)

Class II. Horned Sheep.

The Dorset Sheep.—"Most of these," says Mr. Youatt, "at least of the pure breed, are entirely white; the face is long and broad, and there is a tuft of wool on the forehead; the shoulders low and broad; the back straight; the chest deep; the loins broad; the legs rather beyond a moderate length, and the bone small. They are, as their form would indicate, a hardy and useful breed. They are good folding sheep; their mutton well-flavoured, averaging, when 3 years old, from 16 to 20 pounds a quarter. Their principal distinction and value is the forwardness of the ewes, who take the ram at a much earlier period of the year than any other species, and the supply of the market with lamb at the time when it fetches the highest price. These sheep are principally bred within a circle of 12 miles round Dorchester, where a considerable quantity of house lamb for the London market is produced. In other parts of Dorset the South Down breed prevails; except in Portland and on poor, sandy, heath soils near Warebone and Poole, where a poor small-boned breed prevails, with black muzzles, well adapted for this locality. Their meat is tender."

The Norfolk Sheep.—"A peculiar variety of heath sheep," says Mr. Youatt, "has been found in the localities of Norfolk and Suffolk from time immemorial. The carcass was long and slender; legs long; face and legs black or motled; face long and thin; the countenance lively and expressive of mingled timidity and wildness: taken altogether, there was more resemblance to the deer in the Norfolk sheep than has been observed in any other species. They were attempted to be improved by being crossed with the South Downs; but at length the pure South Down was generally preferred to the pure Norfolk, and, in consequence, the race is now nearly extinct."

The Merino Sheep.—This celebrated breed are, in Spain, divided into the estantes, or stationary, and the transhumantes, or migratory. The first are those which remain during the year in one place or farm: the last travel some hundred miles every year in search of pasture. They are thus described by Mr. Low in his excellent Illustrations of the Breeds of Domestic Animals. "The stationary sheep consist partly of the larger sheep of the lower country, partly of mixed races, and partly of pure Merinos, which do not differ in any respect from the migratory sheep of that name, except in the method of treatment. The stationary Merinos are reared where the district or farm affords them sufficient food during the whole season. They are most numerous in the central countries, where the pastures are less apt to be scorched by the heats of the summer, as in Segovia, and the mountain ranges to north of Madrid. "The migratory sheep have been reckoned to amount to ten millions, which is probably equal to half the whole number of the sheep of Spain. They may be divided into two great bodies: those which are to pass further to the eastward, to Soria, or even beyond the Ebro. These vast hordes of sheep break up from their winter cantonments, south of the Guardina, about the 15th of April, and proceed chiefly northward. The rams having been admitted to the ewes in the month of July, the lambs are born in November. In the course of six months they are reared, and in large buildings erected for that purpose. The western, or Leonese division, crosses the Tagus at Almaray. The eastern, or Sorian division, crosses the same river further to the eastward, at Talavera. and in its course approaches the city of Madrid. Having reached their destination, they are pastured until the end of September, when they recommence their journey southward. Each of these journeys, of several miles in length, occupies about 6 weeks in travelling. The older sheep, it is said, when April arrives, know the time of setting off, and are ten years old. In the ten or twelve latter days, increased vigilance is required, on the part of the shepherds, lest the sheep should break out. Some of them do so, and pursue their accustomed route, often reaching their former year’s pastures, where they are found when the main body arrives; but, for the most part, these stranglers are carried off by wolves, which abound along the course which the migratory flocks pursue.

"These migratory sheep are divided into flocks of a thousand or more, each under the charge of its own mayoral, or chief shepherd, who has a sufficient number of assistants under his command. It is his province to direct all the details of the journey. He goes in advance of the flock; the others follow with their dogs, to collect the stranglers, and keep off the wolves, which prowl in the distance, migrating with the flock. A few mules or asses accompany the caravade, carrying the simple necessaries of the shepherds, and the materials for forming the nightly folds. In these folds the sheep are penned throughout the night, surrounded by the faithful dogs, which give notice of the approach of danger. "When the sheep arrive at the esquilcos, or shearing-houses, which is in the early part of their journey northward, a sufficient number of shearsers are in attendance to shear a thousand or more in one day. The esquilcos consist of two large, rude rooms, and a low, narrow hut adjoining, termed the sweating-house. The sheep are driven into one of the large rooms, and such of them as are to be shorn on the following day are forced into the long, narrow hut as close as it can be packed, where they are kept all night. They undergo in this state a great perspiration, the effect of which is to soften the hardest, most encrusted matter which has collected on the fleece. They are then shorn without a previous washing, and the wool is left in the esquilcos, where it is sorted, and made ready for sale. By this arrangement
1000 sheep, or more, are shorn with only the delay of a day.

"The shepherds employed in tending these sheep amount to 50,000, which, supposing there to be 10,000,000 of sheep, is at the rate of 2 per hundred; the annual produce, calculated at 30,000. These shepherds form a peculiar class of men, strongly attached to their pursuit, and living in a state of great simplicity. Their food is chiefly black bread, oil, and garlic. They eat the mutton of their sheep when they die or meet with accidents. In travelling they sleep on the ground, wrapping themselves in their cloaks; and in winter they construct rude huts to afford shelter. They seldom, it is said, marry, or change their calling.

"The whole of this extraordinary system is regulated by a set of laws; and an especial tribunal, termed the mesta, exists for the protection of the privileges of the parties having the right of way and pastureage. These parties claim the right of pasturage on all the open and common land that lies in their way, a path of 90 paces wide through the enclosed and cultivated country, and various rights and immunities connected with the pasturage of the flocks. The system is opposed to the true interests of Spain. A change of pasture may be required for the flocks in the drier countries at certain seasons, but the periodic migration of so vast a body of sheep cannot be necessary to the extent to which it takes place. Enormous abuses are committed on the cultivated country as they pass along. A fourth part of the year consumed in travelling must be prejudicial to the health of the animals in a greater degree than the benefits they derive from a change of pastureage. A prodigious mortality accordingly takes place among these sheep; and more than half the lambs are voluntarily killed, in order that the others may be brought to maturity. The sale of the lamb-skins, which form a subject of export to other countries, is indeed a source of profit, but nothing equal to what the rearing of the animals to maturity affords. It is said that these extensive migrations are necessary to preserve the fineness of the wool is conceived to be an error. Attention to breeding and rearing would more certainly produce this effect than a violent change of place. In Spain itself there are numerous flocks of stationary Merinos, whose wool is of all the fineness required; and in other countries of Europe, where the sheep are never moved off the farms that produce them, wool is produced superior to that of the migratory flocks of Spain. The system is of great antiquity, and is so riveted in the habits of this ignorant and intractable people, that it is likely to continue long after those ancient abuses which will yield to the desire of change which at this moment agitates the feelings of men in this distracted country. The Spaniards long preserved the monopoly of this race of sheep with jealous care; but other countries at length were able to carry off the Golden Fleece of Spain, and the Merino race is now spread over a great part of Europe.

"The Merino breed, which had extended to so many countries, was at a period more recently introduced into the British Islands. George III., a zealous and patriotic agriculturist, resolved to make a trial of this celebrated breed on his own farms, and means were taken to obtain a small Merino flock. This was done clandestinely; the animals were selected from the flocks of the best individual breeders, they could best be got; were driven through Portugal, and embarked at Lisbon. They were safely landed at Portsmouth, and conducted to the king's farm at Kew. The flock was bad; the selection had been carelessly or ignorantly made; and the animals being taken from different flocks, presented no uniformity of characters. It was then resolved to make direct application to the Spanish government for permission to export some sheep from the best flocks. The request was at once complied with; a small and choice flock was presented to his majesty, by the Marchioness del Campo di Alange, of the Negretti flocks, esteemed to be the most valuable in Spain; and in return his majesty presented to the Marchioness eight splendid coach horses. This flock arrived in England in 1791, and was immediately transferred to the royal farms, while all those previously imported were disposed of or destroyed.

"On the first change of these sheep to the moist and luxuriant pastures of England, they suffered greatly from diseases, and, above all, the rot, which destroyed numbers of them; and from foot-rot, which affected them to a grievous extent. By a little change of pastures these evils were remedied; and, after the first season, the survivors became reconciled to their new situation, and their progeny seemed thoroughly naturalized, and remained as free from diseases as the sheep of the country. The wool was from year to year carefully examined; that of the original stock remained unaffected by the change of climate, while in that of their descendants little degeneracy could be detected either in its felting propensities or its fineness.

"The most distinguished breeders of Merinos at this time in England are Lord Western and Mr. Bennett. Mr. Bennett's stock is either Saxon, or has been crossed by Saxon rams; Mr. Bennett's is pure Spanish, and has undergone progressive improvement by selection of individuals of the same blood. The number of his flock amounted at one time to 7000; it was subsequently reduced to 3500. It was treated in the ordinary manner of sheep in England. Lord Western's, it is believed, is managed more in the Saxon manner, with respect to protection from the weather. Mr. Bennett's fine flock, notwithstanding it had been thus acclimated, perished in great numbers in a severe winter some years ago, proving that this race had not yet yielded sufficient strength in England to be perfectly invulnerable to its cold and variable climate. Other gentlemen have imported Merinos direct from Saxony, and thus obtained at once the highest perfection of the fleece; but there is little reason to believe that their experiments will be more successful than those previously made. Merinos have lately been carried in some numbers to Ireland, and may perhaps prove more advantageous than some of the existing breeds; but this will not show the great value of the Merinos, but the
comparatively little value of the races which they have supplanted.

The impression (says Mr. Youatt) made by the Merino sheep on one unacquainted with its value would be unfavourable. The wool, lying closer and thicker over the body than in most other breeds of sheep, and being abundant in yolk, is covered with a dirty crust, often full of cracks. The legs are long, yet small in the bone; the breast and the back are narrow, and the sides somewhat flat; the fore-shoulders and bosoms are heavy, and too much of their weight is carried on the coarser parts. The horns of the male are comparatively large, curved, and with more or less of a spiral form. The female horns are thin but the head rather low. A few of the females are horned, but, generally speaking, they are without horns. Both male and female have a peculiar coarse and unsightly growth of hair on the forehead and cheeks, which the careful flock-master cuts away before shearing-time: the other part of the face has a pleasing and characteristic velvety appearance. Under the throat there is a singular looseness of skin, which gives them a remarkable appearance of throatiness, or hollowness in the pike: the pike, when pressed upon, is hard and unyielding; it is so from the thickness with which it grows upon the pelt, and the abundance of the yolk detaining all the dirt and gravel which falls upon it; but, when examined, the fibre exceeds in fineness, and in the number of serrations and curves, that which any other sheep in the world produces. The average weight of the fleece in Spain is 8 pounds from the ram and 5 from the ewe: when fatted, these sheep weigh from 12 to 16 pounds per quarter. The excellence of the Merino consists in the fineness and felting quality of their wool, and the weight yielded by each sheep; the ease with which they adapt themselves to the climate, the readiness with which they take to the crops, large dunginess, with its consequent neatness and tractableness. Their defects are their unprofitable and unthrifty form, voracity of appetite, a tendency to barrenness, neglect of their young, and inferior flavour of the mutton. (On Sheep, p. 148; Dr. Parry on the Merino sheep, Conv. Board of Agr. vol. v. p. 337; Sir Joseph Banks on ditto, Ibid. vol. vi. p. 269; Mr. Downie on ditto, Ibid. vol. vi. p. 61.)

The Irish Sheep have been much improved by the importation of English rams. Culley describes them as ugly and ill-formed. Bodies large. Legs long, thick, crooked, and of a grey colour. Heads long, large drooping ears, sunken eyes. Neck long, and set on below the shoulders. Breast narrow, short, and hollow; flat-sided.

The Shetland Sheep are described by Mr. Wilson (Quart. Jour. Agr. vol. ii. p. 557) as small and handsome; hornless, seldom exceeding 40 pounds in weight; hardy, feeding on even seaweed; wool soft and cottony.

The Hebridean Sheep is described by Mr. Wilson as the smallest of its kind. Shape thin and lank. Face and legs white. Tail short. Wool of various colours, bluish-gray, brown, or deep russet. Even when fat, this sheep weighs only 20 pounds; the wool rarely weighs more than 1 pound.

With regard to the profitable management of sheep, it is only possible to offer general suggestions. I consulted the farmer. I have alluded already to the advantages of varying the food of sheep, and I shall refer at the end of this article to various important testimonials in favour of the superior profit derived from keeping sheep dry and warm. In every case they should have access to dry food, and, if possible, occasionally to those lands where heath and other plants which are indigenous to upland soils are to be found: in all cases, too, they should have access to common salt.

The importance of salt to the general health of sheep is now, in fact, generally admitted. Every farmer observes that his fat, his well-fed, horses, &c., are remarkably fond of licking the salt earth of the farm-yard, stables, &c. In Spain, they give their sheep salt with great regularity: 112 lb. in 5 months to 1000 sheep. I subjoin the statement of the late Mr. Curwen. He employed salt to his live-stock daily for years.

If on dry pastures: but if they are feeding on turnips or coales, then they should have it without stint. Some give it to their live-stock in a slate or stone, some lay lumps of it in the crib or mangers. It is an asserted fact, that if sheep are allowed free access to salt, they will never be subject to the disease called the rot. Some recent experiments also lead me even to hope that I shall one day or other be able to prove it to be a cure for this devastating disease. I have room but for one fact. "Mr. Rusher, of Stanley, in Gloucestershire, in the autumn of 1828, purchased, for a mere trifle, 20 sheep decidedly rotten; and gave each of them, for some weeks, an ounce of salt every morning. Two only died of the particular vegetation in which they were cur'd, and have now," says my informant, "lambs by their sides."

The late Mr. Butcher, of Brook Hall, in Essex, for years employed salt for his cattle and sheep on his farm near Burnham, in Norfolk. One of his fields was so very unfavourable for sheep, that before he used salt he had lost 10 and 12 sheep in a night, when feeding on the turnips; but after he had adopted salt, he never lost one. He used to let the sheep have the salt without stint; and he remarked, that the sheep always consumed four times the salt on the particular pasture, in which they were. He then took the surviving 18 were cured, and have now," says my informant, "by their sides."

There are several points in the management of sheep to which I can only briefly allude. Coupling the male and female is too rarely attended to; and, yet, by an attention to this important point, properties are added in one sex which may be deficient in the other; but extreme care is necessary in arranging this, not to introduce other points which may be still more objectionable than those attempted to be removed. Mr. Ellis is of opinion that twin-
getting is hereditary: “Experience,” he says, “has satisfied me that a ram which may be a twin would get double the number of twin lambs than other rams.” He advises that, just previous to lambing-time, the ewes should not be kept too well, but that their food should be increased a few days after parturition. Cleanliness in the lambing-yards he very properly deems to be of the greatest importance. Lambs are best castrated at from 8 to 12 days old. In the performance of this operation it is calculated that, when properly performed, the deaths do not average 1 in a 1000. Mr. Ellman recommends 80 to 100 ewes to each ram, or, when lamb rams are employed, only 40; and that they should remain with the ewes 3 weeks, in separate lots.

Statistics.—The number of sheep in Great Britain has long been gradually on the increase, with the demands of an enlarging population. To this the introduction of turnips and other better supplies of winter food, which much increased the capability of the sheep, contributed. In 1698, Gregory King calculated that there were 12,000,000 sheep in Great Britain; in 1741 the number had increased to 16,640,000; in 1774, according to Arthur Young, the number was 25,589,754; in 1801, Mr. Lucock estimated them at 26,148,463. Mr. MCulloch, in 1834, states the number to be 32,000,000; the value of the wool 7,000,000l.; and that of the manufactured woollen articles 21,000,000l.; and the number of persons employed in the manufacturing of these goods about 332,000. (Youatt on Sheep; Luie’s Pract. Agr., and Trench of Sheep; Baker’s Agr. Lit.; MCulloch’s Com. Dist.)

All the best varieties of sheep known in Europe have been introduced into the United States, where the raising of sheep, both for the profits of carcass and wool, is a highly productive branch of agriculture. The number of sheep in the United States was estimated at about 20,000,000. Immense numbers of these are raised in the high and cool districts in Northern Pennsylvania, New York, and the Eastern States. Various American agricultural periodicals contain valuable observation in regard to sheep in the United States. Jonathan Roberts, Esq., a veteran farmer of Montgomery county, Pennsylvania, who has taken much interest in this kind of stock for the last half-century, has favoured us with the following valuable observations:

“Many of the diseases which prevail among sheep in Great Britain are little known here. The United States, where the air is drier. Such air, associated with a broken and even mountainous country, seems best adapted to the breeds of this animal. Early in my experience I witnessed the renovation of a flock of what we call country sheep, that had been too long propagated in the same blood. This was about the year 1789. An imported ram from England, with heavy horns, very much resembling the most vigorous Spanish Merinose, was obtained. The progeny were improved in the quality of fleece and in vigour of constitution. On repeating this stocking in the later half of the United States, where the air is drier, a great deterioration became apparent. A male was then obtained of the large, coarse-wooled Spanish stock; improvement in the vigour of the progeny was again most obvious. A Tunis mountain ram was then obtained, with a result equally favourable. In this process, fineness of fleece or weight was less the object than carcass. In 1810, a male of not quite pure Merino blood was placed with the same stock of ewes; and a change of the male from year to year, for some time, produced a superior Merino stock. Wool of a marketable quality for fine cloths was now the object, and it was not an unprofitable transaction, when it would sell in the fleece unwashed, from 86 cents to $1. The Saxony stock then became the rage, and the introduction of a top of that country diminished greatly the weight of the fleece, without adequately improving its fineness. A male of the Spanish stock would give sometimes 9 lbs., and the marl graziers say that they went so high as 15 lbs. Saxony males
scarcely exceed 5 lbs., and the ewes 2½ lbs. By running in the same blood, and poor keeping, the fleece may be made finer, but it will be lightened in proportion, and of a weak and inferior texture. There are few stock-keepers who have mixed the Spanish with the Saxon breeds but what either do or will have cause to regret it. In this part of the country a real Spanish Merino is not to be obtained. Sheep-raising has ceased to be a business of any profit nearer to the maritime coast than our extensive mountain ranges, whether for carcass or fleece. I sold, the last season, water-washed wool of very fine quality, for 30 cents per lb. At such a price for wool, land near our seaports can be turned to better account, even in these dull times, than wool-growing. Stock-sheep do best in stony and elevated locations, where they have to use diligence to pick the scanty blade. Sheep on the seaboard region should be kept more for carcass than fleece; and feeding more than breeding, ought to be the object for some 100 miles from tide-water. It is now a well ascertained fact, that health and vigour can only be perpetuated by not running too long on the same piece of land; the evils have witnessed were due to want of care on this head more than to any endemic quality in our climate. Sheep kept on smooth land and soft pasture are liable to the foot-rot. I have found this readily relieved by a little spirits of turpentine or salted grease and tar, or tar only. The hoofs of the Merino require paring occasionally, for want of a stony mountain-side to ascend. It is no longer a problem that this is to be a great wool-growing country as well as a wool-consuming one. There is, in our wool-growing country, land in abundance, held at a price that will enable the wool-grower to produce the finest qualities at 30 cents per lb, the cloths to be manufactured in proportion, and the market to be steady. I have seen Merino wool since 1810 range from $1 per lb. to 18½ cents, though I do not recollect selling below 22 cents. The best variety of sheep stock I have seen, putting fineness of fleece aside, was the mixed Bake-well and South Down, imported by Mr. Smith, of New Jersey. The flesh of the Merino has been pronounced of inferior flavour. This, however, does not agree with my experience, as I have found the lambs command a readiness sale than any other, from being preferred by consumers."

In regard to the particular distribution of sheep through the several states, we find, according to the returns accompanying the census of 1840, that there were in Maine, 649,264; New Hampshire, 617,390; Massachusetts, 378,226; Rhode Island, 90,146; Connecticut, 403,462; Vermont, 1,681,819; New York, 5,118,777; New Jersey, 219,285; Pennsylvania, 1,767,620; Delaware, 39,247; Maryland, 257,922; Virginia, 1,293,772; North Carolina, 596,279; Tennessee, 741,593; Kentucky, 1,008,241; Ohio, 2,008,101; Indiana, 695,992; Illinois, 395,672; Missouri, 348,018.

SHEEP, DISEASES OF. Aploplexy.—Bleed copiously; then give 2 ounces of Epsom salts in a quarter of a pint of water.

Blackwater.—Keep the bowels open with Epsom salts; and give a tea-spoonful of elixir of vitriol, or sulphuric acid, diluted with 7 parts of water, in an infusion of oak bark.

Blackwattle.—Mix an ounce of verdigris (acetate of copper), 4 ounces of honey, half a pint of vinegar; simmer them together over a fire for 10 minutes in an earthen pipkin. Apply it to the mouth on a piece of rag.

Cough, or Cold.—Bleed; give a solution of Epsom salts.

Diarrhaa. See CAVES, DISEASES OF.

Dysentery. See DIARRHA.

Fly.—Fly powder: Two pounds of black sulphur, half a pound of heliebore; mix them together, and sprinkle the sheep from the head to the tail with a dredging-box. Sheep wash: The farmer will find this an excellent recipe: Half a pound of powdered white arsenic (arsenious acid), ¼ pounds of soft soap. Beat these for a quarter of an hour, or until the arsenic is dissolved, in 5 gallons of water. Add this to the water sufficient to dip 60 sheep. The quantity of arsenic usually recommended is too large.

Foot Rot.—One drachm of verdigris (acetate of copper), 1 drachm of blue vitriol (sulphate of copper), 1 drachm of white vitriol (sulphate of antimony), 2 ounces of water, 2 drachms of nitric acid, 2 drachms of butter of antimony; pare away the horn, and apply the lotion upon a feather to the part affected.

Redwater. See REDWATER.

Rot. See Rot.

Scab, or Schab.—Apply a lotion formed of 1 ounce of corrosive sublimate, 4 ounces of sal ammoniac, dissolved in 4 quarts of rain-water. This is a powerful stimulant, and must be used with caution.

Ticks. See Fly.

Wounds.—Wash the part, and apply a lotion formed of vinegar 1 pint, spirits of wine 1 ounce, spirits of turpentine 1 ounce, Goulard's extract 1 ounce. If the wound be a recent one, it is better to stitch it up with separate ligatures, which can be easily withdrawn, and dress with cold water.

SHEEP-FOLD. A yard or other contrivance for the purpose of confining and keeping sheep during the nights or in bad weather, in order to afford them protection and shelter. They are sometimes fixed, being constructed of any convenient sort of light material, so as to enclose a space in proportion to the number of sheep, which is kept constantly well littered with some dry substance, such as stubble, refuse straw, dry sand, &c., during the time the sheep are folded and foddered in them, in order that as much manure may be raised as possible. In some cases, also, for the more perfect protection of the sheep, they have sheds all around them, under which the sheep may lie without injury from rain, snow, or any sort of moisture. These usually are termed standing folds, and are either formed about the homestead or on some dry, rather elevated situation on the farms, having the bottoms well laid with some sort of material that is capable of keeping the sheep dry and clean. See Fold, Folding, and Hurdles.

SHEEP-HOUSE. A slight wooden building constructed for the purpose of containing and protecting sheep in bad weather, &c. Houses
of this kind are usually made low for the sake of warmth in the winter, being mostly a third part longer than they have breadth: they should also be sufficiently large for the quantity of sheep that they are to contain. The sides should be lined with boards, and the bottoms be laid in an even manner with stone or some other material, that the litter may be well impregnated with the urine of the sheep. The sides exposed to the sun should be lined with movable hurdles, that when it shines the whole may be laid open, to give due refreshment and afford the sheep an opportunity of feeding upon the pasture wherein they stand. They should be well and securely covered with some sort of proper material upon the tops. They are sometimes fixed in particular situations, but in other cases, which is the more improved method, so constructed as to be capable of being removed as they may be wanted.

SHEEP-PENS. The divisions made by the small movable gates or hurdles which are set up to keep sheep in some particular spot. They are usually formed on a dry place about the corners where different enclosures of the pasture meet, so as to be convenient for the whole. Pens are useful for examining and selecting the sheep, being divided so as to contain about 300 sheep each, as by this means they are always at the command of the shepherd for any purposes he may have in view. The bottoms should be firm and dry, so that the sheep may not be soiled.

SHEEP-STEALING. By the 7 W. 4, &c. 1 Vict. c. 90, every person convicted in England of stealing any horse, mare, gelding, colt, filly, bull, cow, heifer, ram, ewe, sheep, or lamb, is liable to be transported for a term not exceeding 15 years, nor less than 10 years; or be imprisoned for any term not exceeding 3 years.

SHEEP'S SORREL (Rumex acetosella). A perennial species of dock, which in England is found growing abundantly in dry, gravelly fields and pastures. The herb is acrid, with some astringency. The root is creeping. The stem wavy, slender, often decumbent. The flowers are dioecious, small, separate, in numerous whorled leafless clusters. The leaves lanceolate-hastate above, but hastate in the lower part of the stem. The acid which they contain is the oxalic, combined with potassa, as a binoxalate; but it is less used than its fellow-species R. acetosa. See Sorrel.

Dr. Darlington informs us that there are in the United States 10 or 12 additional species of sorrel, but it is difficult to say how many of these are indigenous.

SHEPARDIA, SILVER-LEAVED. See Buffalo Berry.

SHEPHERD. The person who has the care and management of a flock of sheep. Mr. Bannister says, that it is necessary to have for this employment "a person who is well skilled in the nature and management of sheep, and hath been brought up in that employment from his infancy; who is sober, diligent, and good-natured; qualities essentially necessary in a shepherd, who, although he may seem to lead a life of indolence, when contrasted with the more laborious servants of the farm, need rarely to have a minute's time hang heavily on his hands, if he will be attentive to his business, which will furnish him with sufficient employment throughout the day, particularly in the lambing season, or where there are two folds at work; nor will he want opportunity for the exercise of his patience and good temper in his attendance on the sheep, which is by nature an animal of great obstinacy and perverseness, and hath often paid the forfeit of its life to these innate qualities, where the shepherd was a man of a morose and surly disposition."

SHEPHERD'S NEEDLE (Scandix Procto Veneris). This is a troublesome annual weed, very common in cultivated fields in England. The root is tapering. The fruit is nearly smooth, with a bushy edge, from 1 to 2 inches long; whence the specific name.

SHEPHERD'S PURSE (Thlaspi, from thlaos, to compress; the seed-vessels are compress-ed). In England this is a genus of worthless plants, the principal species of which is the common shepherd's purse (T. bursa pastoris), which occurs in almost every part of the globe. It is an annual plant, with a tapering, whitish root, having a peculiar smoke-like scent. The herbage is rough, with prominent hairs. Stem branched, leafy, from 6 to 12 inches high. Radical leaves deeply pinnatifid. Flower a small corymbose, often tinged with purplish-brown. Pouch inversely heart-shaped, somewhat triangular. Seeds about 5 or more in each cell. Small birds eat the seeds and flowers.

SHEPHERD'S STAFF. See Traveller.

SHERARDIA (named by Dilienius in honour of his patron, W. Sherard, LL.D., consul at Smyrna). This is a genus of uninteresting plants. One species, the blue sherardia, or little field-madder (S. arenaria), is indigenous to England, where it grows in fallow fields, or among corn, on a light or gravelly soil. The plant is annual; herbage generally hairy; stems several, branched, spreading, mostly decumbent, 3 to 6 inches long. Leaves whorled, pale-green. Flowers pale purplish-blue, in a sessile terminal umbel.

SHERDS. In gardening, fragments of earthen pots, &c., employed to drain the soil supplied to potted plants, and also as under-draining for gravel walks.

SHIFTS. See Rotation of Crops.

SHIM. A tool of the tillage kind, used in breaking down and reducing the more stiff and heavy sorts of land, as well as cutting up and clearing them from weeds. They are made of different forms and constructions, to suit different purposes.

SHOCK. See Snack.

SHOREWEED (Littorella, from littus, the shore, in allusion to its place of growth). The planthain shoreweed (L. lucustris) is a pretty little perennial sub-aquatic, indigenous to England, flowering in June. It has no stem; but the root, which is fleshed and tap-shaped, throws up many long, linear, channelled leaves. The flowers are whitish-green.

SHORT-HORNS. See Cattle.

SHRUB. A small, low, woody, free-stemmed plant, resembling a tree, which, instead of one single stem, frequently puts forth from the
SILK CULTURE.

The United States being, like China, situated on the eastern side of a great continent, offer peculiar advantages for the production of silk. From the general predominance of westerly winds in extra-tropical regions, the eastern sides of continents in these possess a dry and warm summer climate, peculiarly adapted to the prosperity of the silkworm. In Europe, the region of the silk-culture is confined to the southern portions, and commences at a distance from the sea, on the eastern side of the mountain ridge of the Cevennes. These mountains offer a barrier to the moisture borne far inland by the prevailing westerly winds sweeping from the Atlantic. In the United States the prevalence of the same winds keeps off a large amount of the moisture from the sea, and leads to a comparatively dry atmosphere. So far as this characteristic of climate is concerned, the culture of silk may be extended to the very shores of the Atlantic. At various times attempts have been made to introduce it into the United States, but it is only within a very few years past that the subject has received the attention which it merits as an important and most valuable agricultural resource. Among other obstacles which have tended to prevent the development of the silk culture, the comparatively tardy growth of the ordinary kinds of mulberry trees cultivated for feeding the silkworm has been not the least, since where immediate sources of profit exist in other products of the soil, few will engage in enterprises, the profits of which have to be so long anticipated. The introduction of a new kind of mulberry, the Morus Mollisculus, a tree of rapid development, having in a great measure removed the obstacle referred to, the silk culture has, to a greater or less degree, been introduced from one end of the country to the other. Strange as it may seem, the Eastern States, with a comparatively rigorous climate, have heretofore been almost the sole producers of domestic silk as an object of profit. In some of the townships of Connecticut and Massachusetts, silk has for many years been an object of domestic culture; but this was carried on to great disadvantage, the cocoons having been usually wound off upon common wheels, and spun into sewing silk. No such thing as a regular filature for converting cocoons into reeled silk, and thus preparing it for being woven into different fabrics, existed in the Eastern States; so that, instead of using only the refuse cocoons in making sowings, the very best were thus appropriated. The introduction of suitable reels for winding off silk and placing it in the best form for mercantile purposes, has been comparatively slow, owing in a great degree to the introduction of many contrivances intended to curtail labour by winding immediately from the cocoons and twisting by the same process into sewing silk. Most or all such contrivances have proved very unprofitable, and have yielded, or may be expected to yield, to the simple, effective and labor-saving machines of the Orient. With the exception of the Spinning Wheel, the most perfect of all devices for taking silk from the cocoons, and placing it in the best forms for market. Many very skilful reelers have been made in various filatures in the United States. Although in every part of the Union the mulberry can be reared, and the silkworm successfully fed, still it cannot be doubted that the southern portions of the Middle, and all the Southern States, afford peculiar advantages to the silk culture. An agricultural resource, which in France and other countries is so highly appreciated and fostered with so much zeal by the government, by the establishment of model filatures, and the zealous attentions of men of skill and science, should be regarded as well worthy the protection of the general and state governments of the Union. Many states already allow liberal premiums for cocoons and raw silk produced within their borders, and these inducements to individuals should be continued until the silk culture becomes fairly established as a regular branch of rural labour; after which it will, like most other branches of industry once fairly set on foot, take care of itself.

LARGE crops of cocoons were last year produced in Pennsylvania, Ohio, Kentucky, Tennessee, and Indiana. The comparatively small cost of conveying to market an article so highly valuable as silk, should encourage its culture in districts from which the heavy and bulky products of agriculture cannot be transported so as to leave a fair profit to the producer. In Ohio many thousand yards of silk stuffs were woven in 1842, the manufacturers paying for the cocoons about $4 per bushel. The cultivators find their advantage in having the silk reeled from the cocoons into organzine, instead of the formerly unprofitable mode of turning the most valuable silk into rewings. American raw silk, when properly reeled, is superior to that generally produced in Europe. A person who had been many years engaged in weaving silk in different establishments in London, having had (as he says) for 15 years from 250 to 300 lbs. of the raw material, of
SILK CULTURE.

every grade and name, passing through his hands weekly, expresses the following opinion relative to silk produced in the United States:

"I am qualified to affirm, from various experiments I have tried, that the silk is superior to any I have seen from Italy, China, France, Piedmont, or Valencia, where the worms are fed upon muliticaulis, or Italian. Its brilliancy, strength, and scent are superior. I am aware that an exposure to the saline air, in the passage across the ocean, may be the cause of the loss of fragrance to imported silk; but the brilliancy is peculiar to American silk, if reeled in a proper manner, with cleanliness.

"I am confident that the mammoth sulphur-worm is the pure Fossam brown. To try this, I had about 3 lbs. of silk reeled, and enclosed it in an air-tight box for 3 weeks. When I took it out it had the fragrance of the Fossam brown stronger than any that I ever smelt in England, which convinced me that the mammoth sulphur is the identical silk which is always from 5 to 8 shillings per pound higher than ordinary silk. The mammoth white and the peanut white is a Novi, and superior to any I have seen in England. The yellow or orange I cannot, satisfactorily to my own mind, yet define, but am trying experiments in order to ascertain. I am strongly persuaded it is a Bergam. Should this prove the case, it will be a great acquisition to manufacturers of silk velvet. Some have supposed the pea-nut white is the Piedmont, but they are mistaken. The Piedmont cocoon is lily-white, very diminutive, with a sharp point."

Where legislative patronage has been extended in the allowance of bounties on cocoons and raw silk, the state treasuries may be referred to as criterions showing the increase or diminution of the silk crop with great precision. The treasurer of Massachusetts has furnished the following report, indicating how the matter stands in that state:

1836 - $27 35 1840 - $1,233 50
1837 - 1850 00 1831 - 2,111 42
1838 - 350 52 1832 to Oct. 1 3,551 91
1839 - 434 62

"Another consideration, calculated to urge the business forward," says the Northampton Silk Convention, "is found in the fact that all our present agricultural staples are now extremely depressed, and are likely to remain so. The market is completely glutted. Our farmers must take up something new, or their sufferings will be prolonged indefinitely. In this crisis, it owes to their aid. In the production of this article they cannot glut the market for one whole generation, most assuredly."

Without desiring to excite undue expectations, it is a question which deserves serious consideration, whether much more may not be realized from the prosecution of this business than has hitherto been? The little town of Mansfield, in Connecticut, by a persevering devotion to it, undiscouraged by the ill-success of others, has been enabled to derive therefrom a good profit; and it appears from the last census that, with a population of 2,276, not less than $50,000 is annually received from this business.

The bounty paid in Ohio, in 1841, amounted to $2681 76; in Pennsylvania $4418 50. In 1842 there was paid as bounty, in Ohio, $6609 61. The whole amount of reeled silk produced in Ohio is set down at 3000 pounds. One person sold 300 pounds of reeled silk for $1600. The whole aggregate of the silk crop throughout the United States, for 1842, is given in a tabular view, by Mr. Ellsworth, at 241,124 pounds of cocoons. (Ellsworth's Report to Congress.)

Under the head of Mulberry, some observations have been made in relation to the varieties of the tree best adapted to the silk culture in the United States. Besides the numerous communications to be found in most of the American periodicals, devoted to agricultural and some especially to the silk culture, many excellent original treatises have been written upon the same subject. Among the last we may name the essay published under the auspices of P. S. Duponceau, Esq., of Philadelphi, one of the greatest champions of the legitimate silk culture that the Union has produced. By legitimate silk culture, is meant the employment of the Piedmontese reel, the use of which is absolutely necessary to give the product of the cocoonery its proper value. The work thus referred to is a duodecimo printed in Philadelphia, Silke Culturist, by M. d'Homergue. It is particularly useful in relation to the subject of the Piedmontese reel. A summary of the principal Chinese treatises on the culture of silk, &c., was published, in 1838, by P. Force, Esq., Washington. An excellent Treatise on the Mulberry Tree, and the Production and Manufacture of Silk, was published in Philadelphia, in 1839, by Mr. John Clarke. Several Manuals on the silk culture, furnishing abundant information, embracing the most minute details, have been published by Roberts, Cobb, Kenrick, Comstock, Clarke, &c., &c. Among the periodicals specially devoted to the culture of silk, is the Silke Culturist, edited by F. G. Comstock, of Hartford, Connecticut, in 1835-6, and the Burlington Silk Record, by E. P. Morris, may be mentioned. In the latter are given the interesting views of Mr. Morris, with a description of his newly invented and valuable feeding-shelves, together with the results of many experiments in raising worms upon an extensive scale.

SILK-GRASS or BEAR-GRASS. See Yucca.

SILK-WEED. See Cotton, Wild.

SILLS. A country name for the shafts of a cart, &c.

SILVER BELL. See Halesia.

SILVER FIR. See Fir and Pine.

SILVER-WEED, or WILD TANSEY (Potentilla anserina). An indigenous perennial plant, which, according to Linneus, indicates clay under the surface. Although it is found frequent in osier holts and spongy meadows, it grows most commonly upon cold, stiff land, and is a sure mark of the sterility of the soil. Flowers large, bright-yellow, the calyx hairy; and each on a long, simple stalk, mostly erect, blowing all the summer. See Closier, George. An able and successful writer and experimentalist on the artificial and other grasses. He carried on a se-
SIT-FAST. In farriery, an ulcerated sore in which a part of the skin has turned horny; if it cannot be dissolved and softened with mercurial ointment, it must have a mild blister applied, which will cause it to separate. It generally proceeds from a warble or little tumour resulting from the pressure of the saddle. See Back-Sore and Galls.

SIZE. See GLUE.

SKEG. A kind of oat, sometimes cultivated as a crop in Nottinghamshire. It is the Avena stipiformis of Linnaeus. See Oats.

SKED. A coarse, round, farm-basket. It is also provincially used to signify a bee-hive.

SKID. The chain by which the wheel of a wagon is fastened, so as to prevent its turning round, upon descending a steep hill. See DRAG.

SKIM COUTLER. See Pulchra.

SKUNK-CABBAGE; Swamp-cabbage; Skunk-weed. Familiar names applied to a plant common in low grounds in the United States. It is the Symplocarpus foetida of some botanists, and the Pothos foetida of others. It has a perennial root, and very large leaves, often, when fully grown, measuring 2 feet long and 1 foot broad. This plant was known to Dr. Darlington, "is notorious for the pole-cat-like odour which it emits, when wounded; and is said to possess some medicinal virtues, as an anti-spasmodic. The root, when chewed, produces a tingling or prickling sensation in the mouth. It is the only species of the genus in the United States: Dr. Barton, however, describes a pretty distinct variety, near Philadelphia."

SLATE. A well-known, neat, convenient, and durable material for the covering of the roofs of buildings. There are many varieties of slate, and it likewise differs very greatly in its sizes and colours. In some places it is found in thick lamina or flakes, while in others it is thin and light. The colours are white, brown, and blue. Slate is so durable in some cases as to have been known to continue sound and good for centuries.

SLAUGHTER-HOUSE. See Abattoir.

SLEET. See Snow.

SLOE. The American species of sloe belong to the viburnum family, and are not to be confused with the black hedge thorn. See Blackthorn.

SLOUGH-HEAL. See Self-heal.

SLUG. A genus of molluscous animals, or naked snails, comprehending several species, which differ only in colour. Slugs infest gardens and fields, and are very injurious to the growing crops; hence it becomes essential to destroy them. Dry lime and slashed lime have been recommended, which, being dissolved by the dew and moisture of the atmosphere, act as a poison to these animals. But pulverized lime is not suitable to all soils, and may even prove injurious to some crops. Lime-water appears to be preferable. But as many husbands may not have an opportunity of liming their fields or gardens, or of keeping a sufficient stock of geese, fowls, ducks, &c., to turn in and devour the slugs, common salt will be found an effectual cure; and tar-water or other refuse of gas-work will prove destructive to them, if sprinkled on the land. See Insects and Snails.

The disgustingslug infesting pear and cherry trees in the United States is a slimy false caterpillar, the nature and characteristics of which, and the parent-fly, are particularly described by Professor Peck and Dr. Harris. See Saw-flies.

SMALLAGE PARSELEY. See Celery, Wild.

SMITHFIELD. The principal market for the sale of live cattle in the United Kingdom. It is very inconveniently situated in the heart of the metropolis. The numbers of cattle slaughtered have been more than double during the last century. See Cattle, outward (p. 292.) Although this increased consumption is scarcely proportioned to the increase of population, it should be remembered that a very different description of cattle are now slaughtered to what were then killed. The present average dead weight of the bullock is about 656 lbs., of the calf 144 lbs., of the pig 96 lbs., and of the sheep and lamb 90 lbs.; approaching to double the weight of these animals in 1780. This renders the number of cattle slaughtered in the metropolis, and the increasing number of the inhabitants, a little more proportionate. From this time to 1825, and the number of cattle sold in Smithfield market in the year 1830, we may now form some not very inaccurate idea of the amount of this branch of the provision trade in London.

Number of lbs. of meat consumed: 248,433,504.

This estimate, at the average price of 6d., would be 8,210,505. 2s. 6d.; but at the 7s. 6d. it would produce 8,968,293. 9s. 4d., exclusive of bacon, hams, and all salted provisions brought from a distance (the importation of Irish bacon and hams into Great Britain is 500,000 cwt.), and also fish and poultry. This calculation will enable us to determine another curious question,—what is the average quantity of meat consumed by each individual in the course of a year! If we divide the gross number of pounds, 248,433,804, by 1,450,000, the estimated number of inhabitants in London and its environs, the quotient will be 170, or each individual consumes nearly half a pound of meat every day. This is a very high calculation compared with that of Paris, where each person is supposed to consume but 80 pounds in the year; and Brussels, where 89 pounds form the allotment of each; but the English is a meat-eating population, and composed chiefly of Protestants; and when we remember that this includes the bones as well as the meat, half a pound a day is not too much to allow to each person.

Cattle are sent from every part of the king-
SMUT.

...and but they he for from envelops; insufficienttion. are infected the diseased the wood-louse, of the diseased, this, Cymen has shown that the male flowers of some plants suffer from smut as well as the female, and the former we know have no embryo.

Some farmers have considered that pigeons' dung induced the disease, but general experience is against this idea. Nor is the disease the consequence of any defect of the sap, for all the parts except the ear are healthy; and there are some plants, observes M. Cymen, having perennial roots, and which are vigorous, yet their seeds are annually attacked with this disease.

Having thus disposed of the several causes which have been erroneously assigned, I will now proceed to detail the more correct knowledge that has been accumulated respecting this plague of our corn crops.

This disease is severally termed smut, dust-brand, blight, burnt corn, &c. In France it is commonly known by the names of charbon and nielle volante. Botanists, aided by the microscope, have discovered that the cause of smut is a parasitical fungus, which preys not only upon the sap, but destroys the very organic structure of the grain and chaff upon which it fixes. The majority of naturalists agree in distinguishing the fungus by the title of Uredo segetum; but as it has other synonyms, these, and the authors who have employed them, may be usefully enumerated. Uredo segetum, Pursh, n. 27; Chaos ustilago, Lin. Syst. Nat. 1326, n. 4; Reticularia des bils, Bulliard's Fungi, vol. i. p. 90, plate 472, f. 2. Reticularia segetum, Withering, iv. p. 388. Charbon, Tessier, Des Maladies des Grains, 299. Bulliard describes this fungus as globular, extremely fine, and attached to a fine elastic thread. They are exceedingly numerous, enveloping the seed and chaff of the plants they affect, and are, as well as their own still more the seed, of an intense black colour, having a disagreeable fetid smell, which has been not inaptly compared to stale lobsters.

Mr. Kirby tells us that Mr. Lathbury examined the dust of this fungus under a powerful magnifier, and found it consisted of numerous minute particles, uniform in shape and size, much smaller and blacker than those of the pepper brand, and less easily separable: they seemed to be contained in little irregular cells. This dust or seed is the food of a small, shining, black insect, the Dermestes a^ta of Marsham.

Chemical analysis has demonstrated that this fungus effects an entire decomposition of the vegetable particles of the grain it infects, the saline constituents remaining nearly unaltered in the grain. Parmentier, Cornet, Girot, Chantians, Fourcroy, and Vaquelin, have successively examined it, and the result of their researches is, that smutted grains of wheat are composed, 1st, of about one-third their own weight of a green, butyrous, fetid and acrid oil; 2d, nearly one-fourth of a vegeto-animal substance, perfectly similar to that which comes from purietia glutin. 3d, a black cool, one-fifth of their weight, similar to that.
which is found in all remnants of putrefied organic compounds; 4th, free phosphoric acid, amounting scarcely to more than 0.004 of the smut; 5th, phosphates of ammonia, magnesium, and lime, in the proportion of a few thousandths. "We must remark," say MM. Fourcroy and Vauquelin, "that in one examination of putrefied gluten, we found characters very similar to those of the smut of wheat; and that the products of the one are so like those of the other as to render it difficult, in certain cases, not to confound them together. It requires a man to be well practiced in chemical experiments to discern the slight differences that exist between these two putrefied matters, because the differences are only delicate shades, not easily discernible. The contagion attacks especially the gluten, and precedes, indeed prevents, the formation of the starch; since we know positively that this feacula, no traces of which are found in the smut of wheat, suffers no alteration from the septic process which so powerfully attacks the glutinous substance." The ravages of this disease are chiefly, though not exclusively, confined to the cereal plants. Mr. Kirby says it is an annual, with wheat, barley, rye, and rye; and that he has seen the flote fescue (Glyceria fluitans), and some other grasses, affected with it. Barley and oats are more frequently affected by it than wheat, which may proceed from the latter being usually steeped before sowing. Wildenow, who, in his Principles of Botany, § 331, describes the smut under the name of "Ustilago," and as being a small fungus, says, "This singular variety of gangrene occurs most frequently in the species of Gramineae, rarely in other plants, sometimes in Scorzonera, Trago-peon," &c.

The ear of corn which is attacked is in general totally destroyed, but sometimes the same ear contains sound as well as smutty grains; and even one end of the same grain has been found diseased and the other end sound. However, as all the grains in an ear are usually infected, so, when one stalk is smutty, it generally happens that all the ears from the same root are so too. In March or April, upon carefully opening the hose or blade (folium vaginatum) which covers the ear, and examining the young ear, although it was not above one-sixth of an inch long, and almost close to the roots, M. Du Hamel found this embryo already black and dismembered; a fact confirmed by the researches of Mr. Kirby. When the diseased ear comes out of the above-mentioned envelope, it looks lank and meager. About half an inch of the upper part of its stalk is commonly not quite straight. If cut asunder at not more than a quarter of an inch below the ear, it will be found nearly solid or filled with pith; the circulation above is therefore obstructed. The next most important point for consideration is, from whence is the infection communicated; and the following experiments will be found to have demonstrated that it is capable of being conveyed to the plants by the agency of the parent seed. These experiments are satisfactory and decisive; for, although they are only in accordance with the most prevalent opinions of farmers upon the point, yet prevalent opinions are not always in accordance with truth, and are never to be implicitly received until sustained by evidence, which is independent of prejudice, and more accurate than surmise.

Mr. R. Somerville, in a paper published in the Communications to the Board of Agriculture, details experiments fully substantiating the fact, that the disease is communicable to the crop from the parent seed. He mixed some smutted grains with others perfectly healthy, and kept them in a box for two months; after which, previously to sowing, he rubbed them together with his hands. The samples were then divided into two equal parts, one of which was well washed with clear water three or four times, and then sown in a drill in his garden. The other half was sown similarly, but without being washed or otherwise prepared. The blades appeared above the surface at the same time, and during the first two months of their growth there was no visible difference in their appearance. Soon afterwards many of the plants from the unwashed seed were observed to have a darker and more dirty green hue than those from the seed that had been cleansed with water. This difference of colour by degrees became more striking, and increased until the grain was protruded from the blade, at which time many of the dark-coloured plants evinced symptoms of decay; and the whole of them, when fully developed, were found to be completely destroyed by the smut. The plants from the washed seed produced scarcely a single diseased ear. These results were not fortuitous, for the experiment afforded a similar testimony when repeated the next season.

The experiments of Mr. Harrup agree with the preceding. In these, wheat, consisting half of sound and half of smutted grains, was sown without being previously at all prepared, and this produced a crop of which nearly two-thirds were smutted. Similar wheat, soaked for twelve hours in a saturated solution of common salt, and then mixed with quicklime, produced on the same soil, in the same situation, and in the same season, a crop in which not a smutted ear could be found.

Similar, but more extended, and even more accurate experiments, were completed by Mr. Bevan, and are recorded in the ninth volume of The Agricultural Magazine. They give the result of his trials with various liquids as steeps for seed-wheat. The wheat was grown on a sandy soil, at Leighton in Bedfordshire. The columns in the accompanying table which are marked A. contain the results from the sound grain that was sown; and those marked B. are the results from smutted samples. (See Table at top of the next page.)

The conclusion from these and many other accordant experiments is, that washing the seed is effective in preventing the communication of the disease to the crop to which it gives birth. If the washing was frequently repeated, or the cleansing made complete, by passing a continual stream through the seed for some hours, it is probable that simple water might be employed for this purpose as effectually as any saline solution. But as this would require more labour than is desirable, and as the salts,
SMUT.

Smut, employed are beneficial in other ways, by protecting the seed from vermin, and ministering to the future vigour of the plants, stews are generally and very properly adopted.

* The seed treated with this acid did not vegetate.

The experiments of Mr. Bevan indicate that lime-water is the most effective of these preparations; and, if this be adopted, it may be prepared by mixing 1 pound of fresh lime with 3 gallons of boiling water, and the clear liquor then to be poured off and immediately used. In this liquor the wheat should be soaked for 12 hours, stirred twice or thrice during the time, and then mixed upon a floor, with the powder made by pouring 3 gallons of boiling water upon 4 pounds of lime. I have had no experience of the effects of lime-water as a preventive of the smut; but with stale urine, and a solution of common salt, I have witnessed numerous and extensive experiments. The results, without exception, were favourable and nearly similar; and this being the case, a preference is to be given to common salt, as being decidedly the most cleanly and the least disgusting. The mode which I have observed to be the most effective is, to wash the seed with pure water, pouring this off with all the floating grains, and then allowing the seed to soak for 12 hours in a solution of common salt, having a strength or specific gravity sufficient to float a hen's egg. I have no doubt that lime, like common salt, is effectual against the disease, by reason of its powerful action upon the texture of the fungus tribe. Every housekeeper knows how completely rooms dissolve away when sprinkled with salt; and in experiments I have made upon the Uredo segetum, I found that the effect of common salt upon this fungus is not less remarkable.

Mr. Tull, MM. de Ligneronle, Douat, and others, agree in recommending that the seed to be sown upon any farm should be frequently obtained from other soils; but, however beneficial this may be for securing other desired effects, I do not understand how it can prevent the occurrence of smut unless the seed is obtained from a crop and a district notably free from the disease. There is little doubt but that the method in which the disease is imparted to the plant is by its root imbibing the extremely minute seeds of the Uredo along with the moisture of the soil. This opinion is confirmed by the observation that the disease is most prevalent when the winter has been mild and the spring wet; for, in such seasons, the abundant moisture passing through the soil is most likely to convey the seeds to the mouths of the plants' radicle fibres.

I remember trying some experiments, the full details of which I have accidentally lost, in which I buried some of the Uredo segetum about an inch below the surface of the soil, in a garden pot in which some wheat was growing, supplying those plants, during their after growth, plentifully with water poured upon the surface of the soil. Not one of these plants escaped infection.

Another garden pot, in which wheat from the same sample was growing, and similarly treated in every respect, but to which moisture was supplied solely by means of the saucer in which it was placed, both pots being sheltered entirely from the rain, produced plants which were not at all infected. Although it is very apparent that the smut is generally imparted to a wheat crop by the agency of the seed sown, yet I am by no means of opinion that this is the only source of infection. I have kept ears of wheat that were covered and destroyed by the Uredo during more than twelve months in a situation where they experienced the vicissitudes of temperature during all the seasons, unprotected by more than the paper envelope in which they were suspended in an outhouse. Yet when the Uredo that had been thus exposed was mixed with healthy well-washed seed-wheat, this produced diseased plants in a triplicate proportion more numerous than that not so mixed. This experiment demonstrates that frost and drought, acting in concert with a damp atmosphere, do not destroy the vegetating power of the Uredo's seed. Such being the fact, why may not this seed remain in the soil ready to impart the plague? We know that, owing to its extreme lightness, the seed floats buoyantly in the air, and may be carried by winds to distant soils, which in the autumn of the same year, before any extremity of cold has been endured, will have to bear the wheat crop for the following harvest. The opinion that the soil is one source of infection, is sustained by the fact that fields in the vicinity of the sea are rarely injured, and never extensively, by the ravages of the smut. Such soils are impregnated more than any other with common salt, and the effect of this saline compound upon the Uredo has been...
SMUT.

noticed already. These considerations suggest that applications to the soil as well as to the seed are necessary for the banishment of the disease; but a more full notice, and some curious particulars upon this point, will be found detailed under the head Mildew.

I have frequently examined the roots of wheat plants affected by the smut, but have never perceived that they had a diseased appearance; a fact which I find confirmed by the researches of Mr. Kirby. Although the root is not affected, yet I have invariably found the smutted plants of a form and habit much less robust than those undiseased. The average result of Mr. Bevan’s experiments is, that smutted wheat produces straw in the proportion of only 30 to 36-75, when compared with wheat unattacked by the smut. This is not a result contrary to that which might be anticipated; for in plants, as well as animals, an organic affection so serious as this is usually accompanied by a general emaciation of the frame. So decidedly is this effect produced upon wheat, that a practised eye can at once detect by its appearance, before the diseased ear is protruded, a plant that is thus distempered. The stem and leaves look upright, thin, and stiff, warding the aspect that is best described, to those who know the appearance, by the term stunting. I cannot conclude without remarking that these facts strengthen the analogy I am so fond of tracing between plants and animals. The atrophy exhibited by both, when under the influence of disease, is strikingly illustrative of their close relationship; and this is further carried on by their being equally liable to the ravages of parasites. The skin of every animal is liable to be infested by vermin, as its intestines and other viscera are by worms and various other creatures. So plants are not only subject to invermination, but, like animals, they are preyed upon by various genera of their own race. Their barks are assailed by numerous lichens and fungi, whilst internally they are a prey to the Oredo I have just described, and to several others of the fungus tribe. Animals have their larger parasites, as the tick, &c., and vegetables similarly bear the missiletoe, dodder, and others. This repeated urging that plants are closely allied to animals in every particular is not without its use. Every year’s experience convinces me that it is not less beneficial to cultivate plants with the least possible injury to their various parts, than it is to treat our farming stock with gentleness and an attention to their comfort; and it is by demonstrating the analogy between the two great divisions of created beings, that the reason of the cultivator is to be drawn to regulate his practice.

Finally, I will observe, that the farmer is much too prone to regard the diseases of his crops as of trivial importance. In such cases as where the curl destroys whole fields of his potatoes, or the mildew reduces the produce of each acre of wheat to a few bushels, he is miserably sensible of the injury he has sustained; but if, within the circle of corn-ears around him, as he surveys his crops, he only sees a sprinkling of those affected with the smut, he looks upon this as of insignificant consequence. Yet, in the experiments of Mr. Bevan, in the instances where only two smutted ears occurred in three sheaves, the weight of the straw was reduced nearly one-third, and that of the grain three-sevenths. (Essay by G. W. Johnson, Quart. Journ. Agr. vol. ix. p. 45.) See Bright and Mildew.

SMUT-MILL. Of late years the millers in the United States avail themselves of contrivances called smut-mills, the passage of the wheat through which clears it very effectually from the offensive dust. Wheat affected with smut was formerly much objected to by the grain merchants and millers, but since the introduction of the machines referred to, it is so readily cleansed that smut is scarcely objected to in the sample, and the market price reduced but little, if at all.

An inquiry made, in March, 1842, into the merits of a smut-mill invented by Mr. Wm. C. Grimes, of York, Pennsylvania, by a committee of the Franklin Institute of Pennsylvania, warranted them in recommending the machine to the notice of millers, as capable not only of making good white flour from wheat so badly smutted as to be generally considered unmerchantable, but which will also improve the general quality of the grain by the removal of cheet, and of the down or furze which covers one end of the grain, and of most other accidental foreign matters which tend to injure the quality of the flour. (Jour. of the Franklin Inst. of Penn. vol. iv., third series, p. 32.)

SNAILS (Helix—Helicidae). A well-known genus of molluscous animals, comprising a great many species. They live throughout the winter in a torpid state, in cavities in the earth, which are covered over with a calcareous kind of wall, partly formed with its mucous secretion. The animal escapes from its cell in April, bursting its operculum, and again breathes as before its hibernation. The species of shell-snaives are very extensive. In the garden, snails do much damage to the vegetables in cultivated grounds, biting off pieces of the leaves by means of a semicircular, dentated, horny plate which is affixed to the upper lip. To extirpate them, it has been recommended to strew the ground with lime and ashes, or salt. Snails seldom annoy farmers, unless it be under the hedges; and if they venture out into the middle of a field, the roller is a certain destructive implement to their fragile coverings. The red, or great vine-snail (H. pouatia), formed one of the luxuries of the tables of the ancient Romans, and by peculiar feeding and other treatment was brought to attain an immense size. It is still an article of food in certain cantons of Switzerland and France, and some of the provinces of Spain and Portugal. This species of helix was brought to England by the Howard family, and placed on the grounds in the neighbourhood of Box-hill, where it is still found; but it does not attain to the size it often displays in Italy. It is supposed to be a good article of food for the consumptive.

SNAKE-ROOT. Several plants in the United States go under this appellation. The Virginia snake-root (Aristolochia serpentaria) is the well-known fibrous root, noted for its intense bitterness, and extensively employed in medicine as
as a tonic. It is found in rich woodlands, in the Middle States. The root is perennial.

The tall snake-root, or black snake-root (*Actea racemosa*). This plant has a perennial root, large and branching. The stem grows 4 to 6 feet high, slender, smooth, leafy near the middle. It flowers in June. "The white racemes of this plant," says Dr. Darlington, "when in flower, are quite conspicuous in our woodlands. The plant itself has a disagreeable odour when bruised. The root is somewhat mucilaginous and astringent; and is a very popular medicine both for man and beast. It is used in infusion, or decoction, chiefly as a pectoral remedy for human patients; and many persons consider it almost a panacea for a sick cow. Its virtues, however, are probably much overrated.

Black snake-root, Maryland sanicula (*Sanicula Marylandica, vel canadensis*). This plant has a perennial root, and is frequent in woodlands and thickets where it flowers in June and July. The stem grows 2 feet high, branched above, grooved and smooth. The flowers are white and sometimes yellow.

Button snake-root, the shining star (*Liatris scapigera*). This plant has a perennial, tuberous root with many small fibres. The stem grows 2 to 4 or 5 feet high, with numerous leaves, disposed alternately. The purple flowers appear in August. The root of this handsome plant is a popular medicine, being employed either as a tea or spirituous tincture for the cure of chronic rheumatism, debility, &c.

The Seneca snake-root or mountain flax, has been mentioned under the head of Milk-wort.

**SNOW.** This well-known precipitation from the atmosphere serves to defend winter grain-crops and all other vegetables from the severity of frosts; for, being a very bad conductor of heat, it prevents the internal warmth of the earth from being carried off through the surface of the land, and consequently ameliorates the soil. The plants being thus sheltered, shoot forth in the spring with renewed vigour; and, cherished by the genial rays of the sun, vegetate with increased luxuriance. As ammonia and other saline matters, possessing fertilizing matters, have been detected in snow, it not only cherishes vegetation by the protection it affords, but by the direct influence of the fertilizers referred to in the above.

**SNOW-BALL.** See Guelder Rose.

**SNOW-DROP TREE.** See Halesia.

**SOAPWORT** (*Saponaria, from sapo, soap*; the bruised leaves are said to produce a lather, like soap, when agitated in the water). This genus contains some truly beautiful plants, well deserving of a place in every garden. One species, with some varieties, is indigenous to England. The common soapwort (§ officinale), a perennial, grows in meadows, by rivers, and under hedges. The root is branching, rather fleshy, with many long, creeping scions. Herbage smooth, or nearly so, a little succulent. Stems about 18 inches high, erect, round, leafy. Leaves eliptic-lanceolate, acute. Panicule dense, of many erect, large, handsome, flesh-coloured, or pale-pink flowers, with an oppressive sweetness.

This plant, which bears the common name of bouncing-bet, has been introduced into the United States, where it often proves somewhat troublesome in gardens and meadows. When bruised, and agitated in water, it raises a lather like soap; and has been used as a substitute for it. A decoction has been employed sometimes as a wash for the itch, and other cutaneous diseases. There are no native species; and this is the only one of the genus which has become naturalized in the United States.

**SODA.** See *Kelp; Salts, their uses to vegetation, &c.*

**SOD BURNING.** See *Paring and Burning.*

**SOFT-GRASS.** See *Holleus.*

**SOIL.** See *Eaths, Analysis and Mixture of Soils.*

**SOILING.** The practice of supporting animals in the summer season, with green food, cut daily and given to them in the houses, stalls, or yards. A number of different plants and grasses may be had recourse to for this purpose, particularly those which have a quick and luxuriant growth; as lucerne, sainfoin, tame, clover, turnips, &c.

Soiling-grasses are to be highly advantageous, in a variety of ways, by the food being consumed with much less waste, by the great increase of good manure that is produced, and by the stock feeding with less interruption and inconvenience, from their being more effectually shaded from the excessive heat of the sun, and better protected from the attacks of flies and other insects. In all these respects it would seem to have a great superiority over that of letting the animals range indiscriminately in the pastures or other grass lands.

Soiling has been found, by the most careful experiments, to answer perfectly both with horses, neat cattle, and swine; and with cows it has been found very beneficial in the trials of Mr. Curwen and several others.

By an extensive and judicious use of soiling, the farmer may derive benefit in being enabled to have a considerably larger extent of land both under the states of tillage and grass, from the considerable increase of manure that is produced.

**SOLAR INFLUENCE.** See *Temperature and Light.*

**SOOT.** is very extensively employed in the east of England, as a powerful manure, and produces, when used at the rate of 12 or 20 bushels per acre, most luxuriant crops of wheat and other grain. This valuable fertilizer is composed of a mixture of charcoal, an oil, salts of ammonia, some muriatic acid, lime, magnesia, silica, and other foreign substances; but the charcoal is by far the largest ingredient, and has a powerful influence on vegetation; and, according to Liebig, it can "completely replace vegetable mould or humus. Plants thrive in powdered charcoal, and may be brought to blossom and bear fruit if exposed to the influence of rain and the atmosphere."

See *Organ. Chem.* p. 61. The substances contained in soot are the natural food of vegetation; the carbon gradually combines with the oxygen of the atmosphere, and is converted into carbonic acid gas, which is readily absorbed by the roots and leaves of plants.
SOUTHERNWOOD.

In Essex, the chief employment of soot is for wheat, and it is generally applied by the chimney sweepers to the land, out of a basket, in the same manner that seed is sown. This is usually done in the spring of the year, in March, April, or May. Wheat so treated speedily attains a deep green, and on some soils grows with greatly increased luxuriance. Soot was employed by the Rev. E. Cartwright as a manure for potatoes, both by itself and in combination with various other fertilizing substances. The experiments were made on a portion of the same soil as that described in the article Ashes. The following were the results obtained:

<table>
<thead>
<tr>
<th>Per Acre.</th>
<th>The soil, without any manure, yielded bushels of potatoes</th>
<th>157</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Soot 30 bushels</td>
<td>159</td>
</tr>
<tr>
<td></td>
<td>Soot 30 bushels, salt 8 bushels</td>
<td>240</td>
</tr>
</tbody>
</table>

Various agriculturists have noticed the good results from mixing salt and soot. Mr. George Sinclair, in his prize essay On Salt as a Manure, mentions it as "remarkable" in the case of carrots. Mr. Belfield of Elford has done the same with regard to wheat.

In Mr. Sinclair's experiments upon carrots, the results without any manure produced:

<table>
<thead>
<tr>
<th>Per Acre.</th>
<th>The soils without any manure produced</th>
<th>114</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>carrots</td>
<td>23</td>
</tr>
<tr>

<td>soil with 6 bushels of salt dug in</td>
<td>14</td>
</tr>
<tr>
<td></td>
<td>soil with 6 bushels of salt, and 6 bushels of soot</td>
<td>40</td>
</tr>
</tbody>
</table>

In both the liquid and solid state, it has been employed by Mr. John Robertson of Kilkenny, with great success. "On meadows," he says, "I have used soot with great advantage in substance; and though sown by the hand, one dressing gave me always heavy crops of hay for two successive seasons. But this is a wasteful mode of applying it, a great portion of its ammonia, one of its most active ingredients, being volatilized, and dissipated in the atmosphere: when dissolved in water, there is no waste, - it is all available; and for horticultural purposes I have mostly used it in that state, mixing it up in the proportion of about six quarts to a bushel of water. Asparagus, peas, and a variety of other vegetables, I have manured with it, with as much effect as if I had used solid dung; but to plants in pots, particularly pines, I have found it admirably well adapted; when watered with it, they assume a deep, healthy green, and grow strong and luxuriant." Mr. A. Main makes some pertinent remarks on soot as a top-dressing to crops, and describes a machine for distributing it, in the sixth volume of the Trans. of the Highland Society, 535.

SORREL (the genus Rumex, from the shape of the leaves in many of the species, resembling a pike or spear). There are in England several indigenous species of sorrel, some of which have already been described. The common English sorrel (Rumex acetosa) is a perennial plant, met with almost everywhere in meadows and pastures, flowering in June. The root is long and tapering, astrigent, and somewhat woody. The herbage is smooth, powerfully and agreeably acid. Stem from 1 to 2 feet high, erect, simple, leafy, striated. Leaves oblong, arrow-shaped. Flowers dioecious, with permanent tuberculated petals. The acidulous taste of sorrel depends on binoxalate of potassa and tartaric acid: the astringency on tannic acid.

The flavor of the wood-sorrel (Oxalis acetosella) is much more grateful, and the leaves are more juicy, than those of the common sorrel (R. acetosa) and the French or Roman sorrel (R. scutata). The acid is merely the oxalic, free and also combined with potassa and ammonia. It likewise contains some saccharine matter. The garden cultivation required by them is identical. The leaves are employed at all seasons of the year, in salads, sauces, &c. "The wood-sorrel requires a silicious, yet moist and moderately fertile soil, in a shady situation, as beneath a hedge with a northern aspect. The garden sorrel thrives best in any mouldy garden soil that tends to lightness rather than tenacity, and is not too poor. The situation must be open. French sorrel is most healthful in a light, dry soil, that is tolerably fertile, in an open compartment. The rumexes are propagated by seed, and all of them by parting the roots, both which modes may be practised from the middle of February until the same period in May, and by the latter also in September and October. The finest plants are raised by seed, but those from portions of the roots are soonest in production. The so-called field-sorrel (Oxalis acetosella), is abundantly diffused throughout the United States, and often forms a great pest to the farmer. The best way to subdue it is by means of liberal dressings with lime. This has been disputed by some, where the application has been made in large quantity, it will seldom or ever fail. Of this genus two other species, troublesome to farmers, have been already mentioned. These are the sour or curled dock (R. crispus), and the bitter or broad-leaved dock (R. obtusifolius). See Dock.

SORREL TREE (Andromeda arbores). This is the only species of andromeda, which rises to the dimensions of a small tree. The other species I have mostly used it in that state, mixing it up in the proportion of about six quarts to a bushel of water. Asparagus, peas, and a variety of other vegetables, I have manured with it, with as much effect as if I had used solid dung; but to plants in pots, particularly pines, I have found it admirably well adapted; when watered with it, they assume a deep, healthy green, and grow strong and luxuriant." Mr. A. Main makes some pertinent remarks on soot as a top-dressing to crops, and describes a machine for distributing it, in the sixth volume of the Trans. of the Highland Society, 535.

SOUTHERNWOOD (Absinthium). The field southernwood (A. campestris) is a rather rare species. It is perennial in habit. The whole herb is without any aromatic or bitter flavour. Stems at first prostrate, becoming more or less upright as the flowers appear, branched, leafy, straight and wand-like, smooth, often reddish, near 2 feet high. Leaves irregularly and doubly pinnatifid, in many linear; blunt segments. Flowers drooping, small, ovate, yellow with a purplish calyx, forming numerous slender leafy clusters at the ends of the stems and branches. See WORMWOOD.
SOWING.

SPAN-WORMS.

The caterpillars of the Geometrae of Linnaeus, earth-measurers, as the term implies, or geometers, span-worms, and loopers, have received these several names from their peculiar manner of moving, in which they seem to measure or span over the ground, step by step, as they proceed. Most of these caterpillars have only 10 legs; namely, 6, which are jointed and tapering, under the fore-part of the body, and 4 fleshy prolegs at the hinder extremity; the 3 intermediate pairs of prolegs being wanting. Consequently, in creeping, they arch up the back while they bring forward the hinder part of the body, and then, resting on their hindlegs, stretch out to their full length, in a straight line, before taking another step with their hindlegs. They have the power of letting themselves down from any height, by means of a silken thread, which they spin from their mouths while falling. Whenever they are disturbed they make use of this faculty, drop suddenly, and hang suspended, till the danger is past, after which they climb up the same thread. These span-worms are naked, or only thinly covered with very short down; they are mostly smooth, but sometimes have warts or irregular projections on their backs. They change their colour usually as they grow older, are sometimes striped, and sometimes of one uniform colour, nearly resembling the bark of the plants on which they are found. When not eating, many of them rest on the two hindmost pairs of legs against the side of a branch, with the body extended from the branch, so that they might be mistaken for the twig of the tree; and in this position they will often remain for hours together. When about to transform, most of these insects descend from the plants on which they live, and either bury themselves in the ground, or conceal themselves on the surface under a slight covering of leaves fastened together with silken threads. Some make more regular cocoons, which, however, are very thin, and generally more or less covered on the outside with leaves. A very few of the span-worms fasten themselves to the stems of plants, and are changed to chrysalids, which hang suspended, without the protection of any outer covering.

In their perfected state these insects are mostly slender-bodied moths, with tapering antennae, which are often feathered in the males. Some of the females are without wings, and are distinguished also by the oval and robust form of their bodies. These moths are most active in the night; but some of them may be seen flying in thickets during the daytime. They are very short-lived, and die soon after their eggs are laid.

It was formerly supposed that the cankerworm moths came out of the ground only in the spring. It is now known that many of them rise in the autumn, and in the early part of the winter. In mild and open winters I have seen them, says Dr. Harris, in every month from October to March. They begin to make their appearance after the first hard frosts in the autumn, usually towards the end of October, and they continue to come forth, in greater or smaller numbers, according to the mildness or severity of the weather after the frosts have
SPAN-WORMS. Their general time of rising is in the spring, beginning about the middle of March, but sometimes before, and sometimes after this time; and they continue to come forth for the space of about 3 weeks. It has been observed that there are more females than males among those that appear in the autumn and winter; and that the males are most abundant in the spring. The sluggish females instinctively make their way towards the nearest trees, and creep slowly up their trunks. In a few days afterwards they are followed by the winged and active males, which flutter about and accompany them in their ascent, during which the insects pair. Soon after this, the females lay their eggs upon the branches of the trees, placing them on their ends, close together, in rows, forming clusters of from 60 to 100 eggs or more, which is the number usually laid by each female. The eggs are glued to each other, and to the bark, by a grayish varnish, which is impervious to water; and the clusters are thus securely fastened in the forks of the small branches, or close to the young twigs and buds. Immediately after the insects have thus provided for a succession of their kind, they begin to languish, and soon die. The eggs are usually hatched between the first and the middle of May, or about the time that the red currant is in blossom, and the young leaves of the apple tree begin to start from the bud and grow. The little canker-worms, upon making their escape from the eggs, gather upon the tender shoots, and on the occurrence of cold and wet weather, creep for shelter into the bosom of the bud, or into the flowers, when the latter appear. Where these insects prevail, they are most abundant on apple and elm trees; but cherry, plum, and lime trees, and some other cultivated and native trees, as well as many shrubs, often suffer severely from their voracity. The leaves first attacked will be found pierced with small holes; these become larger and more irregular when the canker-worms increase in size; and, at last, the latter eat nearly all the pulpy parts of the leaves, leaving little more than the midrib, and on the occurrence of cold and wet weather, a very great difference of colour is observable among canker-worms of different ages, and even among those of the same age and size. It is possible that some of these variations may arise from a difference of species; but it is also true that the same species varies much in colour. When very young, they have 2 minute warts on the top of the last ring; and they are then generally a blackish or dusky brown colour, with a yellowish stripe on each side of the body; there are 2 whitish bands across the head; and the belly is also whitish. When fully grown, these individuals become ash-coloured on the back, and black on the sides, below which the pale yellowish line remains. When fully grown and well fed, they measure nearly or quite 1 inch in length. They leave off eating when about 4 weeks old, and begin to quit the trees; some creep down by the trunk, but great numbers let themselves down by their threads from the branches, their instincts prompting them to get to the ground by the most direct and easiest course. When thus descending, and suspended in great numbers under the limbs of trees overhanging the road, they are often swept off by passing carriages, and are thus conveyed to other places. After reaching the ground, they immediately burrow in the earth, to the depth of from 2 to 6 inches, unless prevented by weakness or the nature of the soil. In the latter case, they die, or undergo transformation on the surface. In the former, they make little cavities or cells in the ground, by turning round repeatedly and fastening the loose grains of earth about them with a few silken threads. Within 24 hours afterwards, they are changed to chrysalids in their cells. The chrysalis is of a light brown colour, and varies in size according to the sex of the insect contained in it; that of the female being the largest, and being destitute of a covering for wings, which is found in the chrysalids of the males. The occurrence of mild weather after a severe frost stimulates some of these insects to burst their chrysalis skins and come forth in the perfect state; and this last transformation, as before stated, may take place in the autumn, or in the course of the winter, as well as in the spring; it is also retarded, in some individuals, for a year or more beyond the usual time. They come out of the ground mostly in the night, when they may be seen struggling through the grass as far as the limbs extend from the body of the trees under which they had been buried. As the females are destitute of wings, they are not able to wander far from the trees upon which they had been hatched; in this caterpillar state, they become therefore naturally confined to a very limited space, from which they spread year after year. Accident, however, will often carry them far from their native haunts, and in this way, probably, they have extended to places remote from each other. Where they have become established, and have been neglected, their ravages are often very great. In the early part of the season the canker-worms do not attract much attention; but in New England it is in June, when they become extremely voracious, that the mischief they have done is remedied, the beautiful foliage and the melancholy sight of the foliage of our fruit trees and of our noble elms reduced to withered and lifeless shreds, and whole orchards looking as if they had been suddenly scorched with fire. In order to protect our trees from the ravages of canker-worms, where these looping spoilers abound, it should be our aim, if possible, to prevent the wingless females from ascending the trees to deposit their eggs. This can be done by the application of tar around the body of the tree, or either directly on the bark, as has been the most common practice, or, what is better, over a broad belt of clay-mortar, or on strips of old canvass or of strong paper, from 6 to 12 inches wide, fastened around the trunk with strings. The tar must be applied as early as the 1st of November, and perhaps in October, and it should be renewed daily as long as the insects continue rising; after which the bands may be removed, and the tar should be entirely scraped from the bark. When all this has been properly and seasonably done, it has proved effectual. The time, labour, and expense attending the use of tar, and the injury
SPAN-WORMS.

that it does to the trees when allowed to run and remain on the bark, has caused many persons to neglect this method, and some to try various modifications of it, and other expedients. Among the modifications may be mentioned a horizontal and close-fitting collar of boards, fastened around the trunk, and smeared beneath with tar; or four boards, nailed together, like a box without top or bottom, around the base of the tree, to receive the tar on the outside. These can be used to protect a few choice trees in a garden, or around a house or a public square, but will be found too expensive to be applied to any great extent. Collars of tin-plate, fastened around the trees, and sloping downwards like an inverted tunnel, have been proposed, upon the supposition that the moths would not be able to creep in an inverted position, beneath the smooth and sloping surface. This method will also prove too expensive for general adoption, even should it be found to answer the purpose. A belt of cotton-wool, which it has been thought would entangle the feet of the insects, and thus keep them from ascending the trees, has not proved an effectual bar to them. Little square or circular troughs of tin or of lead, filled with cheap fish-oil, placed about the trunks, and more above the surface of the ground, with a stuffing of cloth, hay, or sea-weed between them and the trunk, have long been used by various persons in Massachusetts with good success; and the only objections to them are the cost of the troughs, the difficulty of fixing and keeping them in their places, and the injury suffered by the trees when the oil is washed or blown out and falls upon the bark. Mr. Jonathan Dennis, Jr., of Portsmouth, Rhode Island, has obtained a patent for a circular leaden trough to contain oil, offering some advantages over those that have heretofore been used, although it does not entirely prevent the escape of the oil, and the nails, with which it is secured, are found to be injurious to the trees. These troughs ought not to be nailed to the trees, but should be supported by a few wooden wedges driven between them and the trunks. A stuffing of cloth, cotton, or tow, should never be used; sea-weed and fine hay, which will not absorb the oil, are much better. Before the troughs are fastened and filled, the body of the tree should be well coated with clay-paint or white-wash, to absorb the oil that may fall upon it. They should be taken to renew the oil as often as it escapes or becomes filled with the insects. These troughs will be found more economical and less troublesome than the application of tar, and may safely be recommended and employed, if proper attention is given to the precautions above named. Some persons fasten similar troughs, to contain oil, around the outer sides of an open box enclosing the base of the tree, and a projecting ledge is nailed on the edge of the box to shed the rain; by this contrivance, all danger of hurting the tree with the oil is entirely avoided. In the Manchester Guardian, an English newspaper, of the 4th of November, 1840, is the following article on the use of melted Indian rubber to prevent insects from climbing up trees. "At a late meeting of the Entomological Society of London, Mr. J. H. Fennell communicated the following successful mode of preventing insects ascending the trunks of fruit trees. Let a piece of Indian rubber be burnt over a gallipot, into which it will gradually drop in the condition of a viscous juice, which state, it appears, it will always retain; for Mr. Fennell has, at the present time, some which has been melted for upwards of a year, and has been exposed to all weathers without undergoing the slightest change. Having melted the Indian rubber, let a piece of cord or worsted be smeared with it, and then fastened around the trunk. The melted substance is so very sticky, that the insects will be prevented, and generally captured, in their attempts to pass over it. About 3 pennworths of Indian rubber is sufficient for the protection of 20 ordinary sized fruit trees." Applied in this way it would not be sufficient to keep the canker-worm moths from getting up the trees; for the first comers would soon bridge over the cord with their bodies, and thus afford a passage to their followers. To insure success, it should be melted in larger quantities, and daubed with a brush upon strips of cloth or paper, fastened round the trunk of the trees. Worn-out Indian rubber shoes, which are worth little or nothing for any other purpose, can be put to this use. This plan has been tried by a few persons in the vicinity of Boston, some of whom speak favourably of it. It has been suggested that the melted rubber might be applied immediately to the bark without injuring the trees. A little conical mound of sand surrounding the base of the tree is found to be impassable to the moths, so long as the sand remains dry; but they easily pass over it when the sand is wet, and they come out of the ground in wet as often as in dry weather.

Some attempts have been made to destroy the canker-worms after they were hatched from the eggs, and were dispersed over the leaves of the trees. It is said that some persons have saved their trees from these insects by freely dusting air-slacked lime over them while the leaves were wet with dew. Showering the trees with mixtures that are found useful to destroy other insects, has been tried by a few, and, although attended with a good deal of trouble and expense, it may be worth our while to apply such remedies upon small and choice trees. Mr. David Hagarston, of Watertown, Massachusetts, has used, for this purpose, a mixture of water and oil-soap (an article to be procured from the manufacturers where whale-oil is purified), in the proportion of 1 pound of the soap to 7 gallons of water; and he states that this liquor, when thrown on the trees with a garden engine, will destroy the canker-worm and many other insects, without injuring the foliage or the fruit. Jarring or shaking the limbs of the trees will disturb the canker-worms, and cause many of them to spin down, when their threads may be broken off with a pole, and if the troughs around the trees are at the same time replenished with oil, or the tar is again applied, the insects will be caught in their attempts to creep up the trunks. In the same way, also, those that are coming down...
SPAN-WORMS.

the trunks to go into the ground will be caught and killed. If greater pains were to be taken to destroy the insects in the caterpillar state, their numbers would soon greatly diminish.

Even after they have left the trees, have gone into the ground, and have changed their forms, they are not wholly beyond the reach of means for destroying them. One person told me that his swine, which he was in the habit of turning into his orchard in the autumn, rooted up and killed great numbers of the chrysalids of the canker-worms. Some persons have recommended digging or ploughing under the trees, in the autumn, with the hope of crushing some of the chrysalids by so doing, and of exposing others to perish with the cold of the following winter. If hogs are then allowed to go among the trees, and a few grains of corn are scattered on the loosened soil, these animals will eat many of the chrysalids as well as the corn, and will crush others with their feet. Mr. S. P. Fowler thinks it better to dig around the trees in July, while the shells of the insects are soft and tender. He and Mr. John Kenrick, of Newton, Mass., advise us to remove the soil to the distance of 4 or 5 feet from the trunk of the trees, and to the depth of 6 inches, to cart it away and replace it with an equal quantity of compost or rich earth. In this way, many of the insects will be removed also; but, unless the earth, thus carried away, is thrown into some pond-hole, and left covered with water, many of the insects contained in it will undergo their transformations and come out alive the next season. On the 19th of July 1840, and New England Farmer of June 2, 1841, for some valuable remarks by Mr. Fowler.

Canker-worms are subject to the attacks of many enemies. Great numbers of them are devoured by several kinds of birds, which live almost entirely upon them during their season. They are also eaten by a very large and splendid ground-beetle (Calosoma scrutator), that appears about the time when these insects begin to leave the trees. These beetles do not fly, but they run about in the grass after the canker-worms. When we walk through the trunks of coniferous trees to seize them as they come down. The latter are also stung by a four-winged ichneumon-fly, which deposits an egg in every canker-worm thus wounded. From the egg is hatched a little maggot, that preys on the fatty substance of the canker-worm, and weakens it so much that it is unable to go through its future transformations. I have seen one of these flies sting several canker-worms in succession, and swarms of them may be observed around the trees as long as the canker-worms remain. Their services, therefore, are doubtless very considerable. Among a large number of canker-worms, taken promiscuously from various trees, I found that nearly one-third of the whole were unable to finish their transformations, because they had been attacked by internal enemies of another kind. These were little maggots, that lived singly within the bodies of the canker-worms, till the latter died from weakness; after which the maggots underwent a change, and finally came out of the bodies of their victims in the form of small two-winged cuckoo-flies, belonging to the genus Tachina. Mr. E. C. Herrick, of New Haven, Connecticut, has made the interesting discovery that the eggs of the canker-worm moth are pierced by a tiny four-winged fly, a species of Platygaster, which goes from egg to egg, and drops in each of them one of her own eggs. Sometimes every canker-worm egg in a cluster will be found to have been thus punctured and seeded for a future harvest of the Platygaster. The young of this Platygaster is an exceedingly minute maggot, hatched within the canker-worm egg, the shell of which, though only one-thirtieth of an inch long, serves for its habitation, and the contents for its food, till it is fully grown; after which it becomes a chrysalis within the same shell, and in due time comes out a Platygaster fly, like its parent. This last transformation Mr. Herrick found to take place towards the end of June, from eggs laid in November of the year before; and he thinks that the flies continue alive through the summer; till the next year one of the canker-worms in the autumn affords them the opportunity of laying their eggs for another brood. As these little parasites prevent the hatching of the eggs wherein they are bred, and as they seem to be very abundant, they must be of great use in preventing the increase of the canker-worm. Without doubt, such wisely appointed means as these were once enough to keep within due bounds these noxious insects; but, since our forests, their natural food, and our birds, their greatest enemies, have disappeared before the woodman's axe and the sportsman's gun, we are left to our own ingenuity, perseverance, and united efforts, to contrive and carry into effect other means for checking their ravages.

Apple, elm, and lime trees are sometimes injured a good deal by another kind of spanworm, larger than the canker-worm, and very different from it in appearance.

Probably more than one hundred different kinds of geometrids may be found in Massachusetts alone. Seventy-eight are already known to me. Some of these are small, and are not otherwise remarkable; some are distinguishable for their grace and beauty in the forms and habits of their caterpillars. None of them, however, have become so notorious on account of their devastations as the species already described. (Harris's Treatise.) See LIME TREE. INSECT ENEMIES. SPATTLING POPPY. A name sometimes applied to chickweed. SPAVIN. In farriery, a disease in horses, consisting of a swelling in or near some of the joints, by which a lameness is produced, and of which there are three kinds; the blood-spavin, the bone-spavin, and the bow-spavin. SPAVING. The operation of castrating or extracting the ovaries of the females of different kinds of animals, as sows, heifers, mares, &c., in order to prevent any future conception, and promote their fattening. SPEAR GRASS. The American name for the great smooth-stalked meadow-grass. See Poa pratensis. SPEARMINT (Mentha viridis). This species of mint is employed in sauces and salads, as
well as dried for soups in winter. There are two varieties, the broad and narrow-leaved, equally good. See Mint.

**SPEEDWELL** (*Veronica*). An extensive genus of herbaceous or somewhat shrubby plants, with annual or perennial roots.

Common or male speedwell (*Officialia veronica*), called by the French Thé d'Europe, is a common plant in the Middle States, found on dry banks, woodlands, and commons, flowering in June and July, and ripening its seed in August and September. Water speedwell, or long-leaved brooklime, is also occasionally found along the muddy margins of rivulets, and also the scull-cap speedwell, or shield-like *Veronica*, with some other species. (Dr. Darlington's *Flora Cestrica,*). See Bird's Eye.

**SPHAGNUM.** A name used by Pliny for some kinds of moss. The species belonging to this genus are found in bogs at all seasons. The leaves are nerveless, and of a singularly whitish viscid colour.

**SPICEROW** (*Laurens Benzoa*). An American shrub or small tree, called also in the United States by the common names of wild allspice, fever bush, and Benjamin tree. The stems grow to the height of 8 or 10 feet, and are branched, the wood being very brittle, and when broken giving out a very pleasant aromatic odour. It is found in moist low grounds. An infusion of the branches is often used medicinally, more especially in the spring of the year, as a drink for horned cattle. See Laurex.

**SPIGNEL.** See Fenvel.

**SPIEKERBERY.** A native of New Zealand, also called the **BUCKLEMAN** or Conyza, from *Conus*, dust; because it was supposed to have the power of driving away flies; whence also one of the common names, flea (fly) bane. The genus *Eugenia* is, however, the real fly-bane; some of its viscid species, dipped in milk, being used in the south of Europe to catch the various little winged insects so troublesome in warm climates. This is a numerous herbaceous or shrubby genus, of which the only British species (*C. squarrosa*) is the type. This is a perennial plant, growing in chalky or lime-stone countries, frequent in woods, or a marly soil. The root is tapering, fleshy, much branched; the herbage soft and downy, bitter, somewhat aromatic, with a portion of mucilage. The stem is upright, angular, leafy, 2 or 3 feet high, terminating in a corymbose, leafy panicle of numerous dull yellow flowers. The radical leaves bear some resemblance to those of foxglove, but when rubbed are readily distinguished by their aromatic scent.

**SPIKE ROLLER.** See Roller.

**SPINACH** (*Spinacea Oleracea.* From *spinus*, on account of its prickly seed). There are two varieties, the round-leaved or smooth-seeded, and the triangular-leaved or prickly-seeded. The first being the most succulent, and consequently less able to endure a low degree of temperature, is employed for the spring and summer crops, and the latter for autumn and winter. For the round-leaved variety, a rich, moist, and mouldy loam, in an open situation, is preferable; but for the triangular-leaved a light, moderately fertile, and dry one, which may likewise be an open compartment, but a sheltered border is most conducive of a continued supply throughout the winter. The earth should always be well pulverized at the time of digging, as a fine tilth is one of the greatest inducements to its vigour. It is propagated by seed. The first sowing of the round-leaved variety may take place at the close of January, in a warm situation, to be repeated in larger but still small breadths at the commencement and end of February; and thence to be continued, as the plants rapidly advance to seed, every 3 weeks until the middle of April, when, as this affection increases, it must be performed once a week until the close of May, when it may be reduced to once a fortnight, and so practised until the end of July. With August, the sowing of the triangular-leaved variety commences, the main crop of which should be sown during the first 10 days of that month. The sowing may be repeated, after intervals of 3 weeks, until the early part of September.

The sowings may be performed broadcast and regularly raked, which is the mode generally practised in the principal markets; but for the winter-standing always, or in drills an inch deep and a foot apart; in either mode the seed being scattered thin.

Tetragonia, or New Zealand spinach (*Tetragonia expansa*), is much admired as a substitute for summer spinach, being of more delicate flavour, and not so liable to run to seed. It is propagated by seed, which is sown, in the seed-vessel, as gathered the preceding autumn, at the latter end of March, in a pot, and placed in a melon-frame. The seedlings must be pricked out one small singly into pots, and kept under a frame without bottom-heat until the third week in May, or until the danger of frost is past.

**SPINAGE, WILD.** See Goosefoot.

**SPINDL TREE** (*Euonymus Europaeus*). This shrub or small tree grows wild in English hedges and thickets. The very hard and fine-grained wood is preferred for spindles and for skewers. It is fesdy in every part when bruised, and esteemed poisonous. The branches are smooth and even angular when young; afterwards round, with a green, smooth, not very bark. Leaves ovate, pointed, finely serrated, about 2 inches long, furnished with awl-shaped stipules. Flowers fesdy, small, greenish-white, mostly four-cleft. The capsules usually of a fine rose colour: seeds orange-coloured.

**SPINDLE-WORM.** These American insects are fatal to the plants attacked, the greater part of which, however, are without value to the farmer. Indian corn must be excepted; for it often suffers severely from the depredations of one of these Nonagrians, known to our farmers by the name of the spindle-worm. This insect receives its common name from its destroying the spindle of the Indian corn; but its ravages generally begin while the corn-stalk is young, and before the spindle rises much above the tuft of leaves in which it is embosomed. The mischief is discovered by the withering of the leaves, and, when these are taken hold of, they may often be drawn out with the included spindle. On examining the corn, a small hole may be seen in the side of the leafy stalk, near the ground, penetrating into the soft centre of the stalk, which, when cut open, will be found to
be perforated, both upwards and downwards, by a slender, worm-like caterpillar, whose excrementitious castings surround the orifice of the defile. This most mischievous caterpillar grows to the length of an inch or more, and to the thickness of a goose-quill. It is smooth, and apparently naked, yellowish, with the head, the top of the first and of the last rings black, and with a band across each of the other rings, consisting of small, smooth, slightly elevated, shining, black dots, arranged in a double row. With a magnifying glass, a few short hairs can be seen on its body, arising singly from the black dots. This mischievous caterpillar, says Dr. Harris, is not confined to Indian corn; it attacks also the stems of the dahlias, as I am informed both by Mr. Leonard and by the Rev. J. L. Russell, both of whom have observed its ravages in the stems of this favourite flower. The chrysalis, which is lodged in the burrow formed by the spindle-worm, is slender. It is shining mahogany-brown, with the anterior edges of four of the rings of the back roughened with little points, and four short spines or hooks, turned upwards, on the hinder extremity of the body. The moth produced from this insect differs from the other Nonagrians somewhat in form, its fore-wings being shorter, and more rounded at the tip. It may be called Gortyna Zea, the corn Gortyna; Zet being the botanical name of Indian corn. The fore-wings are rust-red; they are mottled with gray, almost in bands, uniting with the ordinary spots, which are also gray and indistinct; there is an irregular tawny spot near the tip, and on the veins there are a few black dots. The hind-wings are yellowish-gray, with a central dusky spot, behind which are two faint, dusky bands. The head and thorax are rust-red, with an elevated tawny tuft on each. The abdomen is pale-brown, with a row of tawny tufts on the back. The wings expand nearly one inch and a half.

In order to check the ravages of these insects, they must be destroyed while in the case. As soon as our corn-fields begin to show, by the withering of the leaves, the usual signs that the enemy is at work in the stalks, the spindle-worms should be sought for and killed; for, if allowed to remain undis turbed until they turn to moths, they will make their escape, and we shall not be able to prevent them from laying their eggs for another brood of these pestilent insects. (Harris's Treatise.)

SPINES. In botany, branches that, being imperfectly formed, lose their power of extension, become unusually hard, and acquire a sharp edge different from aculei, or prickles, which are a kind of hardened hair. In leaves they are processes formed either by an elongation of the woody tissue of the veins or by a contraction of the parenchyma: in the former case they project beyond the surface or margin of the leaf, as in the holly; in the latter case they are the veins themselves indurated, as in the paled spines of Berberis vulgaris.

SPILINT. In farriery, a hard excrescence growing on the Shank-bones of horses. It appears first in the form of a callous tumour, and afterwards ossifies. If the splint interfece with the action of some tendons or ligament, the hair should be removed, a little strong mercurial ointment be rubbed in for two days, and then an astringent blister applied. (Youatt on the Horse, 244.)

SPRING WHEAT. See Wheat.

SPUD. An implement used advantageously in cutting up weeds. It consists of a chisel-formed tool, about 2 inches wide on the cutting edge, inserted into a handle of some 4 or 6 feet in length; it is often made use of by the farmer as a useful substitute for the walking-cane, affording an opportunity of destroying weeds with the utmost facility whilst walking over his ground. Every farmer ought to own a spud.

SPURGE (Euphorbia; Linnaeus named this genus after Euphorbus, a physician to Juba, King of Mauritania). This is an exceedingly variable and a very extensive genus of plants, comprising a number that are entirely un worthy of cultivation. The hardy perennial species thrive in any common garden soil, and increase by divisions of the roots or by seeds. The hardy annuals and biennials merely require sowing in the open ground. The tender kinds must be sown in the hot-house or in a hot-bed frame, and, when potted off, must be set with other tender annuals and biennials. The root of E. ipecacuanha is said to be equal to that of the true ipecacuanha. E. antiquorum, E. canariensis, and some other fleshly species, produce the drug "euphorbium," which is the inspersated milky juice of such plants. There are in England 13 indigenous species, but the only one necessary to be noticed is the lesser spurge (E. lathyris). It is a biennial, flowering in June and July. The stem rises from a strong, fibrous root to the height of 3 to 4 feet, purplish, smooth, round, hollow. The leaves opposite, sessile, in four to six rows; oblong, acute, entire, and glaucous. The flow ers are in a terminal, solitary umbel, consisting of 4 repeatedly forked branches, furnished with cor date, entire bractes: the flowers are variegated with yellow and dark purple. Capsules are large and smooth, and, when half-ripe, are pickled as capers. The seeds, when pressed between moderately heated iron plates, yield a fixed, acrid oil, which might be advantageously substituted for castor oil. See MOLT TREE.

SPURGE-LAUREL (Daphne laureola). A British evergreen shrub, growing in woods, thickets, and hedges, flowering in March. The stems is 2 or 3 feet high, with round, pale smooth, brown, upright, tough, and plant. branches, crowned with tufts of evergreen leaves, elegantly drooping in all directions, and about 2 or 3 inches long, on short foot stalks. The flowers are deep-green, in axillary clusters, with orange anthers. Their scent, re sembling saffron, with an overpowering sweet ness, is perceptible in an evening only. The berries, which are oval and black, are poisonous to all animals except birds. Every part of the plant is very acrid, producing, like the mezereon, a burning heat in the mouth and throat. The bark of its root is commonly used
SPURGE, OLIVE.

instead of mezerone. It is powerfully excitant and diaphoretic. The bark of the stem, soaked in vinegar and beaten out flat, forms an excellent agent for keeping blisters open.

SPURGE, OLIVE. See MEZERONE.

SPURREY (Spergula, from sparge, to scatter, because it expels its seeds.) A genus of herbaceous, annual, or perennial plants, with slender linear leaves and white flowers. There are in England four species, the most common of which is the rough-seeded corn spurrey (S. arvensis), an annual plant, which grows in sandy corn-fields, and flowers from June to August. (See Pl. 9, b.) The stems are spreading, lax, 6 inches to 2 feet long, moderately branched, jointed, leafy, angular, and hairy and viscid in the upper part. Leaves whorled, linear, narrow, fleshy, downy, obtuse, with short stipules. The flowers are white, on slender, downy flower-stalks. The rough-seeded spurrey is a common weed in sandy soils, and is in Scotland called yarr, and in N. England furnished with an annual by all cattle, and appears to be conducive to their health, while it remarkably tends to increase the milk of cows, and to fatten sheep.

Hence a large, smooth-seeded variety of this weed (S. sativa) is industriously cultivated in Flanders, because it is so far superior to other pasture grasses that it continues green till a late period of autumn, and often throughout the winter. Its seeds afford on expression a good lump oil; the flour obtained from them, when mixed with that of wheat or rye, produces wholesome bread, for which purpose it is often used in Norway and Gothland. Poultry eat spurrey greedily, and it is supposed to make them lay a great number of eggs. Whether given as hay, or cut green, or in pasture, Von Thaer observes that it is the most nourishing, in proportion to its bulk, of all forage, and gives the best flavoured milk and butter. It has been recommended to be cultivated in England, but it is not likely that such a plant can ever pay the expense of seed and labour in that country, even on the poorest soil; or, at all events, as Professor Martyn observes, we have many better plants for such soils.

SQUASH (Cucurbita). Of this plant there are many varieties, distinguished by peculiarities of shapes, colours, &c. The young fruit is a rich and excellent vegetable for boiling, stewing, or baking. The common round kind (Cucurbita maxima) is also called Cynobug (and by the French Bonnet de Prêtre). The warty or long squash (C. verrucosa), is said by Mr. Nuttall to be cultivated by the Indians of the Missouri to its source. Mr. Kenrick, of Boston, notices the following varieties:

The early orange is a new summer variety, very early, and of superior quality. The Canada crook neck is, without doubt, far superior to any and all others, for the late or main crop. It is fine-grained, mealy, and of a sweet, excellent flavour. By being kept in a dry and suitable temperature, they may be preserved till the following summer. Sow in April or May, as soon as the frosts are over, and the earth becomes warm; the early or summer varieties in hills 6 feet asunder; the winter varieties in hills 8 feet asunder, and 4 plants may remain in a hill.

Autumnal narrow squash (Cucurbita succedanea), introduced to notice by John M. Ives, Esq., of Salem. A fine, new variety, of an ovate form, pointed; the skin very thin, of a cream-colour; the flesh orange; the granule delicate, flavour excellent; seeds large, pure white. Average weight, 8 pounds. It keeps well in winter.

The scarlet summer squash is a new and beautiful flat variety, from France, of the acorn species, of a fine scarlet colour.

The Valparaíso squash, the seeds of which were brought from the Pacific by the late Commodore Porter, is a splendid vegetable, without any neck, in shape and size somewhat resembling a long watermelon, flattened, and of a rich crimson or orange colour. Mr. Comfort, of Bucks County, near Philadelphia, has raised some weighing 100 lbs., which have been greatly admired at agricultural and horticultural exhibitions. This vegetable possesses all the good qualities of the common kinds of pumpkin and squash, of which it would seem to be a hybrid variety, very superior to either. Being neither watery or stringy, it makes a delicious pie, far more rich and delicate than that of the ordinary pumpkin. It is also served up at table with meat, like the common squash, either boiled, or baked like a loaf of bread or sweet potato: containing a large amount of saccharine and other nutritious properties, they are also excellent food for farm-stock, especially milch cows. They are cultivated like other vegetables of the same family, but much care must be observed to keep them at a considerable distance from other varieties, with which they have a strong tendency to mix, thus leading to depreciation. They keep well in winter.

SQUASH-BUG. The common American squash-bug (Corces tristis), so well known for the injurious effects of its punctures on the leaves of squashes, is one of the most remarkable insects belonging to the natural division, which includes bed-bugs, fruit-bugs, and various other fetid bugs (Hemiptera). It was first described by De Geer, who gave it the specific name of tristis, from its sober colour, which Gmelin unwarrantably changed to mostius, having, however, the same meaning. Fabricius called it Corces rugator, the latter word signifying one who wrinkles, which was probably applied to this insect, because its punctures cause the leaves of the squash to become wrinkled. Mr. Say, not being aware that the insect had already been three times named and described, redescribed it under the name of Corces ordinatus. Of these four names, however, that of tristis is the first, it is the only one which it can retain. About the last of October squash-bugs desert the plants upon which they have lived during the summer, and conceal themselves in crevices of walls and fences, and other places of security, where they pass the winter in a torpid state. On the return of warm weather, they issue from

127

1009
winter-quarters, and when the vines of the squash have put forth a few rough leaves, the bugs meet beneath their shelter, pair, and immediately afterwards begin to lay their eggs. This usually happens about the last of June or beginning of July, at which time, by carefully examining the vines, we shall find the insects on the ground or on the stems of the vines, close to the ground, from which they are hardly to be distinguished on account of their dusky colour. This is the place where they generally remain during the daytime, apparently to escape observation; but at night they leave the ground, get beneath the leaves, and lay their eggs in little patches, fastened to them with a gum, which, in consequence, is visible on the under-sides of the leaves. The eggs are round, and flattened on two sides, and are soon hatched. The young bugs are proportionally shorter and more rounded than the perfect insects, are of a pale ash-colour, and have quite large antennae, the joints of which are somewhat flattened. As they grow older and increase in size, after molting their skins a few times, they become more oval in form, and the under-side of their bodies gradually acquires a dull ochre-yellow colour. They live together at first in little swarms or families beneath the leaves upon which they were hatched, and in the train of their increase of size, are always found on the under-sides of the leaves, and the quantity of sap imbiber by them, soon wither, and eventually become brown, dry, and wrinkled; when the insects leave them for fresh leaves, which they exhaust in the same way. As the eggs are not all laid at one time, so the bugs are hatched in successive broods, and consequently will be found in various stages of growth through the summer. They, however, attain their full size, pass through their last transformation, and appear in their perfect state, or furnished with wing-covers and wings, during the months of September and October. In this last state the squash-bug measures about half of an inch in length. It is of a rusty black colour above, and of a dirty ochre-yellow colour beneath, and the sharp lateral edges of the abdomen, which project beyond the closed wing-covers, are spotted with ochre-yellow. When handled, and still more when crushed, the latter give out an odour precisely similar to that of an over-ripe pear, but far too powerful to be agreeable.

In order to prevent the ravages of these insects, they should be sought and killed when they are about to lay their eggs; and if any escape our observation at this time, their eggs may be easily found. A careful view of this time convinces us that the squash-vines must be visited daily, during the early part of their growth, and must be carefully examined for the bugs and their eggs. A very short time spent in this way every day, in the proper season, will save a great deal of vexation and disappointment afterwards. If this precaution be neglected or deferred till the vines have begun to spread, it will be exceedingly difficult to exterminate the insects, on account of their numbers; and if at this time dry weather should prevail, the vines will suffer so much from the bugs and dried together, as to produce but little if any fruit. Whatever contributes to bring forward

the plants rapidly, and to promote the vigour and luxuriance of their foliage, renders them less liable to suffer by the exhausting punctures of the young bugs. Water drained from a cow-yard, and similar preparations, have, with this intent, been applied with benefit.

The leaves of the squash are also preyed upon by another insect of a very different description, namely, the Cocinella borealis (See Pl. 16, fig. 11). Although the genus of insects to which this belongs destroys Aphides, there are, as Professor Halderman, of Pennsylvania, observes, a few exceptions, among which is the species named, which may be found, both in the leaves and the fruit of the squash in a perfect state, eating the leaves of the squash.

SQUASH-BUG. (American orobanche.)

SQUIZ-ROOT (Scilla, from skyllta, to injure, the bulbs being poisonous). An extensive genus of interesting bulbous plants. A light soil is most suitable for them; and they are readily increased by offsets from the bulbs. The leaves are radical, linear. The flowers in clusters, blue, purple, or white. There are four indigenous species, the vernal squill (S. verna), the two-leaved squill (S. bifolia), the autumnal squill (S. autumnalis), and the harebell squill, or wild hyacinth (S. pratensis). The bulb of the first is cuneiform and hard, and the bulb of the second conical and large, which can be readily separated from an acrid principle which is conjoined with it. It is much employed by calico-printers.

SQUITCH-GRASS. See Bent and Couch.

ST. JOHN'S WORT. See John's Wort.

STACK. Corn in the sheaf, piled up in a circular or rectangular figure, brought to a point or ridge at the top, and afterwards thatched to protect it from the influence of the weather, and more especially from rains. The term is also sometimes applied to hay piled up in the same manner, which, however, in most places is called a rick. The foundation of a corn stack is commonly made of a platform of wood or iron, raised on props to protect it from the moisture of the soil, and also from rats and mice; in which respect stacks of corn differ from ricks of hay, which are built always on the ground. It is of great advantage to soak the props in corrosive sublimate, which not only preserves the wood, but also destroys vermin. Stacks are of various forms and dimensions, according to circumstances; but for grain those of a long, narrow, square shape are probably the most advantageous, where the quantity of corn is considerable; as they are found to stand more firmly, have a better appearance, are more readily built, and preserve the grain better than those of any other form. And they have the great advantage of requiring less thatch as well as labour in putting it upon them than the round stack. But where the corn is only in a small proportion, the round or oblong shape may be more proper and suitable, as being more readily drawn up in the roof; but the circular, with a conical top and cylindrical body diverging a little at the eaves, is esteemed the best form by some. For hay, the form of the rick or stack is a matter of still less consequence; the long square or oblong shapes are perhaps the most safe and convenient, especially when not too
bread, as they admit the air most fully, and are besides the most convenient to cut from in trussing hay for sale at the market.

STAG. A term applied provincially in England to a young horse. Also to the male of the deer kind. See Deer.

STAGGER-BUSH (Andromeda Mariana). This American plant grows in the Middle States, with a stem 2 to 3 and 4 feet high. It is very abundant in New Jersey, where the farmers are of opinion that it is destructive to sheep, when eaten by them, producing a disease called the staggerers.

STAGGERS. See APoplexy.

STALL-FEEDING. The process of fattening cattle in the stall. The best practice in this mode of fattening is probably that of wholly confining them to the stalls, as by this means they are kept quiet, and free from interruption, and of course feed more quickly and with greater regularity, which seem to be points of great importance in this system of management. There are, however, many other methods adopted in different situations and circumstances.

In regard to the sorts of food that may be employed in the way of winter-fattening animals, they are very numerous, but the principal succulent kinds are carrots, parsnips, potatoes, Swedish turnips, cabbages, common turnips, grains, &c.; and of the more dry sorts, oil-cake, oats, barley-meal, rye-flour, bean and pea-meal, and others of the same nature, with different kinds of straw cut into chaff by means of machinery, or hay cut in the same manner. It is generally found best to employ the different kinds of grain or meal in a state of mixture in nearly equal proportions, except bean-meal, which, from its heating quality, is mostly made use of in smaller quantities. But on the principle of fresh kinds of food having a more powerful effect on the systems of animals when first applied, it may be more beneficial to have them given in alternation, or at distant intervals, as their effects may in this way be more fully experienced.

In respect to the cut straw and hay that is made use of in this way, we first should be prepared from that which is fresh threshed out. The hay, instead of straw, is the best, as the field affords, and such as is not in the least injured in the smell or taste by keeping. The more inferior kinds of hay have, however, by the addition of a very small proportion of common salt, been made to be preferred to the best when not prepared in that way. See Cattle, Fodding, Food, Sodding, &c.

STANDARDS. The young trees reserved at the felling of woods, for the growth of timber. It also signifies such fruit trees as are intended to grow in an open exposure, and not to be hacked and mangled with the knife, as the dwarf trees and those planted against walls are.

STARR, or BENT. See Arundo and Eleus.

STARCH (Germ. stärke). One of the common proximate principles of vegetables. It is characterized by its insipidity, and by insolubility in cold water, in alcohol, and in ether. The term "starch" is commercially applied to that obtained from wheat, which for this manufacture is ground and diffused through vats of water, where it remains two or more weeks, and undergoes a slight fermentation, and acquires a peculiar sour smell. The sour liquor is drawn off, and the precipitate washed in sieves, through which the impure starch passes with the water. It is afterwards passed through other waters, drained through boxes lined with linen or canvas, and ultimately stove-dried in paper. When drying, it cracks into the prismatic pieces, resembling miniature basalt, which is its usual form. Starch may be obtained from many other grains, and from potatoes and several esculent vegetables. Arrowroot is the starch of the Maranta arundinacea; British arrowroot that of the root of Arum maculatum; sago, of the Sagus farinifera, an East Indian palm tree; and tapioca and cassava, of the Jatropha manihot. In the process of germination, and by various chemical agents, starch may be converted into a species of gum and sugar. Pure starch is white, tasteless, and inodorous. It consists of two distinct substances, that are readily recognised under a good magnifying lens, namely, a membrane called amygin, and a gummy semisolid matter named amido; the one the husk, the other the contents of the granules. In cold water, unless triturated in a mortar, the grains do not burst, but remain entire and insoluble; but in boiling water they burst and form a mucilage. Starch is a compound of 42 parts of carbon, 635 of hydrogen, and 50.8 of oxygen in 100 parts. Starch is much less nutritious than wheat flour, or the common starch-grains, which contains gluten; and on this account the starch of arrowroot, sago, &c., is used as a diet for the sick. Starch is detected from other mucilages by forming a blue colour with iodine, when the mucilage is cold. Starch in England is charged with a duty of 34d. per lb., and its manufacture is consequently placed under the control of the excise.

STAR OF BETHLEHEM. See Bethlehem, Star of.

STAR-THISTLE. A name applied to some species of Centaurea, viz. Jersey star-thistle (C. insidere), the common star-thistle, or the Scotch thistle, and the yellow star-thistle, or St. Barnaby's thistle (C. solstitialis). The first is a perennial weed, the others are annuals. See Blue-Bottle, Knapweed, &c.

STARWORT (Aster, a star; whence also the common name, the flowers resembling little stars from the rays of their circumference). Many species of this extensive genus are stately and handsome plants. The swellings or galls as large as a walnut, so often found on the stems of some American species of starwort, or aster, are caused by the punctures of a fly.

STARWORT, THE WATER (Callitrichi; named by Pliny from kalos, beautiful, and thrix, hair). Annual aquatic plants, which grow in ditches, ponds, and lakes.

STEAM. Water converted into an elastic fluid by the application of heat. It would be foreign to our subject to go into any detail of the various mechanical uses and improvements to which steam has been applied with 1011
so much success. Latterly, however, a spirit of inquiry has led to an investigation into the application of steam to purposes of husbandry, such as engines for ploughing, draining, &c.; and, though there are obstacles in the way of their successful operation, there is little doubt that eventually the spirit of research and improvement will overcome these difficulties, and create a singular revolution in the practical operations of agriculture, whereby a vast amount of animal power will be saved, and an increased impetus be given to production. A series of very able papers on this subject appeared a few years ago in the Quart. Journ. of Agr. in vols. vi.—vii.

STEAMING FOOD. The advantages to be derived from boiling or preparing the food of live-stock are now very generally understood and appreciated; although it is still a question whether it always compensates for the extra labour and time consumed. We have already gone into this subject under the head Food, and merely revert to it now to call attention to some articles describing apparatuses for steaming food, which will be found in the Quart. Journ. of Agr. in vols. iv.—vi. Steaming is also popularly treated of and explained in the first volume of Brit. Husbandry. Steam has been largely used in American periodicals.

STEARINE (Gr.). That part of oils and fats which is solid at common temperatures. Both in fats and in fixed oils it is associated with a fluid principle, which cannot be rendered solid at the lowest known temperatures. Stearine is only found in animal fats; or, at least, is rarely present in those of a vegetable origin. See Fat.

STEELYARD. A well-known balance, by which the weights of bodies are determined by means of a single standard weight.

STEEN KROUT (Lithospermum arvense). See Red Weed. Steeping. See Brining of Grain and Smut.

STEPPE (Russ.). The name given to the vast extent of plains peculiar to Asia; synonymous with the prairies of North America, and the llanos of South America. The steppes of Russia are not unlike the heaths of Germany; being in part susceptible of cultivation, and affording pasturage for numerous herds belonging to nomadic tribes.

STITCHWORT (Stellaria, from stella, a star; the flowers are star-like). A genus of herbaceous plants which are mere weeds. Some are annual, the others are perennial. See Chickweed.

STIGMA. In botany, the upper extremity of the style without a style, in consequence of which it has almost uniformly a humid and papillose surface. It is the part upon which the pollen falls, and where it is stimulated into the production of the pollen tubes, which are indispensable to the act of impregnation.

STYLES. A well-known contrivance for the admission of foot-passengers, without permitting the stock of the enclosures to escape. Stiles are made in very different forms and manners in different districts, according to the materials, situations, and purposes for which they are intended.

STINGERS and PIERCERS. A class of insects embracing bees, wasps, ants, saw-flies, ichneumon-flies, &c.

STIPULAE. In botany, small scales or appendages situated on each side at the base of the petioles or leaf-stalks, most commonly of a less firm texture than the latter, and having a subulate termination.

STOCK-NUT. See Hazel.

STOLONIFEROUS. Bearing runners which root at the joints.

STOMATA. See Cuticle.

STONE. An English common weight estimated at 14 lbs.

STONECROP (Sedum). A genus of herbs, with alternate, very succulent, either flat, cylindrical, or turbid leaves. Root mostly perennial. Flowers yellow, white, or reddish, usually cymose, rarely axillary. There are, in England, ten indigenous species, which inhabit, for the most part, old walls, roofs, and dry sandy ground. See House-Leek and Orpine.

STONE-PARSLEY (Athamanta). These are chiefly weeds.

STONE PINE. See Firs.

STONE WEADE (Field Lithospermum). See Red-Root.

STOOKING. The Scotch term for setting up sheaves of corn in stocks or shocks. The operation is performed soon after the corn is cut, it being previously tied into bunches or sheaves.

STOOL. The root of a timber tree, which throws up shoots. Coppice wood consists chiefly of the shoots sent up by the roots of stools, or trees or shrubs which have been cut over by the surfage. In general, all dicotyledonous trees are endowed by nature with the property of sending up shoots from the stubs or stools; but this is not the case with most of the gymnosperms or coniferous trees. A wood of pines or firs, therefore, when once cut down, can never be renewed, except by seeds. It is a curious fact that the shoot, however large the stool may be, can be traced to the pith, and therefore appears to have been originally a shoot of the first year's growth of the plant. That its growth has been impeded is evident; but when the tree is cut down, and the whole sap is thrown into a small space, the latent, yet vital gum is stimulated, and a twig hence produced.

STORK'S-BILL (Erodium, from erdos, a heron; the carpels resemble the head and beak of that bird). This is an extensive genus of plants of considerable beauty: they thrive well in any common soil with the usual treatment.

STRAINS.
STRANGLES. In farriery, a disease which is principally incident to young horses, usually appearing between the fourth and fifth year, and oftener in the spring than at any other season. It is preceded by cough, and is a disease to which all horses are subject, but it never returns. A blister will be found the best application to hasten the formation and suppuration of the tumour under the jaw, which, from its situation, has probably given the name to this disease.

STRATH, in Scotland, is generally understood to signify a valley of considerable size, whose appellation is determined by some river running through it, or some particular characteristic.

STRATUM. When different rocks lie in succession upon each other, each individual forms a stratum. See GEOLOGY.

STRAW. The stalks or culms on which corn and other grasses grow, and from which the grain has been separated by thrashing. When chopped or cut small, it affords a wholesome provender for horses and oxen, especially if it be mixed with green food. (See CHAFF and CHAFF ENGINE.) When not allowed to be carried off the premises, the chief value of white straw for farm purposes lies in its conversion into manure; for although it may carry some cattle through the winter, it will neither fatten them nor enable any animal to work; and its intrinsic worth for the uses of litter and of occasional feeding has been estimated by experienced farmers in England at 20s. to 30s. the ton. See HAUL.

STRAWBERRY (Fragaria, from fragrans, fragrant; the perfumed fruit of the strawberry is well known). The strawberry is our earliest fruit, and as the harbinger of the fructus horae, its appearance is as welcome as its flavour agreeable. The cultivation and propagation of this plant is so familiar to every one, as are the wholesomeness and deliciousness of the fruit, that neither need be particularized here. Three species of strawberry found wild in the United States are enumerated by Mr. Nuttall: 1. F. vesca, in the state of Ohio, near Lake Erie. 2. F. Virginiana. 3. F. Canadensis, both common in the Southern, Middle, and Northern States. The species indigenous to Britain are two, the wood strawberry (F. vesca), and the haunboid strawberry (F. elatior). The covering of strawberry plants with sea-weed in the winter has been found to increase the size of the fruit to a prodigious degree. This is much practised in the island of Jersey.

STRAW-BERRY-LEAVED CINQUEFOIL. See CINQUEFOIL.

STRAW-CUTTER. See CHAFF-ENGINE.

STRAW-YARD. The yard into which straw is thrown in thrashing. Also the enclosure in which cattle are confined in winter, for the purpose of being foddered on straw. There ought to be open sheds for shelter in the straw-yard; for though pure air is essential to the health of store and working cattle, cold winds and rain are highly injurious to them. The great use of a straw-yard is for the accumulation of manure, which cannot be rich unless the cattle get some straw to feed on it.

STREET DUNG. The mixture of animal and vegetable matters, comminuted particles, &c., swept up from the streets of large towns, which is found to be an excellent fertilizer; it is composed of a mixture of horse dung, debris of the paving stones, soot, lime, and metallic particles.

STRENGTH, in mechanics, is used in the same sense as force or power. Thus, strength of animals is the muscular force or energy which animals are capable of exerting; strength of materials is the resistance which bodies oppose to a force acting upon them. It is obviously a matter of much importance to be able to estimate with tolerable accuracy the efforts which an animal of the average strength employed in labour is capable of exerting; and, accordingly, many numerous and varied applications. For the purpose of determining his muscular power, the dynamometer may be conveniently used; but, as the action of the animal is very quickly reduced by continued exertion, it is more usual to estimate it according to the amount of daily labour performed. Desaguliers and Smeaton estimate the strength of a horse as equivalent to that of 5 men; the French authors have commonly stated it as equal to 7 men; and Schulze makes it equal to that of 14 men in drawing horizontally. According to Desaguliers, a horse's power is equal to 44 lbs. raised 1 foot high in 1 minute. Smeaton makes this number 22:916, Hachez 28, and Watt 33. The last estimate is commonly understood by the term horse-power as applied to steam-engines. The quantity of action which a horse can exert diminishes as the duration of the labour is prolonged. Tredgold gives the following table, showing the average maximum velocity with which a horse unloaded can travel according to the number of hours per day:

The useful effect a horse is capable of producing, depends much upon the manner in which his strength is applied. See CARTS, DYNAMOMETER, HORSE-POWER, THRASHING MACHINE.

Strength of Materials.—There are four different ways in which the strength of a solid body may be exerted: first, in resisting a longitudinal tension, or force tending to tear it asunder; secondly, in resisting a force tending to break the body by a transverse strain; thirdly, in resisting compression, or a force tending to crush the body; and, fourthly, in resisting a
force tending to wrench it asunder by torsion. Mr. Hodgkinson gives the following results of his experiments on the resistance of a crushing force of short pillars of some of the most common descriptions of wood, the force being applied in the direction of the fibres.

(Braude’s Dict. of Science; Barlow’s Treatise on the Strength of Timber.)

STUBBLE. The root ends of the culms of corn left in the field, standing as they grew, after the corn has been reaped by the sickle or scythe. In some parts of England only a small portion of the straw is cut off with the ears of corn, and the stubble in that case is a foot or 18 inches in length; but in others the corn is cut as close to the surface as possible, in which case the stubble is quite short. In general, long stubble is a symptom of bad farming, because a quantity of straw is in this case left to waste in the field, which might have been carried home and rolled into manure.

STYLE. In botany, is that elongation of the ovary which supports the stigma. It is an extension of the midrib of the carpellary leaf, or is formed by the rolling up of the attenuated extremity of the latter.

SUBSOIL-PLough (Pl. 17, 6, 6). See Plough and Subsoil Ploughing.

SUBSOIL-PLoughing. In farming, the operation of breaking the substratum by means of a plough constructed especially for that purpose. Considerable discussion has taken place with regard to the advantages of subsoil ploughing; a difference of opinion which appears to have been principally caused by an inattention to the chemical effects produced by the subsoil, or Deanstonizing system of tillage, so named from being first employed, or at least first brought into general notice, by Mr. Smith, of Deanston, in Stirlingshire, when the system was examined, in 1836, before the Agricultural Committee of the House of Commons. By this system, by means of a subsoil plough, of which there are several kinds, the subsoil, or under crust of earth, is merely broken and pulverized, say to the depth of from 14 to 20 inches, without being brought to the surface, or mixed with the upper soil; after a lapse of 4 or 5 years, a portion of the previously disturbed substratum is found, by experience, in a state to be advantageously (by deep ploughing) brought to the surface; it being in this time, by the action of the atmosphere, and perhaps by a partial mixture with the surface-mould, rendered sufficiently friable and fertile. It is of necessity a consequence of this subsoil ploughing that all lands thus cultivated must be constructed rather deeper in the soil than is usual with farmers: the top of those at Deanston are placed at a depth of 22 inches from the surface, so as to be completely out of the way of the subsoil which the plough has turned over.

As the description of this valuable ploughing cannot be too generally circulated, I will here introduce it in Mr. Smith’s own words:

"The subsoil-plough has been constructed on principles appearing the best fitted to break up the subsoil completely to a depth sufficient for thorough cultivation, say 14 to 16 inches, whilst the active soil is still retained on the surface; to be of the easiest possible draught in reference to the depth of furrow and firmness of the subsoil; to have strength and massive weight sufficient to penetrate the hardest substratum; to resist the shocks from fast stones, and to throw out all stones under 200 lbs. in weight. All this has been accomplished and practically proved at Deanston, over an extent of at least 200 acres of various soils; and also in various parts of England, Scotland, and Ireland, during several seasons. The plough requires 4 good horses, an active ploughman, and a lad to drive the horses and manage them at the turnings. Six horses, yoked three and three abreast, may be necessary in some very stiff or stony soils. A common plough, drawn by two horses, goes before the subsoil-plough, throwing out a large open furrow of the active soil; the subsoil-plough following, slits up thoroughly and breaks the subsoil, and the next furrow of active soil is thrown over the last opened furrow of the subsoil; the stones brought to the surface by the subsoil-plough being thrown aside on the ploughed part of the land by a lad: thus the work proceeds until the whole field is gone over. The plough should not consist of wooden pins, that he may mark the site of the large fast stones which the plough cannot throw out, and which must afterwards be dug out with the pick, and perhaps blasted.

"The charge of subsoil-ploughing a Scotch acre may be estimated at 24s. or 30s. per statute acre, being one-fifth of what a similar depth with the spade would cost, and, upon the whole, as effectually done. When land which has been opened up by the subsoil-plough shall have undergone the first rotation of cropping, several inches of the subsoil may be taken up by the plough to mix with the active soil; and in proportion as the plough to work the deeper, may the greater depth be taken up with advantage. In the richer subsoils it is sometimes expedient to plough to the whole depth of the moved subsoil on the first application of the trench-plough. The trench-plough recommended for this process should be made in the form of Wilkie’s plough, having all its dimensions made of double size; or, what is found to answer fully as well, by a plough in the fashion of the old Scotch plough; but also of double dimensions. Such ploughs require six horses, yoked three and three abreast, with one man to
hold the plough, and another to manage the horses, to do the work effectually. This operation should be performed in turning over the winter furrow preparatory to a green crop, and the sooner the work is performed after harvest the better. In estimating the expense of this operation, the horses may be charged at 4s. each, to cover all expenses, tear and wear, &c., which will amount to 24s.; two men, 2s. = 4s.; and an attendant lad to pick out stones, 1s.; in all 29s. As the work is heavy; the motion of the horses is necessarily slow, and it will, in general, take 8 hours' working to accomplish one statute acre. The expense of this operation may appear astonishing, but when it is considered that one such ploughing will be more effectual in killing weeds, and in exposing the soil to the air, than two ordinary ploughings, we may deduct the cost of two such = 20s., leaving 9s. to be charged against the deep working.

When land has been thoroughly drained, deeply wrought, and well manured, the most unpromising sterile soil becomes a deep, rich loam, rivaling in fertility the best natural land of the country; and from being fitted for raising only scanty crops of common oats, will bear good crops of 30 bushels of barley, or 30 to 40 bushels of beans, 40 to 60 bushels of barley, and from 48 to 70 bushels of early oats per statute acre; besides potatoes, turnips, mangel-wurzel, and carrots as green crops, which all good agriculturists know are the abundant producers of the best manure. It is hardly possible to estimate all the advantages of dry and deep soil. Every operation in husbandry is thereby facilitated and cheapened; less seed and less manure produce a full effect; the chances of a good and early tid (a Scotch term for that state of the ploughed soil which is most suitable for receiving the seed, neither too moist nor too dry) for sowing are greatly increased, a matter of great importance in our precarious climate; and there can be no doubt that even the climate itself will be much improved by the general prevalence of land dry.

In this instance, as in most other novel agricultural efforts, the zeal of its promoters has sometimes carried them too far; they have even confidently contended that in most situations subsoiling will render draining unnecessary; a result which would hardly have been arrived at by the most sanguine subsoiler, if he had paused to recollect that deepening the soil always destroys a portion of the atmosphere, moisture, can in few situations enable land-springs and stagnant waters to escape. The objects to be attained by these operations are, in fact, diametrically opposite. The one is adopted to increase the gradual healthful supply of food and moisture by the earth to the roots of the crop, in the degree the most grateful to its habits. The other expensive practice is to remove that moisture when (from any cause) it becomes too abundant for healthful vegetation; this removal can only be obtained in very peculiar situations by the mere use of the subsoil-plough; and there to a very limited extent; such, for example, as when the crust or subsoil is of such a degree of thinness as to be completely penetrated by the plough, and thus the upper soil brought, by breaking up the separating crust, into immediate contact with a substratum of earth of greater absorbent properties than the pan-crust which has hitherto separated them.

The farmers of the chalky soils of Sussex, Dorsetshire, Wilts, and Hampshire, very advantageously raise the substratum of chalk existing under their lands, and spread it in considerable quantities on the surface. Those of Essex and Suffolk in many places do the same with the under-stratum of clay or marl on which their surface-soils immediately rest; and generally find very perceptible differences between, the earths which constitute all fertile soils being also the necessary constituents of the commonly cultivated grasses, are gradually and incessantly carried off from thence by continual cropping, and consequently in time an advantageous opportunity is afforded for their being replenished with the earths, perhaps contained in the subsoil, in which they may have become deficient.

The chemical effect of pulverizing and breaking up a subsoil is certainly advantageous to the plant in two ways, besides others with which we are very likely at present unacquainted; for instance, it renders the soil penetrable to a much greater degree by the roots, or minute fibres of the plant, and consequently renders more available any decomposing matters, or earthy ingredients, which that substratum may contain; and, secondly, it renders the soil much more freely permeable by the atmosphere, rendering, in consequence, a greatly increased supply, not only of oxygen gas to the roots of the plants, but also yielding more moisture, not only from the soil, but from the atmospheric air; which moisture, let it be remembered by the cultivator, is in all weathers as incessantly absorbing by the soil as it is universally contained in the atmosphere, abounding most in the latter, in the very periods when it is most needed by the plants—that is, in the warmest and driest weather.

It is, perhaps, needless to prove, that the roots of commonly cultivated plants will penetrate, under favourable circumstances, much greater depths into the soil, in search of moisture, than they can, from the resistance of the case-hardened subsoil, commonly attain. Thus the roots of the wheat plant in loose, deep soils, have been found to descend to a depth of 2 or 3 feet, or even more; and it is evident, that if plants could be artificially sustained in dry weather by the atmospheric, aqueous vapour absorbed by the soil, that that supply of water must be necessarily increased, by enabling the atmospheric vapour and gases, as well as the roots of plants, to attain to a greater depth; for the interior of a well-pulverized soil, be it remembered, continues steadily to absorb this essential food of vegetables, even when the surface of the earth is drying in the sun.

And by facilitating the admission of air to the soil, another advantage is obtained, that of increasing its temperature. The earths are naturally hot, and so increase downwards; thus it is well-known, that, at the siege of Gibraltar, the red-hot balls employed...
SUBSOIL-PLoughing.

by the garrison were readily carried from the furnaces to the batteries in wooden barrels, whose bottoms were merely covered with earth. Davy proved the superior rapidity with which a loose, black soil was heated compared with a chalky soil, by placing equal portions of each in the sunshine; the first was heated in an hour from 65° to 88°, while the chalk was only heated to 69°. (Elements of Agr. Chem. p. 178.)

This trial, however, must not be regarded as absolutely conclusive, since the surface of the black soils naturally increases more rapidly in temperature when exposed to the direct rays of the sun than those of a lighter colour. A dressing of all soils about to their full depth, on the contrary, greatly increases their fertility, by promoting the decomposition of the excretery matters of plants, which otherwise would remain for a longer period, to the annoyance of plants of the same species.

In a recent communication to the secretary of the English Agricultural Society, Sir E. Stracey has given some of the results of his experience with the Rackheath subsoil-plough, and they are of a description which cannot be too generally known:—"On my coming," he remarks, "to reside on my estate at Rackheath, about 6 years since, I found 500 acres of heath land, composing 2 farms (which had been enclosed under an act of parliament about 35 years), without tenants; the gorse, heather, and fern, shooting up in all parts. In short, the land was in such a condition, that the crops returned not the seed sown. The land was a loose, loamy soil, and had been broken up by the plough to a depth not exceeding 4 inches, beneath which was a substratum (provincially called an iron pan) so hard, that with difficulty could a pickaxe be made to enter in many places; and my bailiff, who had looked after the land for 35 years, told me that the lands were not worth cultivation—that all the neighbouring farmers said the same thing—and that there was but one thing to be done, viz., to plant with fir and forest trees: but I proceeded, from a strong attachment, as I had the year preceding allotted some parcels of ground, taken out of the adjoining lands, to some cottagers; to each cottage, about one-third of an acre. The crops on all these allotments looked fine, healthy, and good, producing excellent wheat, carrots, peas, cabbages, potatoes, and other vegetables in abundance. The question then was, how was this done? On the outside of the cottage allotments all was barren. It could not be by the manure that had been laid on, for the cottagers had none but that which they had scraped from the road. To describe the manner of this would be nothing else but the spade; they had broken up the land 18 inches deep. As to digging up 500 acres with the spade, to the depth of 18 inches, at an expense of 6l. an acre, I would not attempt it. I accordingly considered, that a plough might be constructed so as to loosen the soil to the depth of 18 inches, keeping the best soil to the depth of 4 inches, and near the surface, thus admitting air and moisture to the roots of the plants, and enabling them to extend their spong tails in search of food; for air, moisture, and extent of pasture, are as necessary to the thriving and increase of vegetables as of animals. In this attempt I succeeded, as the result will show. I have now broken up all these 500 acres, 18 inches deep. The process was by sending a common plough drawn by two horses, to precede, which turned over the ground to the depth of 4 inches; my subsoil-plough immediately followed in the furrow made, drawn by four horses, stirring and breaking the soil 12 or 14 inches deeper, but not turning it over. Sometimes the iron pan was so hard, that the horses were set fast, and it became necessary to use the pickaxe to release them before they could proceed. After the first year, the land produced double the former crops, many of the carrots being 16 inches in length, and of a proportionate thickness. The general soil of the ploughed land was derived solely from the deep ploughing, Manure I had scarcely any, the land not producing then stover sufficient to keep any stock worth mentioning, and it was not possible to procure sufficient quantity from the town. The plough tore up by the roots all the old gorse, heather, and fern, so that the land lost all the distinctive character of heath land the first year after the deep ploughing; which it had retained, notwithstanding the ploughing with the common ploughs, for 35 years. Immediately after this subsoil-ploughing, the crop of wheat was strong and long in the straw, and the grain close-bosomed and heavy, weighing full 64 pounds to the bushel. The quantity, as might be expected, not large (about 26 bushels to the acre), but great in comparison to what it produced before. The millers were desirous of purchasing it, and could scarcely believe it was grown upon the heath land, as in former years my bailiff could with difficulty get a miller to look at his sample. Let this be borne in mind, that this land then had had no manure for years, was run out, and could only have been ameliorated by the admission of air and moisture by the deep ploughing. This year the wheat on this land has looked most promising; the ears large and heavy, the stalks thick and strong, the produce will be from 34 to 36 bushels an acre: the wheat, the "golden drop." My Swedish turnips on this land this year are very good; my pudding and sugar-loaf turnips failing in many parts, sharing the fate of those of my neighbours, having been greatly injured by the torrents of rain which fell after they had shown themselves above the ground. Turnips must have a deep and well-pulverized soil, in order to enable them to swell, and the tap-roots to penetrate in search of food. The tap-root of a Swedish turnip has been known to penetrate 39 inches into the ground."

Sub-turf Plough.—"Being on the subject of the sub-soil plough," says Sir Edmund Stracey, "I may as well tell you I have contrived another plough, from the use of which the greatest benefit has been derived by my park land. I call this my 'sub-turf' plough. It is used to loosen the turf about 1 1/2 inches deep below the surface, without turning over the flag; loosening the soil underneath, consequently, admitting the air and the rain, and permitting the roots of the herbage to spread in search of food. There are no marks left by which it can be known that the land has been so ploughed, except from the straight lines of the coulter, at.
the distance of about 14 inches one from another. In about three months from the time of ploughing these lines are totally obliterated, and the quantity of aftermath, and the thickness of the bottom, have been the subject of admiration of all my neighbours. Another advantage from this subplot-ploughing is, that, before that took place, water was lying stagnant in many parts (after heavy rains), especially in the lower grounds, to a great depth: now no water is to be seen lying on any part, the whole being absorbed by the earth." (Journ. of Eng. Agr. Soc. vol. i. p. 253.)

And for heavier soils, the evidence in favour of subsoil-ploughing is equally valuable. In the year 1838, an experiment was made by Sir James Graham, which is important in several respects. It was on a field of about 8 acres, of the poorest and wettest land. "The surface-soil is about 5 inches deep of black earth, of a peaty quality. The subsoil is a weeping retentive clay, with sand and rusty gravel intermixed. This clay extends to the bottom of the drains, which are of tile, laid 30 inches deep in every furrow. This field was rented by the out-going tenant at 4s. 6d. per acre. It was in pasture of the coarsest description, overrun with rushes and other aquatic plants. After draining, on one-half of this field I used Mr. Smith's subsoil-plough. On the other half I trench-ploughed to the depth of 10 inches, by two ploughs following in succession. In the first part, not mixing with the surface any of the subsoil; in the last part, connecting the top soil and the subsoil in nearly equal proportions. The whole field was heavily, but equally manured, and planted with potatoes; and though the potato crop, even on good land in this neighbourhood (Cumberland), was below an average, yet the crop in this field exceeded an average, and yielded about 12 tons per acre. The field is equally drained in every part. The crop was so equal throughout the field, that I am unable to pronounce positively which part was the best, but I am inclined to give the preference to that portion where Mr. Smith's subsoil-ploughing was used." (Journ. of Eng. Agr. Soc. vol. i. p. 253.)

SUBSTRATUM. A stratum lying under another stratum. The term subsoil is generally applied to the matters which intervene between the surface soils and the rocks on which they rest; thus, clay is the common substratum, or subsoil, of gravel.

SUCRITY. See Chicory.

SUCULENT. A botanical term, signifying fleshy, or filled with juice.

SUCKER. A young twig or shoot from the root of a plant. See Propagation.

SUDORIFIC. Having the power of producing perspiration.

SUEDE. The fat situated about the loins and kidneys, which is harder and less fusible than that from other parts of the same animal. That of the ox and sheep is chiefly used; and, when melted out of its containing membranes, it forms tallow, and is largely used in the manufacture of candles and the ordinary soaps. Beef and mutton suet, when fused, concrete at a temperature of about 106°. Like other kinds of fat, it is a compound of carbon, hydrogen, and oxygen. See Deeps, Fat, Lard, &c.

SUFFRUTICOSUS (Lat. suffruticus, an under-shrub). Any plant which is not exactly either a shrub or an herbaceous plant, that is, which has not hard woody twigs and complete buds, like the one, nor perishable, succulent leaves and shoots, like the other; the total average of lavender is an instance of a suffruticosus plant.

SUGAR (Fr. sucre; Germ. Zucker). The great commercial demand for sugar is almost exclusively supplied from the sugar-cane (Arundo saccharifera), which contains in it greater quantity and purity than any other plant, and consequently affords the greatest facilities for its extraction. Cane sugar is combined, in the juice of the plant, with a number of other substances. The following analysis of M. Avequin shows the nature and proportions of these:—0.46 albumen, 0.81 gum, 10.2 crystalizable sugar, 4.6 uncrystalizable sugar, 0.85 chlorophyle and oil, 0.75 stearin, 1.28 resin, 3.58 salts, and 700-8 water, in 1000 parts. The juice, after expression, is freed from some acid which it contains, by means of lime, and then concentrated by boiling; after which, as soon as brown grains form, the syrup is purified, and allowed to crystallize. The crystals are next separated from the molasses, or uncrystalizable sugar, by dripping. This forms muscovado or brown sugar, which is afterwards purified. The purest raw sugar comes from Demerara. Pure sugar is a compound of 44-44 of carbon, 6.15 of hydrogen, and 49-78 of oxygen. The purity of sugar is therefore a matter of demulcent, and powerfully antiseptic. Sugar undergoes fermentation more readily than cane sugar. A large quantity of sugar, identical to cane sugar, is contained in the sap of the American maple (Acer saccharatum), that of the cocoa-nut (Cocoa nucifera), and in the juice of the beet-root (Beta vulgaris), from each of which it may be economically obtained: it has also been extracted from grapes or raisins, and, as is well known, is contained abundantly in many ripe fruits and esculent vegetables. It is, however, in these seldom so pure or in such quantity as to admit of ready separation, or of crystallization. The total average quantity entered annually for home consumption in England, is, in round numbers, nearly 4,000,000 cwt. See MAIZE, MAPLE, MOLASSES, &c.

The sugar-cane, under the name of the sugar-reed, is mentioned in the oldest records of antiquity as a product of the Eastern world. It would also appear, that the sugar-cane was found growing luxuriantly in Hispaniola, when Columbus first discovered America, according to the account given by Peter Martyr, written during the second voyage of Columbus. There are many varieties or species of the reedy grass producing sugar, both cultivated and growing wild on the banks of rivers and meadows, in both the Indies, China, Africa, the South Sea Islands, and America. The common sugar-cane (Saccharum officinarum), Plate iv. d., is a perennial-rooted plant, very susceptible to frost, and therefore restricted in its cultivation to a belt or zone extending from 35° to 40° on each side of the equator.
United States the cultivation cannot be carried on advantageously higher than about the 32d degree of latitude, and here the cane dies down annually, unless cut in time to escape the effects of frost. It attains the height of 7 or 8 feet, or more, and its broad leaves, and large, silky panicles, give it a beautiful aspect. The stems are jointed, very strong, and contain, when filled with a spongy pith: the flowers of the sugar-cane are small, and very abundant, being clothed externally with numerous silky hairs. But, in the regular course of cultivation, it never flowers in Louisiana, and but rarely in the West Indies. Consequently, seed is difficult to be procured, short of Otaheite or China. It is well known that where the plant is allowed to go to seed, this natural process interferes with the development of the saccharine materials. In the West Indies, it is propagated by cuttings from the main stalk, planted in hills or trenches in the spring or autumn. The cuttings root at the joints under ground, and send up shoots, which, in 8, 12, or 14 months, are from 6 to 10 feet long, and fit to cut down for the mill. A plantation lasts from 6 to 10 years, but in Louisiana the planting has to be renewed every 2 or 3 years.

The juice of the sugar-cane is so palatable and nutritive, that, during the sugar harvest, every creature which partakes freely of it, whether man or animal, appears to derive health and vigour from its use. The meager and sickly negroes exhibit at this season a surprising alteration; and the labouring horses, oxen, and mules, though constantly kept at hard work, are never allowed to eat, almost without restraint, of the refuse plants and scumings from the boiling-house, improve infinitely more than at any other period of the year. The sugar-cane is now cultivated in all the warm parts of the globe. The variety from Otaheite has lately, in the West Indies, superseded all other kinds of cane, and succeeds in soils too poor for the common varieties. The qualities of the sugar are also very superior.

Sugar is now cultivated to considerable extent in the United States. On the northern coast of the Gulf of Mexico, for the distance of about 300 miles, the sugar region is almost entirely embraced within the limits of Louisiana. Here, the soil being all alluvial and of the richest description, the cane is forced by its exceeding fertility, together with the warmth of the long summers, to a state of maturity which enables it to yield sugar in the greatest abundance, and of the finest quality. Thus, the natural strength of the soil and warmth of the summer compensate in a great degree for other defects of the climate. The extent of lands in this portion of the United States admitting of the profitable culture of sugar, is sufficient not only to supply the home consumption, but for foreign consumption, but for large exportation. The sugar culture in the United States is now protected by a duty on muscovado or brown sugars of 2½ cts. per lb. White sugars from Havana pay a duty of 4 or 4½ cts. per lb. Louisiana brown sugar has been sold in the spring of 1843, at 4 to 5 cents. per lb. wholesale, in all of the Atlantic cities.

Varieties of the Cane.—There are four varie-

ties of cane mostly planted in the West Indies and Louisiana. The Otaheite cane is, as has been before observed, more extensively cultivated at present in the West Indies than any other. It will grow better on the lighter and older cultivated soils, and has several peculiar advantages over the Brazilian or Ceylon canes. It is used in the manufacture of rum, but now generally superseded. The last named is more delicate and requires more culture than any other variety, but produces sugar of the finest quality. The variety most extensively cultivated on the rich lands of Louisiana, is the Blue-ribbon cane, the most luxuriant of all others. All the varieties "rattoon," that is to say, produce a growth from the roots two and sometimes three successive years in Louisiana. The consumption of England now amounts to upwards of 400,000,000 pounds, which gives an average of about 30 pounds for each individual. That of the United States is about 250,000,000 lbs. per annum, which, considering the population, gives a larger individual rate of consumption than any other country in the world.

In an interesting communication in the *Farmers' Register*, vol. iii., Mr. Macrae, a Florida sugar planter, speaks of the sugar culture in that region as profitable, but still, he thinks, too uncertain, from the effects of frost, to be depended upon to the exclusion of other southern crops. The season for manufacturing, he observes, may not admit of the saving of 500 acres of cane; but it assuredly admits of 100 acres being profitably saved, with 50 effective hands, or work, and that, too, without any serious sacrifice of cotton, or great loss of labour. The opinion there generally maintained, that the manufacture of a sugar crop will essentially interfere with and diminish the cotton crop, he regards as erroneous. In the proportion of one-fifth cane, he says there need be no such interference—admitting that the earliness and severity of frost is such as to compel the immediate service of all other labours to the security of the cane. "Your 50 hands will mattress it (100 acres) in from 3 to 5 days, where it may lie for a month. Half your force, with tried machinery, will then manufacture it in a week, without any extra labour; and your other remaining half of labourers will certainly, at that season, save all the cotton that is liable to fall. It is not, however, one year in ten, that the season would compel this entire disposition of your labourers; and certainly your chance of revenue from two crops, not liable to the same disasters (for none can deny that the cotton plant has nearly as many risks to run before its fruit is saved, as the cane), is more than equivalent to a moderate loss by a heavy blow of cotton. No one should attempt the cane cultivation, be it of rice or cane, with a less force than 50 effective hands; and I attribute the heretofore failures of sugar here, in a great measure, to overcropping, and a poverty of labourers."

The operation termed "mattressing," consists in piling the cane which is cut, to prevent injury from frost, in rows in the field. The plan recommended by Mr. Macrae, is to cut the cane down close to the ground, and
throw three rows into one, thus forming windrows across the field, taking care to place the foliage of one stool of cane over the butts of the previous one, and laying them to the height of 3 or 4 feet, like a thatched roof. In this way the cane can be kept several weeks for grinding and pressing. “Mattressing” the cane for a limited period, even after the frost, so far from injuring its product, will, he says, increase it in Florida. “As long as the demand for cotton will give 20 cents, or even 15 cents per pound, it is undoubtedly a more profitable article of culture, and sufficiently so to annihilate any other substitute; and even at 10 cents per pound, it is unquestionably a more expedient entire crop than sugar; and no prudent man will, under any circumstances, in my opinion, here attempt a sole sugar crop; its results will be, nine times in ten, complete ruin. I advocate only sugar in combination with cotton.” In his estimate of the comparative profits of cotton and sugar, both rated at 10 cents per pound, he computes the product of an acre of cotton at 1000 pounds, and an acre of cane at only 1000 gallons of juice, equal to 500 pounds of sugar. In Louisiana, about 1000 pounds of sugar per acre is considered an average yield, while, “in the West Indies from 3000 to 6000 pounds.”

At present the cane crop of sugar in the United States is almost exclusively confined to Louisiana. The capital employed in its culture in 1842 has been estimated at about $52,000,000. In 1840 the sugar crop of Louisiana was reported in the census returns at 119,947,720 pounds. In 1842 the crop was estimated at 130,000,000 pounds, being the greatest ever before known. The annual average for several years is represented to exceed 80,000,000 pounds, with an addition of 4,000,000,000 gallons of molasses.

Whilst the crop of cane sugar is increasing annually at the South, that from the maple is becoming greater in the Northern and Western States. The amount of sugar made in 1840, from both sources, has been reported at 155,100,809 pounds. In Michigan alone, there is said to be no less than 30,000 acres abounding with the maple. These trees have been estimated at an average as worth to the farmer, for the purpose of sugar-making alone, from 2 to 3 dollars each. The proportion of sugar-maps per acre in the sugar districts has been computed at 30. See Maple.

Under the head of MAIZE reference is made to the proposed manufacture of sugar from Indian corn, one acre of which, of luxuriant growth, has been estimated to produce from 600 to 1000 pounds and more of good sugar. The manufacture of sugar from the beet, so extensively carried on in France, Germany, and other European countries, has never been successfully introduced into the United States. To succeed fully, the manufacture must be carried on upon a large scale, with ample capital. Many excellent essays upon the subject may be found either separate or published in various agricultural periodicals.

Chemical composition of Sugar.—The progress of modern chemistry in ascertaining the precise elements of various substances, has developed some highly interesting facts relative to sugar, showing the very slight difference between its composition and that of many other matters to which it apparently bears not the least resemblance, such as starch, saw-dust, or common woody fibre, linen rags, &c., by which slight additions have been actually converted into sugar. By some chemists, and particularly Prout, starch is considered as sugar partly organized, containing but a small quantity of carbon and hydrogen more than sugar, the excess however being sufficient to prevent crystallization or conversion by nature into sugar. Through the present table, statements of Berzelius, Raspail, and Dumas, by Dr. Prout, shows in a curious and interesting light, by what mere shades of difference in their constituent atoms, substances, which to the sense appear as far apart as the zenith from the nadir, are separated. Water is composed of definite and well-ascertained proportions of oxygen and hydrogen, and in the formation of sugar, starch, acetic acid, and lignin, or the pure woody fibre of trees and plants, these two materials are found united in the same proportions as in water; the only ingredient added for their completion being carbon. These substances, sugar, acetic acid, and lignin, may therefore be considered as composed of carbon and water in the proportions here given.

Dr. Prout, in his Bridgewater Treatise, remarks, “that both starch and wood can by different artificial processes be converted into sugar or vinegar. But we are unable to reverse the process, and convert vinegar into sugar, or starch into wood.” The chemist Braconnet has ascertained that a pound of linen rags yields rather more than a pound of sugar.

Mr. Guthrie of Sackett’s Harbour, in his attempts to make sugar from potatoes, produced large quantities of molasses, but with all his skill was unable to crystallize or grain it, without the introduction of some deleterious substance, lead, for instance; and consequently all his was used in a liquid form, of the consistency of thick syrup, or rather honey. The potatoes were first converted into starch, and then, by boiling in sulphuric acid, diluted, for some hours, into sugar. The directions in the Encyclopedia Americana for this process are, 2000 parts of starch, 8000 parts of water, and 40 parts strong sulphuric acid—the mixture to boil some 30 hours in silver or lead; but Mr. Guatere accomplishes the conversion by the use of steam in about 6 hours. The production of sugar or molasses is possible from a great variety of materials provided by nature, such as the cane, maple, beet honey—all plants.
SUGAR BEET.

that afford starch, or substances that by chemical process can be converted into gum, as flax, linen rags, &c.; still none have yet been found, which can successfully enter into competition with the cane.

SUGAR BEET. The white beet already mentioned under the head Beet. As it is not probable that this root will soon be brought into requisition for the production of sugar in the United States, where so many other sources exist from which this may be readily procured, we shall confine our observations to it as an article of food for farm-stock.

The following information relative to the beet culture, &c., is from Mr. Colman's Fourth Report upon the Agriculture of Massachusetts:

"Beets are often a very profitable crop. They are raised in considerable quantities; are packed in barrels and shipped to the south. One dollar and a half is a common price for a barrel containing 2½ bushels. The farmer giving this statement has often produced 600 bushels to the acre. They are planted on ridges about 4 feet apart, in double rows; and the intermediate spaces are often sown with turnips. The ridge planting is decidedly preferred here for all vegetables of this kind. In my opinion, and so far as my own experience goes, which has not been small, it would be better to make the ridges about 27 inches apart, plant the beets in single rows, and cultivate them with a plough. A very useful machine for planting beets is a wheel, set like that of a wheel-barrow, with pins projecting from the rim 2 inches, and placed 8 inches apart, which is passed along on the top of the ridge, and the seeds dropped by hand into the holes marked by the pins. They may then be covered by drawing a rake-head along the top of the ridge. Too much care cannot be taken to perform all operations in planting, where the vegetable is afterwards to be cultivated, in straight lines. The work is by this means greatly facilitated."

A crop of sugar beets was raised at Nahant, in 1840, by Mr. Frederick Tudor, of 42,284 lbs. on 93 rods, or at the rate of 36 tons 746 53 lbs. net weight per acre, being about 1300 bushels per acre, allowing 56 lbs. per bushel. One of the roots cropped and cleaned, weighed 31 lbs. The ground was trenched to the depth of 20 inches, and well manured, the stones removed being all laid at the bottom of the trenches. Allowing the beets worth $5 a ton, this would give $180 to an acre, leaving the land in high tilth for further rich crops. The expenses of cultivating an acre of sugar beets in the New England States, have been thus stated by the editor of the Yankee Farmer.

Use of an acre of land well prepared for beets, and manured, or managed in the previous crop --- $12 00
Ploughing --- --- --- 4 00
Cultivator- ing, horse, cultivator and hand, two hours --- --- --- 50
Twice more before sowing --- --- --- 1 00
Harrowing --- --- --- 50
Seed $2 50, sowing with a machine 75 --- 3 25
First hoeing --- --- --- 4 00
Second hoeing, thinning, and transplanting to supply deficiencies --- --- 4 00
Hoeing again, and loosening the ground with machines --- --- 2 00
Harvesting --- --- --- 9 00

$40 00

This we think a high estimate. Still, it must be admitted that the cost of cultivating an acre of sugar beets much exceeds that of an acre of Indian corn. In some places the proportional expense of a root over a corn crop is double, in others treble. The following observations upon the mode of cultivating the beet crop, are also taken from the Yankee Farmer. i

Making rows 2 feet 4 inches apart, and then a cultivator can be used in hoeing. If the beets stand one foot apart in the rows, and weigh 24 lbs. each, the yield will be 20 tons. In rich ground, at that distance a great number will weigh 4 or 5 lbs. each; 20 tons is a good crop, but not extremely large, for in some cases 25 or 30 tons to the acre have been raised in this country. At the above expense of $40 to the acre with a yield of 20 tons, the cost would be $2 per ton. We make this estimate, to show how cheap beets may be raised under favourable circumstances, such as good land at a fair farming price, cheap machinery, and the most prudent management in the culture, with labour at a moderate price, and a favourable season.

Supposing we reckon the produce only two-thirds as much as above, say 13½ tons, and the cost 33½ per cent. more, which will be $53 33; then the cost of the beets will be only $4 per ton, one-fifth less than Mr. Bosson reckoned in his calculation on the cost of beet sugar. If we reckon 50 lbs. to the bushel, 13½ tons per acre would be only 533 bushels, which would be no more than a middling crop, not half as much as has been raised in a number of cases that have been mentioned.

In estimating the value of sugar beets for feeding stock, &c., Mr. P. Diehl, of Pennsylvania, says that in his neighbourhood, persons feeding the beet to cows, readily procure 2 cents per lb. more for their butter than their neighbours who do not use the beet. His hogs are wintered entirely on beets and kitchen slop, and kept in fine condition. He states that he has fattened solely on sugar beets, beeves, which when sold, were pronounced by the butchers the best they had killed for many years before. In contrasting the probable amount of profit to the farmer, in a crop of corn and a crop of beets, he says: "Allowing for the average crop of beets 1000 bushels per acre, which is moderate, this quantity will fatten 1 ½ head of steers in 90 days, at one bushel per day for each steer. Allowing the average corn crop to be 50 bushels per acre, which is very large, this product will fatten only 1 ½ head, in the same time, feeding at the usual rate of ½ pecks per day. This leaves a balance in favour of beets, fractions aside, of about 800 per cent. (See Cultivator, vol. viii. p. 119.) There is perhaps no food which will contribute in winter so much to increase the quantity and quality of the dairy products as the sugar beet. But it should be used along with good hay, fodder, and other dry provender."

Under the head of Mangel Wortzel, a tabular view is given of the comparative nutritive materials in several of the roots most usually cultivated for agricultural purposes. From this, it will be seen, that in saccharine matter as
SUNDEW.  

well as in the total amount of soluble matter, the beet transcends all the other roots taken into the estimate. The proportion of nutritious matter in carrots and parsnips is also very considerable. See table, Art. Food, p. 499.

SUNDEW (Drosera, from drosera, dewy). This is a most singular and beautiful genus of plants, whose leaves are ornamented with red glandular hairs, discharging from their ends a drop of viscid, acrid juice, which, from its resemblance to dew, has given rise to the common and generic name. These hairs are so irritant as to contract when touched, imprisoning insects, after the manner of Dionaea muscipula. In their native state they are found growing on mossy, turfy bogs. They are all increased by seeds, which should be allowed to sow themselves. In England there are three indigenous species, all perennial. The leaves are either undivided or lobed, entire. Flowers terminal, racemose, rarely solitary. Petals red or white. Several species are found in the United States.

SUNFLOWER (Helianthus, from helios, sun, and anthos, a flower; on account of the brilliant colour of the flowers, and from the erroneous idea that the flowers always turned towards the sun). A highly ornamental and extensive genus of plants; and from their tall growth they are particularly adapted to the back of flower-borders or the front of shrub-nets, in which situations they make a splendid appearance in autumn: they grow well in any common garden soil, the tender kinds being best treated in a greenhouse. It appears to possess far more profitable qualities than were hitherto supposed, and, besides forming a beautiful object in a bed of flowers, it may be cultivated with advantage, and applied to many useful purposes. An acre of land will contain 25,000 sunflower plants, 12 inches distant from each other. The produce will be according to the nature of the soil and mode of cultivation; but the average has been found to be 50 bushels of the seed per acre, which will yield 50 gallons of oil. The oil is excellent for table use, burning in lamps, and for the manufacture of soap. Seeds after the oil has been expressed, made into cake, will produce 1500 lbs., and the stalks, when burnt for alkali, will give 10 per cent. of potassa. The green leaves of the sunflower, when dried and burnt to powder, make excellent fodder for milch cows, mixed with bran. From the ease with which sunflowers are produced in gardens (for they seem to flourish in any soil, and to require no particular care), we may safely say that an acre of land will yield a considerable return. Poultry are very fond of the seeds.

SUNFLOWER, WILD OR FALSE. Sweeze-weed (Helianthus europaeus). A plant with a biennial root found in the United States.

SWAMP. Ground habitually so moist and soft as not to admit of being trod by cattle, but at the same time producing particular kinds of trees, bushes, and plants. A swamp differs from a bog and a marsh in producing trees and shrubs, while the latter produce only herbage, plants, and mosses. In autumn and spring, the exhalations from swamps are productive of agues, consequently it is important to fill them up or drain them.

SWAN (Cygnus). Of the noble web-footed birds so called there are three British species: the Hooper, or Bewick's; the wild, and the tame swan. The wild swan and Hooper ought, perhaps, to be regarded as the only true native species. The tame swan (C. olor) is superior in bulk to either of the wild species, and is at once distinguished by a large, black, callous knob on the base of the bill. Our remarks in this place will be exclusively directed to the domesticated swan. These graceful birds are rarely dressed for the table; they are considered too ornamental to destroy. They are not destructive to fish, and they keep the water free from weeds. Mr. Main, who long studied their habits, in his work on Domestic Poultry, says the tame swan is herbivorous and granivorous; that is, they feed upon weeds and grain. They love also bread, vegetables, &c., which they eat greedily from the hand.

The swan lays from 5 to 8 eggs in the summer, and breeds only once in the year. They love an islet to breed their young upon, for the sake of its quiet; and a little straw deposited there is all they require for making their nest. The swan sits a month, but if the weather is bad, they are known to remain longer before they hatch. The cygnets, or young swans, remain a year with their parents; but when the breeding season approaches, the old cob or male bird drives them away. This is the period to sell; and if the birds have paired, they fetch a high price in the market. Swans are not in full plumage till the third year. These birds often take flight at the fall of the year, therefore the old birds should have the first joint of one wing removed, which would prevent their roving. Two pair of swans will seldom agree together upon the same piece of water. The cob, or male swan, is larger than the female, and bolder. They require feeding in very severe winters, and the ice should be broken for them to swim about. At other times they feed on weeds growing in the water, or herbage on the banks of it. Swans and cygnets are caught by nets which is a long pole of 10 or 12 feet, with a blunt hook 10 inches in length, bent at right angles to the pole; the angle should be turned like a ring, and opened in the inner side, to let in the neck of the bird. The swan has a peculiar kind of snout, but no voice. They hiss when angry.

SWARD. Green turf; that is, the surface of land under pasture grasses. A fine sward may be called the characteristic feature of British landscape, not being found in the same degree of perfection in any other country, not even in Ireland.

SWEAL. To singe or burn off the hair, as in dogs.

SWEET-BRIER. See Eglantine.

SWEET FLAG. See Acorus and Aromatic Reed.

SWEET-GRASS (Glyceria, from glukeros, sweet, alluding to the herbage; whence also the common name). A genus of grasses of which some of the species are aquatics. Dr. Smith enumerates 6 species indigenous to 4 R 1021
SWEET POTATO.

England: viz. the reedy sweet-grass (G. aquatica), the floating sweet-grass (G. fluitans), the reflexed sweet-grass (G. distans), the creeping sea sweet-grass (G. maritima), the procumbent sea sweet-grass (G. procumbens), and the hard sweet-grass (G. rigida). The only species which have been thought worthy of trial by Mr. Sinclair and other experimental cultivators of grasses are:

1. The floating sweet-grass (G. fluitans). Marona grass. The panicle is oblong, branched, divaricating. Spikelets close pressed. Florets numerous, obtuse, seven-ribbed, with short intermediate ribs at the base. Nectary obtuse, umid. This species appears capable of being cultivated as a permanent pasture grass. The seed will not vegetate unless kept very moist. It flowers from the first or second week of July till the end of summer. Birds are fond of the seeds, and generally strip the panicle ere the seeds are all perfected. Schreber informs us that it is cultivated in several parts of Germany for the sake of the seeds, which are esteemed a delicacy in soups and groats. When ground into meal, they make bread, very little inferior to that from wheat. The bran is given to their horses, and they must be kept from water for some hours afterwards. Fish, particularly trout, are said to be very partial to the seed.

2. The reedy sweet-grass (G. aquatica). In this species the panicle is erect, repeatedly branched, spreading. Florets numerous, obtuse, with seven ribs. Nectary cloven, acute. This grass is common on the banks of rivers, and frequent on the margins of standing pools. On the banks and little islands of the Thames, where it is generally mown twice in the year for hay, it affords abundant crops of valuable winter fodder. Mr. Curtis informs us that in flat countries, which do not admit of being sufficiently drained, it is almost the only grass for hay and pasturage. In the fens of Cambridge, Lincoln, &c., immense tracts which used to be overflowed and produce useless aquatic plants, and still retain much moisture, though drained by mills, are covered with this grass, which not only affords rich pasturage in summer, but forms the chief part of their winter fodder. Its powerful creeping roots make it a dangerous and troublesome weed in ditches, where, with other aquatic plants, it soon chokes them up. In the fens of the Isle of Ely this grass grows to the height of six feet, and proves excellent fodder for milch cows, though horses are not fond of it. The nutritious matter of this grass contains a greater proportion of sugar than exists in any of the superior pasture grasses. The best manner of propagating it is by planting the roots either in autumn or spring. It flowers about the second and third weeks of July, and the seed is ripe in the second week of August.

SWEET POTATO (Convolvulus battatus). Carolina potato. The fine, esculent, tuberous root of this species of low-creeping vine or convolvulus, is perennial. It flourishes in the Middle and Southern States—to which last it is native—wherever the soil is light and sandy, refusing to grow and perfect itself on clay or stiff loam soils. The plant is propagated by planting the tubers in beds early in the spring, from which the young sprouts are subsequently planted out in hills 5 or 6 feet apart. The trailing vines must not be allowed to strike root. The long roots are of different colours, being rich yellow, red, or white, and attain a large size, from a few ounces to several pounds in weight. When boiled, baked, or roasted, they have a sweet and very agreeable taste, and are very nutritious.

SWEET SCENTED SHRUB (Calycanthus Floridus). Carolina Allspice. An American spicy shrub, the flowers of which are extremely odoriferous, the perfume resembling that of the strawberry. The wood and especially the root are strongly camphorated, and may, Mr. Nuttall thinks, probably produce this drug as abundantly as the Laurus camphora. By cutting off the terminal leaf-buds after the usual season, it is said that a succession of flowers may be obtained throughout the summer, every leaf-bud so extracted being constantly succeeded by two flowers. The flowers of the Calycanthus rarely produce seed, even in its native mountains of Carolina.

SWINE (Genus Sus). The hog has been a generally useful animal, and a creature of grass habits and unclean tastes, as having the senses of touch and taste obtuse, and even as being so insensible that mice may burrow in his skin without his seeming to feel. But these opinions are most unjust and incorrect. Far from being unclean, nature has furnished him with powerful organs of digestion, enabling him to derive sustenance from a variety of substances, and his voracity is only the result of the extent and perfection of his digestive and respiratory organs. Although one of the pachydermous, or thick-skinned animals, the hog feels blows acutely, and manifestly suffering by loud cries. Indeed, the inference that his sense of touch is dull, because of the thick layer of fat with which his body is enveloped, is most erroneous, for it is well known that the plexus of nerves which gives sensibility to the body is exterior to this fatty layer. So far from being insensible to pain, the hog even suffers under the irritation arising from the punctures of gnats, mosquitos, and other small insects, and endeavours to protect himself from their persecution by rolling in moist places and covering himself with mud.

Natural History of the Hog.—"The hog (says Prof. Low) is subject to remarkable changes of form and characters, according to the situations in which he is placed. When these characters assume a certain degree of permanence, a breed or variety is formed; and there is none of the domestic animals which more easily receives the characters we desire to impress upon it. This arises from its rapid powers of increase, and the constancy with which the characters of the parents are reproduced in the progeny. There is no kind of live-stock that can be so easily improved by the breeder, and so quickly rendered suited to the purposes required; and the same characters of external form indicate in the hog a disposition to arrive at early maturity of muscle and fat as in the ox and sheep. The body is large in proportion to the limbs, or, in other words, the limbs are
The hog family includes several species, but these have usually been divided into three genera:

1. The true hog, which is the most diffused and important class, comprehending the wild boar (Sus asper) of Europe, Asia, and Africa; the babirossa (Sus babirossa) of the islands of the Eastern Archipelago, which is of lighter form than the common wild hog; the Papuan hog (Sus papuensis) of New Guinea, and the wood swine, or masked African boar (S. larvatus), of Southern Africa and Madagascar.

2. The wart-bearing hogs of Africa (Phacochoeres).

3. The peccaries of America. Of these there are two species, the collared peccary (Dicotyles torquatus) and the white-lipped peccary (D. labiatus), both inhabiting the countries of the Atlantic from Georgia and Paraguay, extending into the northern continent, being common on Red River. The peccaries are rather smaller than the common swine of Europe: they are covered with stiff bristles, very long upon the neck and spine, which they erect when irritated, are nearly destitute of tail, and are further characterized by a glandular opening in the back, whence the generic term dicotyles, signifying a double navel.

The true hog does not appear to have been indigenous to America, but was taken over by the early voyagers from the old world, and it has now spread and multiplied throughout the continent.

The first settlers of Canada, the British North American settlements, and the United States, carried with them the swine of the parent country, and a few of the breeds still retain traces of the old English character. From its nature and habits the hog was the most profitable and useful of all the animals bred by the early settler in the distant clearings. It was his surest resource during his first years of toil and hardship. It arrived earlier at maturity, required less care, sought out, for the most part, its own food, was the least subject to ac-
cidents and diseases in a new situation, and therefore best repaid any portion of attention bestowed on the breeding and rearing it.

Their widely extended foreign commerce afforded the Americans opportunities of procuring the varieties from China, Africa, and other countries. The large consumption of pork in the United States, far exceeding the consumption of any other country, has also contributed mainly to the improvement of the breeds, by causing the Americans to pay considerable attention to the rearing of swine, which have thus become one of the most important articles of commerce, and a source of considerable profit to the large country.

Breeds.—The various breeds which have been reared by crosses between those procured from different countries are so numerous, that to give anything like a detailed description of all would fill a volume instead of an essay. I shall, therefore, confine myself to a short notice of those which are either considered as the origin of some peculiar race, or most generally bred for their fattening or other profitable qualities.

The celebrated English breeds, Cullery, only distinguishes four breeds, the Berkshire, the Chinese, the Highland, and the Irish spitz.

The principal breeds of England have been usually named after the particular counties or localities where they have been, for the most part, reared. Thus, we have the Berkshire, the Hampshire, the Essex, the Suffolk, and a dozen others, each supposed to be distinguished by a certain set of common characters. Those approved on account of their superior size, and therefore usually reared for the purpose of making bacon, are the Berks, Hants, Hereford, Salop, Norfolk, and Chester breeds. The breed best adapted for table pork is the small white Chinese. There are, however, particular breeds preferred by individuals.

The Berkshire Breed. This is one of the earliest improved of the English breeds, and it is now the most widely distributed, as it is the most superior, of the numerous varieties of England. It is a breed which is distinguished by being, in general, of a tawny white, or rufous-brown colour, spotted with black or brown; head well placed, large ears, generally standing forward, though sometimes hanging over the eyes; body thick, close, and well made; legs short, small in the bone; coat rough and curly, wearing the appearance of indicating both skin and flesh of a coarse quality. It is noted, for its fattening power, and the animals attain to a very great size, averaging from 50 to 60 stone, although they have not uncommonly reached to the prodigious weight of 100 stone and upwards.

The county of Berkshire has long been celebrated for its famous breed of swine, and the breed has, by frequent and judicious crossing, been much altered for the better. The original breed was of the larger race of swine, and is described as being long, and rather crooked-nosed, with uncouth, heavy ears; body long and thick, though not very deep; legs short, with much bone; although slow feeders, they always made great weights. The character of the true Berkshire seems to indicate that one of the earliest means employed to improve them was a cross with the wild boar. The improved breed is lighter in the head and ear, shorter in the carcass, with somewhat less bone, and higher in the leg: in colour generally dark spotted. They have little offal, thin rind and hair, and few or no stout bristles. The native breed is still occasionally crossed, either with the pure Chinese or the Tonquin race; and it is asserted, on good authority, that if not crossed once in 6 or 7 years with the Asiatic breed, they will degenerate in shape, and quality. The improved Berkshires will be found excellent in all respects, but particularly as a cross for heavy, slow-feeding hogs. The unqualified approbation which this breed has obtained, renders it incumbent on every breeder who wishes to improve his stock of swine to obtain a cross with that race. Although hardy and thrifty in its nature, the Berkshire hog requires constant good keep, or it will decline fast.

The old English Breed.—The original native breeds of Great Britain may be arranged into two general classes; but between these extremes there are so many varieties, that numbers cannot be reduced to either class.

1. Those of small size, with the ears erect, or partly so, of which the most marked are those of the Highlands and islands of Scotland. They are hardy creatures, usually of a dusky-brown colour, having an arched back, with coarse bristles on the neck and spine; and approximate closely in character and habits to the wild hog. They are, for the most part, left to provide for themselves, ranging at large over the heaths and moors, grubbing up roots and destroying the eggs of birds, and even newly-born lambs, when they come in their way. These hogs are usually very meager and thin; flesh coarse and fibrous; but it is greatly improved when the animals are confined and properly fed. When roaming at large on the sea-coast, their flesh, from feeding on shell-fish, sea-weed, and the bodies of fish which are cast up by the tide, acquires a rank and unctuous taste.

2. The second class comprises those of a larger body, with long, pendent ears. Although their colour varies considerably, they are, for the most part, white, or white spotted with black. The characteristics of this old race, when it is kept without mixture with foreign blood (which is not often the case in the present day), are a huge, uncouth form, large bones, long limbs, arched and narrow back, low shoulder, and long snout, with the ears large and flapping, covering the greater part of the face. They consume much food, are slow feeders, and their only recommendation is that of being prolific breeders, and attaining to a large size when fattened at the age of two or three years. The old English breed, and many other once celebrated local races of that country, have all had their distinctive characters more or less effaced by crossing.

The Chinese or Siamese breed.—The varieties of this widely-extended race which are the most common in England, were brought to
The Swine.

America and England from Canton and other Indian ports, for the most part as sea-stock, by the vessels employed in the tea trade, &c. Ow- ing to the much larger consumption of pork by the Chinese than of any other animal food, they pay great attention to the rearing and fattening of their swine. It is said they even use the milk of the sow for domestic purposes. The pure Chinese breed is too delicate and sensible of cold to be of much value in climates that are subject to frequent changes of temperature. It is chiefly, therefore, by intermixture that its value is recognised; and it is for this reason that its introduction has proved so beneficial in England, by correcting the coarseness of form, quieting the restless disposition, and adding a greater tendency to mature quickly and fatten kindly. The flesh of the Eastern hogs is more suited for pork than for bacon. Mr. Culley subdivides the Chinese breed into seven varieties, but there appear to be only two distinct species—the white and the black; the former better shaped than the latter, but less Hardy, and prolific. Both breeds have hard, short ears and hairy coat; tail thin and transparent, small and fine; neck thick; the body close, compact, and well formed; legs very short; flesh delicate; round in the carcass, thin-skinned, and the head so embedded in the neck that, when quite fat, the end only of the snout can be seen. They are rather difficult to rear; the sows are bad nurses; and, from their small size, they seldom reach to a greater weight than from 10 to 12 stone when one year old, and 16 to 18 stone when two years old.

The black race, from their valuable properties of fattening on a small proportion of food, being very thrifty, and prolific breeders, notwithstanding their inferior size, have been advantageously crossed with other breeds.

There is a mixed tawny breed, or patched with black and white, which is valuable for breeding sows and roasters.

The Hampshire breed. This is a very large breed, which is longer in the neck and body, but not so compact in form as the Berkshire. They are mostly of a white colour, or spotted, and are well disposed to fatten, coming up to a great weight when properly managed in respect to food. The goodness of the Hampshire hog is proverbial; it is principally fattened for large hams and bacon.

The Shropshire breed is large and coarse; but these hogs are found profitable where the keep is in sufficient abundance for their support; hence they are held in estimation in England by distillers, and are commonly fed to 30 score weight and upwards. They are neither so well formed as those of the Berkshire breed, nor do they equal them in their disposition to fatten and thrive on cheap food. The standard colour of the Shropshire hog appears to be white, or brindled with black, and sometimes sandy patches. The breed may be described as flat-haired, deep and flat-sided, harsh or rather wiry-haired, the ears large; head long, sharp, and coarse; leg too long, low, although very substantial, yet not sufficiently wide, considering the great extent of the whole frame. Within the last 15 or 20 years this breed has been much improved by a cross with the Berkshire, which has reduced the length both of their legs and carcass, and rendered the head lighter.

The Rudwick breed. This is the most numerous breed in Great Britain, and is reared about the neighbourhood of a village on the borders of Sussex and Surrey, whence it takes its name. They feed to an extraordinary size without any peculiar care, and weigh, at two years old, on an average, fully 10 stone, which is nearly double what other kinds will weigh at the same age. The Rudwick sows are accounted good mothers, very prolific and hardy, and are particularly noted as being an extremely large sort, having been known to weigh from 80 to 116 stone, 8 lbs. to the stone. Indeed, some have reached to the extraordinary weight of 182 stone. As large breeds pay the farmer the best in many cases, such a breed as the Rudwick deserves to be attended to in the system of hog management.

The Suffolk and Norfolk breeds have been long in repute as hardy and prolific species, and when crossed with either the Dishley or the Berkshire breed, produce animals which are held in very general esteem.

The Norfolk breed. This is described as being a small, short set-earred, thin-skinned porking sort, various in colour, white, bluish, striated; generally an inferior kind. But on the Lincoln side of the county there is a large spotted variety of very good form and quality.

The Suffolk breed is a small, delicate, white race, which has for many years been held in good estimation. They are shorter and more pug-formed than the Normarks; and by their dish face and pendent belly, it is to be presumed that the variety proceeded originally from the white Chinese breed. Their defects are, that they are great consumers in proportion to their small bulk, and that they produce little flesh.

The Woburn breed. This is a large, hardy, well-formed, and very prolific variety, introduced by the late Duke of Bedford, which is generally white, spotted with various colours, round in the carcass, small-limbed and headed, and so kindly disposed to fatten, that they are said to attain about twice the size and weight of other sorts of hogs within the same given period of time.

The Tonkeley or Tonquin breed is a cross between the Berkshire and the Chinese, which has produced a species possessing very many good points.

The Dishley breed, reared by the celebrated cattle-breeder, Bakewell, are remarkably fine-boned and delicate, besides possessing considerable beauty, and are said to lay on a larger quantity of meat, in proportion to bone and offal, than any other kind known. When fat, they are nearly equal in height, length, and thickness, their bellies almost touching the ground, the eyes being deep-set and sunk from fat, and the whole carcass appearing to be a solid mass of flesh. As a set-off to these good qualities, the defects of their being slow of growth, tender constitutioned, bad nurses, not very prolific, and requiring more food in fattening than the larger hogs. By a cross with a Dishley boar, several of the native breeds of the different English counties have been much

129
SWINE.

1. of ears bare colour hardy, and with roundness upon the derers, light colour. long-bodied, and quality ably thin-skinned, few in rieties the place. a disposition. It prevails upon the abridgment to fatten. It is of a white colour, thick, compact, and well made in the body, short in the leg; the head and neck well formed, ears slouching a little downwards; hardy, and well disposed to fatten.

The Essex breed.—The original Essex breed was not held in much repute. Their peculiar character was a long, sharp head; round-backed; carcass flat, long, and generally high upon the leg; bones not large; colour white, or black and white; bare of hair; quick feeders, but great consumers, and of an unquiet disposition. A variety known as the Essex—half-blacks, which were introduced some years ago by the late Lord Western, as descendants from the Berkshire, have now justly acquired such very great celebrity, as to be considered by many good judges superior to most breeds in the kingdom. They are described in the Essex Report as black and white, short-haired, thin-skinned, with smaller heads and ears than the Berkshire, but feathered with inside hair, which is a distinctive mark of both; having short, snubby noses, very fine bone, broad and deep in the belly, full in the hind-quarters, but light in the bone and offal. They feed remarkably fast, and are of an excellent quality of meat. The sows are good breeders, and bring litters from 8 to 12; but they have the character of being bad nurses.

The Wiltshire Breed.—Originally this was a long-bodied, low hog, hollow about the shoulders, and high on the rump; with middling large pointed ears; round bone; and light in colour. But of late years this breed has been advantageously crossed with the pig and Berkshire sorts, and a smaller and better variety produced.

The Gloucester, the Yorkshire, the Northampton, and the Hereford breeds, call for little notice. The Hereford appears to be a descendant of the Shropshire, and is a large, useful race; but the others are very inferior kinds, possessing few good points.

In reviewing the various breeds of swine, a brief survey of the principal continental varieties and distinct races may not be out of place. I shall therefore give a slightly altered abridgment of a diffuse article which some time since appeared in the Quart. Journ. of Agr. vol. iii. p. 49.

France.—In the time of Buffon, the greater disposition of France was white; while in Dauphiny, Languedoc, and Provence, they were all black: black pigs still prevail both in Spain and Italy. The variety known in France under the name of porc de nobles appears to be derived from the improved English breed, which originated in a cross between an Anglo-Chinese sow and an emancipated American boar. The French breeds of swine are in general bad, but excellent hams are sent from Bretagne from hogs reared on acorns and fattened with maize. The principal breeds of France at the present time are—

1. The race of the Pays d'Auge, in which the head is small and sharp, ears narrow and pointed, body long, legs broad and strong, hair coarse, white, and bones small. It attains to the weight of 800 lbs.

2. The race of Poitou.—The distinguishing characters of which are head long and thick, with the point projecting, ears large and pendulous, body long, bones large, but broad and strong, bristles coarse. Its weight seldom exceeds 500 lbs.

3. The race of Perigord.—Neck thick and short, body broad and compact, hair black. This race, crossed with others, has produced the pied swine, so common in the south of France.

4. The race of Champagne.—These do not fatten well, they are of large dimensions, with long, flat pigs, broad, pendent ears, and coarse white hair.

5. The race of Boulogne are also of considerable size, and disposed to fatten quickly; ears very broad, general colour white. This breed has sprung from a cross between the larger English breed and one of the common races of France.

The French pigs, although they have excited many facetious observations from travellers, and not unfrequently been compared to greyhounds, may be fatten, we are assured, at a small expense; and the method of doing this is well worth investigating to be understood. The Chinese and English breeds are also getting into use for crossing. The fact that 4,000,000 pigs are killed yearly in France, shows of how great importance they are to the small agriculturist. (For. Quart. Rev.)

Other European breeds.—In some parts of Hungary the breed of swine is excellent. In Germany swine are common, but the breed is everywhere indifferent. Of the other continental races only a very few require particular notice.

The Jutland swine, which are of a large size, and form an important branch of Danish commerce, have the ears large and pendent, body elongated, back somewhat curved, legs long.

The Swedish swine.—The most peculiar and characteristic breed of Sweden are supposed to contain a cross of the wild boar, and have the head broad, turned upwards; ears unusually erect, body lengthened, legs long.

The Polish and Russian pigs are generally small, and of a reddish or yellowish colour.

Race of the Cape of Good Hope.—This breed is somewhat less in size, but else approaches closely to the Siamese pig, and is nearly identical with the breed of the South Sea Islands. It probably originated in India. The hair is black or deep chestnut, hard, and thinly scattered; the ears are straight, and tail pendent and terminated by a tuft of bristles. This race is now very generally distributed; it has been propagated extensively in Australasia, and now occurs not only in Southern Africa, but in several parts of South America.

The smooth or short-legged swine, a breed derived from the Chinese, are bred in Spain, Por-
**SWINE.**

tugal, Savoy, and the north and south of Italy. This pig is of small size, very productive, and a ready fatterner; it is usually of a copper colour, but sometimes occurs of a bright fiery red. The head is unusually short, the jaws thick, the forehead stunted; the skin falls in folds above the eyes; the ears are short, pointed, and almost erect; the neck is thick and strong, the chest very vigorous, the body round and lengthened, the legs short and strong, the skin very thin, and the bristles short and slender.

**The Zealand hog** is of a mixed Chinese race, and weighs from 160 to 240 lbs. about the end of its second year. It has the ears erect, body short, back strongly bristled, tail small.

**The Turkish hog** fattens in half the time required by many of the larger and more common breeds, and weighs from 300 to 400 lbs. It prevails throughout European Turkey, and a great portion of the Austrian dominions.

**Ears straight and pointed; legs short and fine; body scarcely longer than high, and covered all over with slender frizzled bristles, of a gray colour, more or less deep, approaching to rufous brown.**

**The pig of Guinea (not the Guinea pig) is a remarkable variety, which is little known. The back is bare; head small; ears long, slender, and much pointed; tail long, naked, reaching to the ground; hair short, red, shining, finer and softer than that of any other known race.**

In Asia only Europeans and the low Hindoos eat pork. Wild hogs are abundant, and do so much injury to the rice fields that it is a material part of the ryot's business to watch them, which he does night and day, on a raised platform of bamboos.

**Of the Mediterranean breeds there are several, which are approved and held in much estimation; among these are the Maltese, the Neapolitan, &c., and hogs are occasionally brought from the sea-port of Turkey and Spain.**

The Maltese breed was at one time in great favour in England; it was of small size, of a black colour, nearly destitute of bristles, with an aptitude to fatten readily. A breed from the country near Naples has been recently introduced, which is extensively employed as a cross with the existing native breeds. This Neapolitan breed is very similar to the Maltese breed already alluded to. Their flesh is good and delicate, but the animals are not hardy, and quite unfit for general use. The duchy of Parma is said to produce the best hogs of Italy, which possess all the good qualities of those about Naples. They are also more hardy, and of larger size.

In Mexico they have a very fine race of hogs, which are regarded as an important article of commerce. They are kept very clean, and often given a cold bath, as the breeders find from experience that cleanliness contributes mainly to their rapid growth, upon less food. This is fully corroborated by the following experiment, which was recently made by a gentleman from Norfolk. Six pigs of nearly equal size were put to keeping at the same time, and treated the same as to food and litter for seven weeks. Three of them were left to shift for themselves as to cleanliness; the other three were kept as clean as possible by a man employed for the purpose, with a currycomb and brush. The last consumed in seven weeks fewer pens by five bushels than the other three, yet weighed more when killed by two stone and four pounds upon the average.

Bullock informs us that the Mexicans are very curious in rearing and feeding swine, and that an essential requisite in a Mexican swine-herd is an agreeable voice, in order that he may sing or charm the animals into peace when they quarrel and fight, and lull them to sleep at proper times, to promote their fattening. *(Travels, 1824.)* There are many wild swine in Paraguay.

**Characteristics of a good hog.**—There is evidently much diversity in swine in different circumstances and situations. Like other descriptions of stock, they should be selected with special reference to the nature of the climate, the keep and the circumstances of the management under which the farm is conducted. The chief points to be consulted in judging of the breeds of this animal are the form or shape of the ear, and the quality of the hair. The pendulous or lop ear, and coarse, harsh hair, are commonly asserted to indicate largeness of size and thickness of skin; while erect or prick ears show the size to be smaller, but the animals to be more quick in feeding.

In the selection of swine, the best formed are considered to be those which are not too long, but full in the head and cheek; thick and rather short in the neck; fine in the bone; thick, plump, and compact in the carcase; full in the quarters, fine and thin in the hide; and of a good size according to the breed, with, above all, a kindly disposition to fatten well and expeditiously at an early age. Depth of carcase, lateral extension, breadth of the loin and breast, proportionate length, moderate shortness of the legs, and substance of the gammons and fore-arms, are therefore absolute essentials. These are qualities to produce a favourable balance in the account of keep and a mass of weight which will pull the scale down. In proportion, too, as the animal is capacious in the loin and breast, will be generally the vigour of his constitution; his legs will be thence properly extended, and he will have a bold and firm footing on the ground.

For head and ears, the small Berkshire or Oxford pigs are good models; and for true shape, the improved Shropshire, Hereford, and Gloucester. If colour deserve any consideration, perhaps the light, sandy, and yellow spotted are to be preferred, as these appear to afford by far the most delicate meat when dead.

**Procreation.**—The sow generally goes with young four lunar months, but the period of gestation in different species varies considerably. According to the experiments of M. Teissier on the gestation of animals, it appears that the extreme periods of 25 sows were 109 to 143 days, which would lead to the inference that they go on an average 127 days from the time of taking the boar until they farrow; but experience proves that they most commonly farrow within little more than 16 weeks, although they occasionally go with young 20 weeks. *Both*
the sexes manifest a desire for coition at 7 or 8 months old; and although frequently brought together at a still earlier age, it is more preferable to restrain them until they have attained to the age of 12 months, as a larger and stronger litter will be produced. The boar should be castrated some time between 7 and 8 months, and he may be considered in his prime at 2 years old. He should not be restrained by being allowed to serve too many sows; from 12 to 14 being sufficient. The sow should rarely be put to the boar before 8 months old.

See GESTATION.

The animals when collectively spoken of are usually either termed swine, hogs, or pigs; but when distinctively named, the young gelded male is called a "barrow," the male when not castrated is called a "boar," and the female a "sow," or "shoot"; their progeny when very young being styled "suckling pigs," and when advanced somewhat larger in size, "pokers.

There is much difference of opinion as to the best age for breeding sows. Some consider that sows at 3 years old throw their stock much larger and stronger than when of a less age; while others are of opinion that they are never such good breeders as at the age of from a year and a half to two years and a half old; after which they throw the pigs unevenly. Regarding the sex of the progeny, it is asserted in a recent French work on the subject of generation (Giron, sur la Reproduction des Animaux Domestiques), that among females those which receive the male first produce generally more males than females. This is not a matter of much consequence in swine; but in horses and cattle it is a question of some moment: and if this theory is borne out by experience, the hint thrown out may prove useful to breeders. The sow will produce two litters in a year (occasionally five in two years), and from 8 to 12 pigs in each farrow. The number of pigs to be kept will be easily indicated by the number of teats which the mother has; and on no account should more be attempted to be retained than nature has thus provided for.

"The choice of a boar," says a modern writer, "depends so much upon fancy, or local prejudice, in favour of a particular breed, and is so little governed by either soil or climate, that no other general rule can be laid down upon the subject, than to avoid an animal which is not small-headed, deep and broad in the chest, the chine rather arched, the ribs and barrel well rounded, and the hunch falling full down nearly to the hock. He should also be more compact in his form and rather smaller than the sow; for, if she be coarse, her progeny will be coarse in form and flesh by the cross, and the more roomy she is, the better chance will she afford of producing a large and healthy litter." (Brit. Hubb. vol. ii. p. 511.) The boar cannot be too well kept; but the sow should not be highly fed before taking the boar.

The plan or custom of breeding in and in from close relations is a most injudicious course, and seems to bring on degeneracy in the offspring. In selecting both sows and boars, a due regard must be paid to the object for which the progeny are designed. Small bone is desirable in stock reserved for breeding, as this description produces the least offal.

Uses.—A pig, for its size, is one of the most useful animals in the whole creation, inasmuch as he is food for man and beast, and a useful herd, which cannot be turned to account. His fat is made into lard, which is used in medicine, as well as by housekeepers, confectioners, and others. That about the loins is the firmest and the most dense. For ordinary use it must be separated from the membranes, which is effected by melting it over a slow fire and straining through cloths. It should be stirred as it cools, to prevent the separation of the solid part or stearine from the elastic or oily part. The flesh is either eaten fresh when young, or of the adult animal, bacon hog, salted in brine or with dry salt, and then either kept moist, as pickled pork; or merely dried, white bacon; or cured, dried, and smoked, bacon; that of the hind legs, ham, equally nutritious, but less easily digested; the collar and head of the old boars are made into brown; the skin or rind is eaten with the flesh, if not smoked, and is also tanned for saddle-seats; shoes, covers for pocket-books, &c.; the bladders are prepared as ox bladders. The bristles clean our teeth and brush our clothes: those of superior quality from Russia, fetch 14l. to 26l. the cwt.; the second quality, from 8l. to 10l. The abdominal fat is used; as also the blood for food, and it yields a brawn, principally from a morbid concretion in the stomach of the wild hog. Even the intestines are used for chitlings, and converted into an inferior kind of lard, by being cut open and washed clean, and (after the water is well pressed out of them) melted in the same way as lard: this substance is very useful for making common candles, greasing wheels, and other general purposes. To sum up all, the hog multiplies his species in a degree proportioned to its usefulness.

The flesh of the hog, when fresh, is easy of digestion and nutritious; but it is not a food capable of being eaten for a length of time with impunity. Its chiefpart is a brawn, produced from a morbid concretion in the stomach of the wild hog. Even the intestines are used for chitlings, and converted into an inferior kind of lard, by being cut open and washed clean, and (after the water is well pressed out of them) melted in the same way as lard: this substance is very useful for making common candles, greasing wheels, and other general purposes. To sum up all, the hog multiplies his species in a degree proportioned to its usefulness.

Bacon.—In Great Britain the curing of bacon, as an article of commerce, prevails most in the counties of York, Hants, Cumberland, Northampton, Dumfries, Galloway, and the northern and other ports of Ireland.

For bacon fitches, the larger breeds, such as will weigh, when killed, from 18 to 22 imperial stone, are always preferred, from being the most profitable to the farm and readily taking the market. In selecting pigs for this purpose, the sow should be of a large, deep carcass; head long, with deep ears, straight chin, and of equal symmetry from the shoulders to the tail; fine skin, which shows an aptitude to fatten, and the boar should be of a thicker and closer make than the sow.

Small hogs for bacon will be ready for the knife in 12 weeks, and the larger from 16 to 20 weeks. The girth of fat bacon hogs is about as follows:—When ten score, 4 feet 1 inch; twelve score, 4 feet 4 inches; fourteen score, 4 feet 7 inches; sixteen score, 4 feet 11 inches; eighteen score, 5 feet 2 inches; twenty
score, 5 feet 7 inches. (Hillyard's Pract. Farm. p. 51.)

"In Hampshire, and some adjoining counties, after the hog is killed, they first swale him, or singe off the hairs, by kindling a fire round him, which is far preferable to scraping off the bristles with warm water, as the latter mode softens the rind, and injures the firmness of the flesh. He is then put into flitches, which are well rubbed with common salt and salt-petre mixed, and are laid in a trough, where they continue for three weeks or a month, according to size, and are often turned. They are then taken out, suspended in a chimney, over a wood or turf-fire, or in regular curing-houses, till they are quite dried. In Kent they are dried before a slack fire, which requires a similar method and time to that employed in salting. They are hung up or deposited on racks for use. Somersetshire or Wiltshire bacon, which is the best in England, is cured as follows:—The sides of the hogs are laid in large wooden troughs, sprinkled with bay salt, and left unmoved for 24 hours, to drain off the blood and juices. Then they are taken out, and wiped quite dry, and some bay salt, previously heated in an iron frying-pan, is rubbed into the flesh, till enough of it is absorbed. This is continued for four successive days, during which the flitches are turned every second day. With large hogs, the flitches must be kept in brine for 3 weeks, and must be turned every other day, after which they are dried as usual. In these methods the hide or skin is left on; but in some counties there is a different practice, which is more consummated and preferable, because it offers an opportunity of converting the skin into leather, while the meat takes the salt and is cured as well as in the former mode. The hides of swine have long been made into shoes in China. Where the consumption of bacon is very rapid, the last-mentioned practice may be adopted; but it is certain that bacon will in a short time become rusty, and consequent loss be incurred, if it be not cured with the rind, and kept in a dry room." (The Complete Grazier.) See Bacon.

Pork.—In England, mess or table pork, or that for the London market, is generally cured near the principal sea-ports, and along the coast, from whence it can easily be shipped to the metropolis. If the object of breeding hogs is for pork and hams only, it is evident that pork from a hog of 35 to 35 stone (8 pounds to the stone) is by far more profitable than those from 35 to 50 stone; in which case a cross between the Chinese and Essex will be found to answer very well, as the progeny come to early maturity. (Baxter's Agr. Lib.)

The middle-sized hogs, such as the Northumberland, the Berkshire, the Suffolk, and Oxford breeds, are those generally preferred for this purpose, and their ordinary weight will be from 8 to 10 or 12 imperial stones.

For delicate pork for family use, the smaller kindly-feeding pigs are chosen. The Berkshire and the Suffolk breeds, when not too large, will be the best for this purpose. The Chinese will answer well at 6 or 8 months old, when it will weigh 4 to 8 imperial stones. By higher feeding it may be made, when a little older, to attain to double this weight; but the meat will then be found coarse. Weanlings are generally fatted in a very short period. A pig of 5 or 6 months old will fatten, if in good condition, in 8 or 10 weeks.

The fat of the hog is neither mixed with the flesh nor collected at its extremities, but covers the animal all over, and forms a thick, distinct, and continued layer beneath the integuments, and in this respect may be said to resemble the whale and other cetaceous animals. It is termed lard, and differs in chemical composition and properties from the fat of the ruminating animals. It more readily imbibes salt than any other kind of fat; and the same property being possessed by the flesh, there is no animal food better suited than pork for preservation by salting. See Lard.

Statistics.—The number of swine sold in Smithfield market in 1830 was 234,672, which, at the average weight of 96 lbs. each (a very moderate computation), gives the number of pounds of pork consumed annually, 24,448,512. (Youatt on Cattle.) The swine sold in Glasgow market in 1822 were 65,399. The exports of swine from Ireland in 1825, were 65,919; in 1835, 376,191. Estimated value in the latter year, 892,389,376. Increase between these two periods, 310,272.

In the United States of America a very large number of hogs are reared; and latterly much attention has been paid to the improvement of the breed by judicious crosses. The piggeries are on an extensive scale; and it is no uncommon thing in some of the Western States for a farmer to drive pork to market of 30,000 or 40,000 lbs.

In a letter written from Michigan city, dated 11th September, 1841, the writer, a farmer, states that he had then 3500 pigs up to fatten! The bountiful crops of Indian corn raised on the fertile Western lands afford greater advantages than any other part of the world for the rearing of this kind of stock. Corn-fed bacon is proverbially excellent.

The states producing most swine are—Tennessee, 2,920,607; Kentucky, 2,130,533; Ohio, 2,099,749; New York, 1,900,605; Virginia, 1,992,155; North Carolina, 1,649,716; Indiana, 1,829,608; Pennsylvania, 1,503,904; Illinois, 1,495,254; Georgia, 1,457,755; Mississippi, 1,271,161.

Dioceses.—This subject has been so much neglected by practical men, that but little is known in the way of cure. In the absence, therefore, of scientific prescriptions, it will be most advisable to study prevention rather than hazard a trial of the numerous recipes recom-

† Martin's British Colonies.
mended as cures. The diseases of swine are generally the result of want of care and cleanliness, or arise from injudicious and irregular feeding; from their being kept in loathsome and uncomfortable situations, inhaling the most noxious vapours, and at one time overfed, and another stinted in their supply of food. Is it to be wondered at that they become subject to internal and cutaneous diseases? Fortunately they will generally eat when even sick; and salts (1 to 2 oz.), sulphur (2 to 3 drachms), antimony, and such like aperients, may be mixed with their food for measles, and other disorders arising from an impure state of the blood. If they will not eat, there can of course be no cure applied.

In swine-pox, sulphur and madder may be administered in small quantities, with treacle, in the wash; fresh brewer's grains, or pollard, may also be given. Madder and sulphur will also be found the best alterants in foulness of the skin or habit. Salt, mixed with ground ivy, leeks, or other similar vegetables, is one of the best applications for the sores of swine. But for cutaneous diseases in general, an ointment formed of equal parts of mutton suet and tar, with the addition of a little sulphur, will be found beneficial. Strong beer and peapod ridge are the most mended as tonics.

In cases of surfeit, indigestion, or injury from eating slightly poisonous matter, swine will refuse their food, constantly lie down, and have the stomach distended. In this case, two heads of garlic, mixed with 6 oz. of fresh butter, will afford relief, given every 6 hours. Soap-suds are said to have the effect of emptying the stomach.

The most formidable of the diseases to which swine are liable, is inflammation of the lungs, and other internal parts. This disease has been known to destroy a fourth of the hogs in a distillery in the course of a few weeks. The chief indications of the disease will be the distressing cough, the heaving of the flanks, and the refusal of all food. Bleeding must be promptly resorted to, and moderate purges cautiously administered. The safest aperients are castor oil or Epsom salts, after which the following sedative powder may be given: foxglove (digitalis) 2 grs., antimony (ants), 2 grs., nitre half a drachm.

In cases of murrain, a species of leprosy, which prevails chiefly in hot seasons, the best advice that can be given is to keep the animal cool, and not suffer carrion or portions of animal food to be given.

The health of the swine is to be estimated by their cheerfulness, by the gloss upon their coats, their skin being wholly free from eruption. If pigs snort on being disturbed, it is an excellent sign of sound health and good keep. The state of the excrement or digestions will generally indicate pretty correctly the thriving condition of the animal, for unless these are of a firm consistence, the hog will not fatten rapidly. If store or stock-pigs are kept well and in good condition, it will prevent most of the diseases to which the animals are subject, and they will also thrive and fatten at half the expense when shut up for that purpose. From the confinement of the hog, and the nature of his food, a description of dyspepsia takes place, a superabundant acid is formed in the stomach, and, the skin sympathizing, cutaneous eruptions display themselves; one of the best prophylactics in such a condition is cinders or charcoal. It operates as a most salutary tonic, and improves the general powers of digestion. Hogs are so fond of ciners, that when a handful of them is thrown into a sty, the animals fight for them.

Warning.—If the young pigs have been well fed, they may be weaned after six weeks, and in all cases in two months. In their after treatment, when separated from their mother, they should be regularly fed 3 times a day, and their food should at first consist of warm liquid food, such as whey, milk, or the refuse of the dairy and kitchen, &c., raised to the temperature of the mother's milk by the addition of a little warm water. They will soon learn to partake of more solid substances.

The rearing and fattening of the hog presents little difficulty, for this animal is reared equally well on a small or a large scale; by the cottager, from the wash and refuse of his house and garden, or by the extensive breeder, who has more abundance and variety of food at command.

As the situation, climate, crops, and other local circumstances must to a great extent regulate the breeding and feeding of swine, it is quite impossible to lay down rules of general application, or to describe a practice which necessarily varies in almost every district. I shall content myself, therefore, with noticing a few of the substances upon which the animals are usually fed and found to thrive best.

It constitutes the principal value of swine, that they can be maintained on almost any kind of aliment. In America, Indian corn or maize is largely used. In the West Indies, the cane tops, refuse trash from the cane after the juice has been expressed, and the washings of the sugar-casters, the sugar-casters' washings, &c., form their principal food. In Newfoundland, Labrador, and other parts where fish is plentiful, they are freely fed upon the waste refuse from the fisheries; and although they thrive well upon this food, their flesh is coarse and strong.

Where the farmer or breeder has a rich piece of grass or clover unemployed, hogs which are not put up for feeding may be turned into it with advantage; but there is an objection to this on the score of the manner which is lost. When the field is so situated that the hogs can return at night to the well-littered sty, the practice may then be found beneficial.

But roots, rather than herbage, is their natural food, such as earthnuts, the roots of couch grass, &c.: acorns, chestnuts, beechmast, hazel-nuts, and other dry seeds and fruits, are eagerly consumed by them; and hence, in the countries in the south of Europe, in the neighbourhood of forests where these abound, they are frequently suffered to range at large and collect their own food. Hogs are also very partial to juicy and pulpy fruits, such as the grape, the orange, the refuse of apples, pears, olives, &c., after the juice has been expressed. Although hay and dried fodder is not adapted
Moist, succulent, green food, such as clover, tares, lucern, sainfoin, buckwheat, succory, chicory, cabbage, lettuce, &c., is more suited to their taste. Every kind of farinaceous substance, such as oat-meal, barley-meal, bran, maize, millet, peas or beans bruised, and indeed the seeds of all graminaceous and leguminous plants, are the most fattening substances that can be given to them. They will feed greedily, and thrive surprisingly, on most kinds of roots and tubers, such as carrots, turnips, beets, potatoes, the Jerusalem artichoke, &c., particularly when prepared by boiling. It may be taken as a general rule, that boiled or prepared food is more nutritious and fattening than raw or cold food; the additional expense and labour will be more than compensated by the increased weight and quality. Thus cabbage, turnip and potato tops, the husks of peas and beans, and even many green weeds, such as nettles and thistles, fatten; and others, void of poisonous qualities, will be found very fattening if boiled and mixed with other food, and given, as most food should be, lukewarm. The refuse of the kitchen, garden, and dairy, the grains and wash or liquid refuse of breweries, distilleries, and sugar manufactories, where they can be obtained, the sweepings of barns and granaries, will all be found to be more suitably fattening. Animal substances, particularly fish, should, however, be seldom or never given as food, since they will necessarily impart a strong and disagreeable flavour to the meat. A little salt should be generally added to all their victuals, which will create thirst, and induce the animals to consume a greater quantity of food. Fermented wash is found to fatten swine much quicker than fresh food.

RINGING.—The practice of ringing swine, which was usually performed at the time of weaning, is growing into disuse, and the ringing is not advisable in such as it not only improves painful to the animal, but troublesome to the owner; for it frequently happens that the ring breaks, or is worn out; the cartilage gives way, and the ring has to be as often replaced by a fresh operation. A more preferable and lasting process is now adopted, which consists in either cutting the two strong tendons of the snout (the cartilaginous and ligamentous prolongations) about an inch and a half from the nose, by a slight incision with a sharp knife, or else to shave or pare off the gristle on the top of the nose, which may be done without prejudice to the animal, when about two or three months old. The place heals over in a short time, and the animals are thus prevented from grubbing or tearing up the ground. (Prize Essay on Swine, by P. L. Simmonds; Wilson “On the Hog,” Quart. Jour. of Agr. vol. iii. p. 38; Lew’s Illustrations of the Breeds of Dom. Animals.)

SYTHE. See SCTR.

TAG. A term applied to a young sheep of the first year. See SHEEP.

TALLOW (Germ. talog). The fat obtained by melting the suet of the ox and sheep, and straining it so as to free it from membrane. When pure, it is white, tasteless, and nearly insipid; but the tallow of commerce has usually a yellow tinge, and is divided, according to the degree of its purity and consistency, into candle and soap tallow. Tallow consists of stearine, eluine, margarin, and traces of hircin. According to Chevreul, its ultimate components are 78.956 of carbon + 11.708 of hydrogen ÷ 9804 of oxygen in 100 parts. It is used in medicine as an emollient and a demulcent. Tallow is an article of great importance. It is manufactured into candles and soap, and is extensively employed in the dressing of leather and in various processes of the arts. Besides the supplies of native tallow, a very large quantity is annually imported into England, principally from Russia. The exports of tallow from Petersburg amount, at an average, to between 3,500,000 and 4,000,000 poods, of which the largest portion by far is brought to England. (Mc Culloch’s Comm. Dict.)

TAMARISK (Tamarix). This is a genus of very elegant shrubs. The hardy indigenous species, or French tamarisk (S. Gallica), is well suited for ornamenting shrubbery; it will grow in any soil or situation, and is freely increased by cuttings planted in the open ground, in spring or autumn. Sheep feed greedily on this species for the sake of its salt taste. The stem is slender, with abundance of long, drooping, smooth, red, shining branches. Leaves minute, lanceolate deciduous, spurred, acute. Lateral cylindrical clusters of numerous, nearly sessile, reddish or white bracteate flowers, without scent.

TANK. In gardening, a cistern or reservoir made of stone, timber, or some other material. Tanks are used for collecting and preserving water during a scarcity or drought. They are sometimes built in the ground, and lined with lead or cement. Where wells cannot be sunk, and water is scarce at some seasons, tanks are necessary appendages to a house. A tank, 12 feet by 7 feet, has been found sufficient to supply with water a large family and 6 horses: this was surrounded by only 4½ inch brick-work, resting solid against the sides, in consequence of being, like a decanter, smaller at the bottom than higher up; and the dome is constructed on the Egyptian plan, by projecting horizontally each row of materials one-third of their length beyond those below, by filling up the back with earth as it proceeded, to balance the weight of this projecting masonry.

At the Eastbourne work-house for 14 parishes, a tank has been made 23 feet deep by 11 wide, of the roughest materials, being only flint stones, and though they require more mortar than if they had been regularly shaped, only 90 bushels of lime were allowed, including 2

1031
coats of plaster, and the workmanship is executed like field walls at 10s. per 100 square feet; the only essential being that no clay be used (which worms in time bore through), and that the lime, or Parker's cement, be good.

A current of air is said to promote the purity of water in tanks, which is easily effected by the earthenware or other pipe which conveys the water from the roof being of 6 or 8 inches in diameter, and an opening left for the surplus water to run away; and where the prevailing winds do not blow soot and leaves on the house, the water remains good, even for drinking, without any precautions to keep it fresh and clean; but, in some cases, filtering by ascension may be found useful, and effected by the water being delivered by the pipe at the bottom of a cask or other vessel, from which it cannot escape till it has risen through the holes in a board covered with pebbles, sand, or powdered charcoal. See Reservoirs, Ponds, &c.

TANNER'S BARK. The bark of oak, chestnut, willow, larch, and other trees, which abounds in tannic acid, and is used by tanners for preparing leather. After being exhausted of the tanning principle by being chopped into small pieces, or bruised and steeped in water, it is laid up in barrels, and sold to gardeners for the purpose of producing artificial heat by fermentation in pits or beds, in bark-stoves or other out-houses. See Bark and Farm-Yard Manure.

TANNIC ACID. This term has been especially applied to a substance obtained by Pelouze, by acting upon bruised galls by common unrectified ether, in a long, narrow funnel or percolator. Tannic acid is a white uncrystalline powder, very astringent, little soluble in water, and reddening litmus. When moistened and exposed to air, it attracts oxygen, is decomposed, and is converted into gallic acid. It is extremely astringent, and appears to be the active principle of tanning substances (tannin) in general. Its ultimate elements are 30 atoms of carbon, 18 of hydrogen, and 24 of oxygen.

TANNIX. A word synonymous with tannic acid, the pure astringent principle upon which their power of converting skin into leather depends. Its leading character is its property of producing a dense whitish precipitate in a strong solution of animal jelly, such, for instance, as isinglass; and on this account it condenses the gelatin of animal hides, and, rendering them impermeable to water, converts them into leather. It may be obtained tolerably pure by infusing bruised grape-seeds in cold water, or more circuitously by adding acetate of copper to filtered infusion of galls, washing the precipitate, and decomposing it (diffused through water) by sulphuretted hydrogen. On evaporating its solution, it is obtained as a pale yellow extract of a strong astringent taste. The action of astringents upon persants of izzan has given rise to its distinction into two varieties, the first changing them to deep blue or black, the second to green. The tan of galls, oak, bark, grape-seeds, &c., bears but little resemblance to either that of catechu and tea, the latter. (Braun's Dict of Science.)

TANNING. The art of preparing leather from raw skins and hides so as to render them more plant, durable, and impermeable to water. The processes employed for this purpose are various, every tanner adopting some peculiar or favourite method.

A discovery has recently been made which seems likely to revolutionize the tanning trade. By means of a tanning machine, or pair of horizontal rollers fixed over a tan-pit, between which is fixed a band or belt of hides attached by ligatures to each other, to the number of 50 to 100, and by which the rollers are constantly fed or supplied, the hides are lifted out of the pit on one side of the machine, as they pass between the rollers, the tanning liquid is pressed out of them, and they are deposited in folds in the pit on the other side of the machine, where they absorb another supply of fresh tannin. The first hide having been inserted between the rollers, the others follow in succession, and upon arriving at the end of the band the motion of the roller is reversed, and the belt is returned through the machine to receive another squeeze. This alternating motion is constantly repeated, the pit being replenished from time to time with fresh solutions of tan, till the operation is completed. The effects produced by this simple plan, are—1. The shortening of the time of tanning to one-fourth of that generally required. 2. The production of a considerable increase of weight. 3. The leather tanned by this method resists water longer than that tanned by the old process. 4. The new method is cheaper than the old. 5. It is applicable to the existing tanneries, at a comparatively trifling expense, with a capability of working in rounds or series, and of expending tan or liquor. 6. That it is available for all sorts of leather.

TANSY (Tanacetum). The species of tansy are not possessed of much beauty. The hardy kinds succeed in any common soil, and are readily increased by rooted slips of the fibrous creeping root. They increase freely by cuttings. Withering asserts that if meat be rubbed with the leaves of tansy, the flesh-fly will not touch it. In England the only indigenous species is the common tansy (T. vulgare). Every part of the herb is bitter, with a strong but not unpleasant scent. The qualities are esteemed of a tonic and cordial nature, expelling intestinal worms, and strengthening the digestive powers. The plant, however, does not agree with every stomach. There are two varieties of this species, the vulgar, and the curled or double tansy, which is kept for use in gardens, as being more wholesome or milder than the wild sort; but in England tansy pudding is out of fashion.

TAPE-GRASS or EEL-GRASS. See Valvesemia.

TAPIOCA. A white, edible substance, consisting of very pure starch, obtained from the root of a tropical plant called manioc (Jatropa manihot) or cassava.

TAP-ROOT. A root which penetrates deep and perpendicularly into the ground without dividing, and has few lateral fibres. In shape it resembles a spindle; hence it is botanically termed a fusiform root. But the main trunk of any root that penetrates vertically deep into the ground is called the tap.
TAR. A dark brown, viscid liquor, obtained by chairing the wood of the fir tree; it consists of resin, empyreumatic oil, and acetic acid. When inspissated by boiling, it is converted into pitch. The manufacture, which is carried on in the pine forests of Northern Europe, is simple. A conical hole, usually in the side of a bank, being made, roots and fillets of pine are let into the cavity, and the whole is covered with turf, which is beat firmly down above the wood. The wood being kindled, a slow combustion takes place. A cast-iron pan at the bottom of the cavity receives the fluid, and has a spout which projects through the bank and carries the tar into barrels. As quickly as the barrels are filled, they are closed with bungs, when the material is ready for exportation. This manner of preparing tar has been derived from the earliest ages. Tar is a very compound substance; it contains modified resin, and oil of turpentine, acetic acid, charcoal, and water. It is an excellent topical stimulant, when made into an ointment with lard, in dry skin diseases. These two substances, tar and pitch, are of extensive use in the arts.

Tar may be found useful as an application for cuts in sheep by clipping, and also to the parts affected by the fly. It is also of great use in some cases for applying as a paint to boarding, &c.; but in this use a little tallow or other coarse fat should be melted with it, as by this means it goes farther, and resists the weather more effectually. Large quantities of tar are made in the abundant pine forests of North Carolina. See also GAS-TAR.

TARE EVERLASTING. See LATHYRUS and VETCHING.

TARES (Eremum, from eros, tilled land; some of the species are a pest on cultivated ground). The word tare is frequently applied to what is properly the common vetch (Vicia sativa). There are in England two indigenous species of tare, which are troublesome annual weeds.

1. Smooth tare (E. tetraspernum, Pl. 10, r), which grows in corn-fields, hedges, and thickets, particularly such as are rather moist. The root is small and tapering. The herbage is bristly, downy hair, furnished especially by the flower-stalks and calyx. Stem weak, quadrangular, branched from the bottom, leafy, climbing to the height of 2 or 3 feet. Flowers mostly in pairs, small, drooping, pale gray; the standard streaked, and the keel tipped with a deep blue. Legumes pendulous, oblong, bluntish, smooth. Seeds most generally 4.

2. Hairy tare (E. hirsutum), which is in habit much like the foregoing; the flowers are in clusters of 5 or 7, very small, pale blue, or almost white, with two dark spots on the keel. Legumes short, dark brown, bespinkled with hairs, to which the specific name alludes. Seeds two in each legume, large and prominent. See LATHYRUS, SOILING, VETCHING, &c.

TARO. A bulbous-rooted plant of the genus Arum, a native of the valley of the Columbia river. It is planted on hills, and cultivated in the manner of rice, on ground so situated as to be partially flooded with water. It comes to maturity in 8 or 10 months from the time of planting. To prepare them for food, they are roasted; they then become a substitute for bread; or they are made into poi, by pulverizing and converting them into a paste.

TEAM. A number of horses or oxen drawing at once in the same plough, cart, or other carriage.

It has been long a disputed point among farmers whether horses or oxen form the most economical and advantageous team, for the purpose of the cultivator in performing his work. The question remains still undecided, though many intelligent farmers in England now incline to the side of horse teams, except in particular circumstances and situations.

TEASEL, or TEAZLE (Dipsacus, supposed to be derived from dipsa, to thirst; in consequence of the leaves holding water). It is a curious genus of plants; some of the species are pretty flowering plants, especially the small teasel. They grow well in any common soil, and are readily increased by seeds. There are in England many native species, but they are rendered serviceable for teasing woolen cloth, being fixed in several rows in wooden frames with handles adapted for that purpose. The scales are just strong enough to raise the wool, giving way before they can injure the cloth. Many mechanical inventions have been attempted to set aside the teasel, but without success, all of them having proved inefficient or injurious. The dressing of a piece of cloth consumes from 1500 to 2000 teasels. They are repeatedly used in different parts of the process. Some esteem this but a luxuriant varity of the following, as it requires a very richly manured soil to preserve its characters and useful properties.

1. The manured or fuller's teasel (D. folliu- rum), although growing about hinges, can scarcely be considered wild. This species is extensively cultivated in the west of England, the dried heads of which furnish the teasel used by fullers in dressing cloth. The root is fleshy, branched, and tapering. Stem 5 to 6 feet high, erect, strongly furrowed, prickly, leafy, branched at the top. The leaves sessile, combined, serrated, with prickly ribs. Flowers white, with pale purple anthers, very numerous, in a close, obuse, conical head, the intermediate scales bristly at the edges; rigid and hooked at the points, by which they are rendered serviceable for teasing woolen cloth, being fixed in several rows in wooden frames with handles adapted for that purpose. The scales are just strong enough to raise the wool, giving way before they can injure the cloth. Many mechanical inventions have been attempted to set aside the teasel, but without success, all of them having proved inefficient or injurious. The dressing of a piece of cloth consumes from 1500 to 2000 teasels. They are repeatedly used in different parts of the process. Some esteem this but a luxuriant varity of the following, as it requires a very richly manured soil to preserve its characters and useful properties.

2. Wild teasel (D. sylvestris). In England a very common species about moist hedges and by road-sides, less robust than the foregoing; about 4 feet high. Leaves opposite, serrated. Scales of the receptacle straight. Common calyx inflexed, longer than the head.

3. Small teasel, or shepherd's staff (D. pilosus). This species grows in moist, shady places, on a chalky or limestone soil. This is a useless weed, but not troublesome to the farmer.

TEETH. See Age of Animals.

TEMPERATURE. See Atmosphere, Altitude, Climate, EARTH, Elevation, Meteorology.

TENANT (Tenens, from the Latin tener, to

4 S. 1033
TENDRILS. In law, one who holds or possesses lands or tenements by any kind of right, either in fee for life, for years, or at will. See Lease. TENDRILS. The curling, twining organs of prehension, by which some plants lay hold of others.

TEN-O’CLOCK. A troublesome perennial plant and weed, with a bulbous, fibrous root, difficult to destroy, as it will grow even years after the tops are cut off. Fields must not be ploughed. This foreigner has escaped from the gardens, and has become a grievous nuisance on many farms. Although it rarely perfects its fruit, the bulbs are propagated laterally with great rapidity; and are extremely difficult to extirpate. One native species has been found at the United States, on the Rocky Mountains. (Flora Cestrina.)

TETHERING. The practice of confining to precise limits or pasturage any kind of stock, by means of light chains or ropes fastened to iron pins (with swivel rings) driven into the ground. For the small farmer with indifferent fences, or for gentlemen with limited and ornamental lawns, this practice, which secures shrubs and pleasure-gounds from injury, is obviously often an advantageous system; and indeed a rich lawn immediately in view of a house is the finest decoration for tethering, as an imperfectly enclosed field would disappoint and demand a too frequent and therefore troublesome change of tether. The practice is almost universal throughout France, even in common farms.

THATCH. Straw, or any other dry vegetable substance, laid on the top of a building, thatch, &c., to keep out the wet.

There are many different sorts of materials that may be made use of as thatch, but the straw of wheat and rye, when well laid, forms the nearest and most secure covering for general purposes.

The reed is a highly valuable article for the purposes of thatch, where a lasting roof is required; but is much too expensive at first, although it is cheapest in the end. Reed is also thought to be too stubborn for common purposes. Fern is also occasionally used. See Fern.

THERMOMETER (Gr.). An instrument for measuring variations of heat or temperature, too well known to need description. See Atmosphere, Climate, Meteorology, &c. See also Table in next column.

THISTLE. A well-known prickly weed, common in corn-fields and pastures. Wherever this thistle grows naturally it is a sure sign that the land is strong, and of a tolerably good quality; but they are at the same time a great annoyance to every plant intended to be cultivated.

By an excellent regulation in France, a farmer may sue his neighbour who neglects to thistle his land at the proper seasons, or may employ people to do it at the other’s expense: and it were to be wished that a similar law was in force here, to prevent the wide-spreading mischief occasioned by the seeding of this pernicious weed among which may be reckoned, besides its choking the young corn, that if wheat in particular be not well thistled, the reapers take up the grip so tenderly, lest they should prick themselves, that, by their loose handling of them, they sometimes leave upon the ground corn enough to sow the whole field. There are no plants over which the economical farmer ought to keep a more watchful eye than the thistle tribe, as they are not only useless, but occupy much ground, and, being furnished with winged downy seeds, are capable of being multiplied and carried almost to any distance; besides, they do much mischief by impeding the work both in handling hay and corn crops. It is, of course, a matter of much consequence to be well acquainted with the qualities of each kind, in order to enable us to judge with certainty how far and by what means their destruction may be effected in the most certain and ready manner.

There are in England many sorts of thistles, but those which chiefly deserve the attention of the farmer are either of the annual, biennial, or perennial kinds. The annual species of thistle are the musk-thistle (Carduus nutans), the milk-thistle (C. marianus), the welded or curled thistle (C. acanthoides), the slender-flowered thistle (C. tenuiflorus), the common sow-thistle (Sonchus olera-
THISTLE.

The principal biennial thistles are the spear or bull-thistle (C. lancolatus), the marsh-thistle (C. palustris), and the cotton-thistle (Onopordum acanthium). The perennial species are two, the common saw-thistle (Senecio arvensis), and the common or field-thistle (Cnicus arvensis), or Canada thistle. The annual or seedless thistle (C. arenarius), the star-thistle (Centaurae calcitrapa), and the common cardine-thistle (Carlina vulgaris), are more frequently found to infest dry sandy pastures and calcareous soils than loamy or damp grass-lands. Where they prevail to a great extent, there is no remedy like breaking up the land and taking a course of crops; for palliative remedies are of little avail. Hand-weeding, when the seeds are confined to local spots, and are only just beginning to spread generally over the soil, will be found effectual; but when once the pasture becomes generally infected with the seeds and roots of these plants, no time should be lost in using the plough, harrow, and horse-hoe, and a judicious course of cleansing crops before returning the land again to permanent pasture.

Among the species of pasture-weeds that generally prevail in loamy soils, and are also prevalent in clayey and damp soils, are the marsh or red plume-thistle (Cnicus palustris), the meadow or small purple plume-thistle (Cnicus pratensis), and the melancholy plume-thistle (Cnicus heterophyllus). In crops of artificial grasses, such as sainfoin, lucern, &c., where the dwarf plume-thistle (Cnicus arenarius) prevails, and when it is impracticable, under such circumstances, to draw out this weed without injuring the crops, a good remedy will be found in the use of common salt. Children may be employed to apply the salt by hand to the crown of the weed. If the least part of the root of the thistle be left, it springs up season after season. Besides possessing this principle of vitality in the root, its seeds are so winged with down as to render dissemination, even to a great distance, by means of the wind, almost certain.

It is obvious that the annual and biennial species of thistles may be readily removed by preventing their running to seed and disseminating themselves, which is best effected by carefully eradicating them, or frequently mowing them over close to the surface, and rolling. But in the perennial kinds, from their roots continuing in the earth, increasing and throwing out new shoots or stems every year, there is much difficulty in extirpating them, and they perhaps can be no other way destroyed than by rooting them out of arable land by deep ploughing and frequent harrowings, or by following or laying the land down to pasture; the annual species seldom appear in pasture-lands. But for destroying the common thistles the best method is by weeding-pincers, or the finger and thumb when in loose land, cutting them over in the bleeding season frequently by weeding-knives, and applying salt to the cut stalk.

The most common thistle found in the United States is the C. lanceolatus, a biennial. The most troublesome pest, the C. arvensis. (See Canada Thistle.) Dr. Darlington thinks the yellow thistle a foreigner introduced into the United States. It is the most prickly of all the tribe, and hence called by botanists Carduus spinosissimus, and Cnicus hordius. The root of this is considered by some biennial, by others perennial. The tall or tallest thistle (C. altissimus), is common along fence-rows, &c., in the Middle and other States. The small thistle (Carduus Pilula), is common in Pennsylvania and other Middle States, growing in old fields, &c., from 1 to 2 feet high, with flowers of a pale reddish-purple, and quite fragrant. The heads are handsome, and the largest of any other American species. Several other species of thistle are found in the United States. See Canada Thistle.

THISTLE, PLUME (Cnicus). This is a separation from the genus Carduus made by Sir J. E. Smith. They are prickly, herbaceous plants, and differ chiefly in the down being evidently feathery, not merely rough. The biennial species may be readily destroyed by mowing before the flowers form seed. There are in England nine indigenous species of plume thistle. Some of which are common in waste ground, moist meadows, &c. Those which give most trouble to the farmer are, the Marsh plume-thistle (C. palustris), a biennial, growing plentifully in moist meadows or pastures, and watery spots by road-sides. Stem from 3 to 6 feet high.

Creeping plume-thistle (C. arvensis). A very troublesome perennial weed in cultivated fields and by ways-sides, from its fleshy root, which is very tenacious of life, creeping deeply into the earth to a great extent. Stems 3 or 4 feet high.

Branching bog plume-thistle (C. Forsteri). A perennial, flowering in July and August, with a tapering root.

Woolly-headed plume-thistle (C. criophorus). A large and conspicuous perennial plant, growing in waste mountainous ground, and by roadsides, on a limestone or chalky soil.

Melancholy plume-thistle (C. heterophyllus). A perennial, growing in moist mountain pastures in the north.

Meadow plume-thistle (C. pratensis). A perennial, growing in low, wet meadows and pastures, especially among trees. Root fibrous.

Dwarf plume-thistle (C. arenarius). A perennial, growing on chalky and gravelly soils. Root woody, running deep into the ground. Stem entirely wanting. The large bright-green leaves, spreading close to the ground, in a circle near a foot in diameter, choke all other herbage.

THORN (Crataegus). A name given to several indigenous shrubs and small trees. See Black-Thorn, Buckthorn, Hawthorn, White-Thorn, &c.

Of this genus of thorny trees so valuable in an agricultural point of view, there are many species and varieties. Dr. Darlington describes the following as found in Chester county, Pennsylvania: 1. The Newcastle or cockspur thorn (C. crus galli). Two varieties of this exist, the most common of which is much employed in making the fine hedges for which New-carlton county, Delaware, is celebrated. Dr. Darlington thinks that, with proper management, this kind will ultimately make a more
durable and effective hedge than the Washington thorn (C. cordata), which is now generally used in Chester county. It is a more rugged plant, and seems to be less liable to disease, or to be injured by insects, than the Washington thorn (C. pumila)."

2. The small-leaved thorn (C. parvifolia), a rugged little bush abundant in New Jersey.

3. Thorn-bush or dotted crataegus (C. punctata), a red-fruited variety. The fruit is large, half to two-thirds of an inch in diameter, mostly three-seeded, red, sometimes yellow when mature, dotted and esculent.

4. Black-thorn (C. flava), yellow crataegus, an apparent misnomer. The fruit is pear-shaped, large (about half an inch in diameter), three or four-seeded, greenish-yellow, with a tinge of dark red when mature, esculent, but rather insipid.

5. White-thorn or crimson crataegus (C. coccinea). This is the most common species in Chester county, Pennsylvania. The thorns have more resemblance to the cock-spar, than those of the real Crataegus or Newcastle thorn. The fruit is one-third to half an inch in diameter, and bright purple when mature.

6. The Washington thorn (C. cordata). This species, says Dr. Darlington, was introduced into Chester county from the neighborhood of Washington city, and is now extensively used in hedging. It grows fast in favourable situations, under good management, and will make a handsome hedge in about 10 years from the time of planting. It does not succeed well on dry, rocky banks, and especially in the red shale districts. The young branches are also subject to disease from the puncture of insects. "I have used this thorn," says Dr. Darlington, "to a considerable extent, and have succeeded in obtaining some pretty fair hedges; but I am now strongly inclined to the opinion that the C. crus gollii, or cock-spar thorn, is entitled to the preference, for that object. One important fact, however, applies to every sort of thorn, and should be remembered by all persons who undertake hedging, which is, that if they are not carefully attended to, and skillfully managed, the hedges will become a nuisance and a source of vexation, rather than a benefit, and had better never be attempted. With due care and skill, they make a valuable and ornamental enclosure.

7. Hawthorn or English thorn (C. oxyacantha), sharp-thorned crataegus. This species (of which there are several varieties in Europe) was introduced many years ago, and is apparently naturalized in a few localities; but does not seem to extend itself much. It is said to be the favourite thorn for hedging in England; but is rarely applied to that use here. Some 10 or 12 additional species have been enumerated in the United States; but the genus stands greatly in need of a careful revision. (Flora Cestrica.)

Many species of the thorn genus are highly ornamental. Of these the most beautiful of all thorns when in bloom, is the C. oxyacantha rosea superba, with deep crimson flowers and small red fruit. The sweet-scented thorn (C. odoratissimum) has very large, pale red fruit. The large tansy-leaved thorn (C. leptane), has large pale red fruit. The small black-fruiting thorn (C. Oliveriana), bears very profusely, but matures late. The new double-scarlet is a most beautiful variety of the C. oxyacantha rosea superba, just mentioned.

THORN-APPLE (Datura). An ornamental genus, composed of plants possessing very deleterious qualities. One species indigenous to England, is the common thorn-apple (D. stramonium), an annual, which grows in waste grounds and dung-hills. It is a bushy, fetid herb, 2 or 3 feet high, of a narcotic quality, and greatly in repute as a remedy for the asthma, being smoked like tobacco. The leaves are ovate, smooth, sinuate. The flowers are axillary, erect, white, sweet-scented, especially at night, about 3 inches long. Fruit as big as a walnut in its outer coat, very prickly. Seeds black. In the United States it goes by the name of Jamestown weed, doubtless from the place where it was first naturalized, in Virginia.

THRESHING, or THRASHERING. The act of beating out the corn from grain or other crops. The flail was the implement formerly used for threshing corn, and which separated the grain from the straw and husks very effectually and expeditiously; but as it is now become expensive, and always bruises a great many seeds, it has been attempted to avoid these inconveniences by proper machines provided with a number of flails, or other parts answering the same purpose, made to move by the power of water, wind, or horses. By this means the business of threshing is found to be performed cheaper, more expeditiously, and with less damage to the health of the thrasher, which is frequently thought to be injured by the dust, &c., which arises in the common way of threshing, as well as by the extreme laboriousness of the work. Various machines for effecting the purpose of threshing have been lately invented. See Flail, and Threshing-Machine.

THRESHING-MACHINE. To the farmer on an extensive scale, the threshing-machine is absolutely necessary. The farmer wait for the tedious operation of the flail to prepare a delivery of corn for a given day, or pressing purpose; nor can he, without the risk of pilfering and imposition, keep his barn constantly open for threshers. The flail, however, is still the implement in general use among all who farm on a scale not sufficiently extensive to require any of the complex machinery which modern skill has invented. The advantages of the flail are, its simplicity, the power of giving employment to the labourers in the barn during wet days, and the convenience of having fresh straw for fodder every day.

The following description of the threshing-machine is chiefly derived from the valuable essay On Agricultural Implements, by Mr. J. Allen Ransome, of Ipswich, England.

In ancient times various modes of threshing out grain were resorted to, and we read of "the bruising with the cart-wheel," "the sharp threshing instrument having teeth," "the trampling under the feet of the unmuzzled ox," or "the rollers plain or fluted" mentioned in the later practice of continental agriculture. But of all these the flail alone remains in use-
THRASHING-MACHINE.

in England; and it is with this instrument, preserving very nearly its original form, by which till very lately the entire growth of corn and seeds in this kingdom were thrashed.

That the flail may be made thoroughly to effect, though at great cost of labour and time, the purpose of clearing the grain without damage either to the corn or the straw, is a point none will be inclined to dispute. But the disadvantages attending its use are not confined to waste of labour and time; for, though it may be granted that the separation of the grain, properly performed, may be perfect, how difficult it is to secure its proper performance, every agriculturist whose journeys to his barn have from time to time interrupted his surveys of other not less important agricultural operations, can fully testify. It is evident that the latter part of this operation will require much more labour to produce a given quantity than its earlier stages; and hence the straw is frequently passed away partially thrashed, in order to procure a greater bulk in a given time. Nor are these disadvantages all with which we have to contend: constant inspection really, perhaps, is something, may be required; but not attention will altogether suffice to remove the temptation to pilfer, which is continually presented where large quantities of grain are ever under the eye and in the possession of those to whom a small portion is of great importance; and hence arises, even when undetected, and often indeed when not committed, a cause of painful temptation on the one hand, and injurious suspicion on the other.

To overcome these evils, prejudicial not only to the true economy of the farm, but to those feelings of confidence which, justly to sustain the social bond, should ever exist in the relation between the labourer and his employer, the attention of our enterprising neighbours in Scotland was first directed to the construction of machinery; and in 1732, Michael Menzies, a gentleman of East Lothian, invented and patented a machine for thrashing grain.

We regret that, as nothing but the bare record of this invention is enrolled in the Patent-office, we have not been able to learn more of this, the germ of the thrashing-machine invention, than that it was a contrivance by which a series of flails were made to revolve upon a cylinder; but we are pleased to be able in some degree to redeem it from the "condemnation of faint praise," with which we find its memory generally accompanied, by reference to the report of a committee appointed by the Society of Improvers in Scotland, to inspect its operation, and determine upon its merits. This committee, after various trials, reported it to be "their opinion that the machine would be of great use to farmers, both in thrashing the grain clean from the straw and in saving a great deal of labour; for one man would be sufficient to manage a machine which would do the work of six." They further recommended the society "to give all the encouragement they could to so beneficial an invention, which, being simple and plain in the machinery, might be of universal advantage." The society approved of the report, and acted upon the recommendation.

During the next period of twenty years we are not aware of any other attempts to carry out the object of thrashing by machinery; but in 1753-8, Michael Sterling, a farmer in the parish of Dumblane, Perth, applied the principle of the mill in common use for holling flax to this purpose. This mill had a vertical shaft, with 4 cross arms enclosed in a cylindrical case, 3 feet 6 inches high, and about 8 feet in diameter. The shaft was made to turn at considerable velocity, and the sheaves were gradually let down from an opening at the top; the grain and straw, after being subjected to this beating, were then pressed through an opening in the floor, where rakes and fanners completed the separation of the grain from the straw and chaff. It was, however, found that this machine broke off the ears of barley and wheat instead of clearing them of the grain, and that at best it was only fit for oats.

It is curious to trace the various plans by which the desideratum of thrashing by machinery was attempted to be accomplished; a few of these we shall venture to bring before our readers, as a slight sketch of the experiments which may suffice satisfactorily to show that in following out the principles which distinguish Meikle's machine (hereafter to be mentioned), little of value has been lost to the public of those which have fallen into desuetude. In 1772, two gentlemen residing in Northumberland, Alderton and Smart, invented a machine, by which the sheaves were carried round between an indented drum of 6 feet diameter and a number of fluted rollers, which, pressing by means of springs against the fluted concave, rubbed out the corn from the ears; and in 1785, William Winlaw, of Mary-le-bone, patented an invention which he denominated a "mill for separating grain from straw."

This mill was made on a principle similar to the coffee-mill, but was found to exceed the simple object proposed in the specification, by grinding the grain as well as separating it from the straw. Other machines upon the plan of rubbing out the corn were also tried, but, on account of the damage done to the grain, were discarded. In addition to the mill invented by Winlaw, a machine was in 1792 patented by Willoughby, of Bedford, Notts, the principle of which appears to have been somewhat similar to that of Menzies; how nearly so, we regret we have not the opportunity of judging. It comprised a series of loose flails made to act upon a grated floor, and turned rapidly round by means of a horse-wheel. The straw was presented by hand to the action of the flails.

In 1795, an individual of the name of Jubb, residing at Lewes, obtained a patent for an invention of which the principal feature was the passing the straw between two rapidly revolving beaters, under which it was held by two feeding rollers, whence the corn fell into a winnowing-machine. The inventive talent of the Americans was at this time brought to bear upon this important subject. James Wardrop, of Amphil, Virginia, invented a machine, which was introduced into England about 1796, to be worked by two men; it was made with flails or elastic rods 12 feet in length, of which 12 were attached 4 & 2

1037
in series, each having a spring requiring a power of 20 pounds to raise it 3 feet high at the point; a smaller shaft, with catches or teeth, in its revolution successively lifted each flail in alternate movements, so that three of the flails were operated upon by the whole power, viz., 20 pounds. The flails beat upon a grating to which the corn is introduced by hand.

In 1785, Andrew Meikle, an ingenious mechanic of Tyningham, East Lothian, first introduced to the public, through the medium of a gentleman named Kilbowie, the invention whose principle has been the basis upon which the machines in use in Britain up to the present time have been mainly constructed. It appears that, his attention having been long turned to the subject, he discovered that the plan of rubbing would never be otherwise than attended with the disadvantage before alluded to; and his son George agreed with the gentleman above named to erect a perfect machine, and in 1786 he completed the first that was ever made, adopting the plan of introducing between two rollers the corn, which was then thrashed out by flails, instead of a revolving drum. Each striking, as it revolved, the corn held between the rollers. The machine alluded to was erected, and found to work exceedingly well. A patent was accordingly applied for, and, after some opposition from a party not concerned in the invention, obtained.

In the trials between the erection of the original machine and the obtaining the patent, a new principle appears to have suggested itself, viz., that of stricking off the corn from the ear by a comparatively sharp edge, or, as termed by him, "scutching out the grain," instead of beating it by a flat surface. The difference has been partially illustrated by supposing a handful of straw with the corn in the ear to be held in the hand, while with the flat sides of a two-foot rule the ears should be struck or beaten; this is the operation of the common beater. If, instead of striking the ears with the flat side, a sharp blow be given with the thin edge of the rule in the direction of the ear where the rule touches, it will strip the corn from the ear with less labour and with greater certainty. This may be called the scutching principle to which Meikle's beaters in his patent were applied.

It will not be uninteresting to learn, upon the authority of Sir John Sinclair, "that the inventor of this important machine was rendered comfortable in his old age, and enabled to provide for his family after his death, by the voluntary donations of his grateful countrymen." Not less gratifying is the testimony of Professor Low, in his admirable treatise on the Elements of Practical Agriculture, that "to Andrew Meikle, beyond a question, belongs the honour of having perfected the thrashing-machine. Changes and improvements have indeed been made on certain parts of the original machine; but in all its essential parts, and in the principle of its construction, it remains as it came from the hands of its inventor."

By the drawings and specification of Meikle's machine, it appears that, at the time of taking out this patent, the plan of shaking the straw by means of circular rakes had not been sug-
THRASHING-MACHINE.

The thrashing part, commonly called the barn work, occupies a space of 6 feet by 4 feet, and the apparatus by which motion is communicated (which is made either for 2, 3, or 4 horses' power), may at pleasure be elevated upon a pair of wheels and axle, and thus removed by two horses.

Many of these machines are made by persons who possess little claim to any mechanical knowledge, and who, purchasing the unfitted castings, by the help of village artisans, produce an imitation of those which are considered good. As the perfection of these machines must depend upon mathematical accuracy in the adjustment of all their parts, and in the truth and precision of their fittings, it is unreasonable to expect that this can be accomplished where no facilities exist beyond the forge and the work-bench; and hence arises a degree of discredit, which is unfairly thrown upon the principles upon which the machine is constructed.

With these machines, properly constructed, barley may be thoroughly thrashed with as little or less damage than with the flail, and wheat straw need not be so broken as materially to diminish its usefulness even for the purpose of thatching. We cannot, with Sir John Sinclair, reckon the circumstance of breaking the straw one of the advantages of thrashing by machinery, as we do not think it desirable that any slovenly performance of the thrashing-machine should trench upon the legitimate occupation of the chaff-engine; and we repeat our opinion that all disadvantages from the above-mentioned causes may, by a well-constructed machine and a competent manager, be entirely remedied.

The latest patent which is at present in operation is one taken out by Joseph Atkinson, of Braham Hall, Yorkshire, which appears to be of American origin. The thrashing or beating mechanism is obtained by means differing from any previously mentioned; the drum being surrounded by a series of pegs, so arranged as in its motion to pass similar rows of pegs placed at intervals in a concave, surrounding nearly one-half of the circumference of the drum. This machine is not at present so fully introduced into England as to afford opportunity for fairly testing its comparative merits; and it would be unfair to give, upon slight evidence, an opinion which may have any tendency to increase the difficulty of the introduction of a new article. We can therefore say little more than that while such trials as have fallen under our notice in this case are not calculated to show its superiority, we are inclined to the belief that the principle is not so defective as to prevent its being carried out to advantage, under such modifications as may be suggested upon further trials.

We have now to draw the attention of our readers to a machine in operation upon Lord Ducie's example-farm at Whitefield, of which it is probable, in a forthcoming report of that interesting establishment, that a full account, accompanied by the necessary drawings, will be given. Through the kindness of the manager, John Morton, in accordance with whose suggestions it was constructed, we have been favoured with an opportunity of witnessing its performance, and with the following description, which we have, with his assistance, written down:

"This machine is worked by a steam-engine of six horse power. The corn is brought from the stack upon wagons running along a tram-road upon an inclined plane, to the doors of the building, whence, shewn by hand, it is thrown by children into the buckets of an elevator, which, in its rotation, carries them to the feeding-board. This feeding-board is placed at a tangent from the drum parallel with its top; and, as in Lee's machine, and the portable machines in Suffolk and Norfolk, the feeding-rollers are dispensed with, an endless web gradually carries the unthrashed straw to the feeding-mouth, from which the revolving scutches rapidly convey it to the concave.

"The drum and concave, being the part on which the separating of the corn or thrashing principle depends, we shall first describe:

The drum is about 18 inches diameter, formed of sheet-iron strained round a cast-iron skeleton accurately turned; upon this the beaters, or rather scutches, formed of angle-iron with its edges planed, are so placed as to describe an angle with the surface of the drum, pointing forward in the direction of its motion; these project about seven-eighths of an inch. The screen or concave encloses the drum to the between about one-third of its circumference, and consists of 4 or 5 arched pieces of grating, 3 inches wide, jointed together. It is made of cast-iron bars, having a square section placed so that every one shall present an edge to the passage of the straw, uniting (as is not uncommon in other machines) the fluted concave of the Scotch machine with the wired grating of the English ones; the screen is supported on iron bolts, so that it approaches to within about one-eighth of an inch of the edge of the scutter. Spiral springs surround these bolts, which permit the bars of the concave to yield when too much pressure is put upon them, and the revolving drum. The grain is thus separated, most of it passing through the screen of the concave; but in order that no grain shall be allowed to pass away with the straw, it is thrown upon the shaker below.

The motion given to the straw by this shaker is the most perfect we can conceive; the blows occasioned as each series of strakes strike it from beneath, effectually remove every particle of loose grain, while the shaker rapidly carries forward the straw, and at its termination deposits it in the straw-house, while the corn sifted out by its action falls before the blast of a fanter (the construction of which is peculiar); and all the light grain and short straws thrown out by the first winnowing into the light corn spout is then taken up by another elevator, deposited again upon the feeding-board, and passed a second time through the drum, in order effectually to separate any that may remain. After passing through another winnower, the thoroughly cleaned corn is taken up by a third elevator, and dropped again upon the feeding-board, and passed a second time through the drum, in order effectually to separate any that may remain. After passing through another winnower, the thoroughly cleaned corn is taken up by a third elevator, and dropped again upon the feeding-board, and passed a second time through the drum, in order effectually to separate any that may remain. After passing through another winnower, the thoroughly cleaned corn is taken up by a third elevator, and dropped again upon the feeding-board, and passed a second time through the drum, in order effectually to separate any that may remain.
We have introduced at length the description of this machine, or rather series of machines, as being the most complete of any that have fallen within the range of our observations. In the thrashing-machine, performing every operation, from receiving the sheaf at the barn-door to depositing its grain in a clean state weighed up in the sacks, and excellent in the greater part of its detail, which is carried out, both as regards ingenuity and workmanship, in a style very superior to the general character of agricultural machines.

With regard to the moving power most advantageously connected with the thrashing-machine, it may be observed, that where the locality admits of the use of a water-wheel, this power is most economical and easily managed; but the advantage is limited to peculiar situations.

Where the quantity of work to be performed is sufficient to repay the interest of outlay, expense of wear and tear, &c., a steam-engine would be most advantageously employed on the farm. Of its economy, as compared with either horse or manual labour, there need be no question. But as few farms in England at present have these appendages, the question for consideration is narrowed to the comparison between horses and manual labour. On the authority of Dr. Gregory, the dynamic power of a horse at a dead pull may be calculated in the main as equivalent to that of six men, or to 420 lbs., if exerted in a direct line; but the result of experiments made by Tredgold tend to prove that sustained effort at the rate of three miles per hour must not be calculated at more than equivalent to 120 lbs. drawn over a pulley. This, taking six hours of labour per diem as the utmost he would recommend, would be the maximum of useful effect. Under the circumstances of any deviation from a straight line, this must be materially reduced; and in describing a circle of 18 feet radius, the cramped position of the horse will probably prevent his power from being advanced to the extent of much more than half. It will, therefore, be seen that a very large proportion of dynamic effort is wasted; and this not only arises from the constrained position of the horse’s movement, but from the friction of the mill by means of which motion is communicated to a machine.

It is affirmed by Emerson that a man of ordinary strength, turning a roller by the handle, can act for a whole day against a resistance equal to 30 lbs. weight; and if he works 10 hours a day, he will raise this weight through 31 feet in a second, or about 53 miles per hour. At this power, however, so varied by the character of the exertion, that it is difficult to arrive at a correct calculation. The late Roberton Buchanan ascertained that in the action of working a pump, of turning a winch, of ringing a bell, or rowing a boat, the dynamic results were respectively as the numbers 100, 167, 257, and 248. See Strength.

Having caused a machine with beaters to be constructed, worked by 4 men whose force should be exerted as in the manner of rowing a boat, the results, as compared with a machine requiring the force of 4 horses in a circle of 18 feet radius, we found might be taken on an average as 5 to 12. It was thought the continuous effort might be for an equal length of time exerted by 6 men relieving each other at intervals, as by the same number of horses relieved in the same way.

We have not yet had opportunity to repeat the experiment; and we instance this only to show that, although advantage may be on the side of horse-labour for large quantities, manual force is not so applicable to this object as most writers have represented it to be; and we are of opinion that, on small farms, hand-machines may with great advantage be used. A simple and effective hand thrashing-machine, which was exhibited at the Royal Agricultural Society’s meeting at Liverpool, obtained the commendation of the judges (vide their report). It is worked by 4 men, and the moving power being obtained by means of a lever on the one side, and by a crank handle on the other, the men working it may relieve each other by change of motion. It requires one man to feed the machine, and the number of hands necessary to bring the sheaves and remove the straw will depend upon the distance it has to be conveyed. When the straw is short, and the wheat of average yield and in good condition, it will thresh at the rate of 12 to 16 bushels per hour.

In England, most of the thrashing-machines of former days varied considerably, and their performances were very unequal. It may not be uninteresting to compare them with those of the present day. The following are extracted from the Agricultural Reports:

In the reports of Roxburgh and Solkirk, in 1769, R. Douglas states that

In the report of Kent, R. Boys, in 1855, remarks on the only thrashing-mill then in Kent, which, by a number of improvements, and after many alterations, he finds to answer extremely well; and he states that it requires 4 horses and 12 men to work it.

In Sir John Sinclair’s System of Husbandry, published in 1812, we find an account of R. Kerr’s machine, which, with 6 horses, 4 men, and 4 women, would thresh

1406.
THRASHING-MACHINE.

Considerable improvements have since been effected. In the statements of the trials of improvements at the Royal English Agricultural Society's meeting at Cambridge, in 1841, the quantity of wheat thrashed by two four-horse portable machines manufactured by J. R. and A. Ransome, of Ipswich, and being rendered fit for market, Son, Leiston, was respectively 61 bushels and \( \frac{3}{4} \) of a peck, and 61 bushels and \( \frac{1}{2} \) of a peck per hour; and the corn was clean thrashed and uninjured.

This must not be taken as a criterion on which to found an average, as it was doubtless the result of stimulated exertion; but it is not unusual with machines of this construction, with reaped wheat in fair condition, to thrash 100 co. or 400 bushels in a day of 10 hours, and the same quantity of mown barley.

It should, however, be observed, that these, having neither rakes nor fans, the work of which is done by hand, would require 8 men and 5 boys, and a change of horses in the day.

Thrashing-machines are now very generally used in the United States, to get out the crops of wheat, &c. Before their introduction flails were employed in the Northern and Eastern States, whilst in the Middle and Southern States, treading with horses and cattle was the customary mode of thrashing. The cost by employing the flail was generally estimated at 10 bushels out of every 100, which, when wheat was a good price, proved very expensive. The employment of horses, though expeditious, is very objectionable, the grain being rendered gritty and filthy, so as to lessen its value in the market. The practice, too, of setting horses at such hard and peculiar work in hot weather proved injurious and often destructive to them.

The notice furnished in this article of the successive improvements made in Britain, in contrivances for thrashing out grain, will show the efforts there made and the results obtained. Ingenuity would seem to have been still more actively employed in the same pursuit in the United States, where, within a few years past, many improvements of machines obtained. The improvements and inventions of the thrashing-machine. These have nearly all involved two main principles: 1st, a beater consisting of bars; and, 2dly, a cylinder furnished with spikes instead of bars. This last may perhaps be called the American principle, \textit{par excellence}.

Where bars are used, the machine requires an increased velocity equal to 300 revolutions per minute, over what is requisite. Where the cylinder is furnished with spikes, it is for this reason chiefly, that the spike machines have been so much more generally used. It must, however, be observed, that where the beater is composed of bars, the force required to work the machine is about one-third less in performing the same amount of work. In Eams's patent, the bars are of wrought or cast-iron, notched on the edges.

Pitts's Thrasher and Separator is considered a machine by which a great saving of labour is effected over the ordinary machines, the operations of thrashing and cleaning being performed at the same time. The bundles are led to the machine at one end, and the clean seed, without a kernel being scattered, taken from the other. Its weight is about 700 lbs., and it occupies a space about 8 feet by 2 feet 4 inches. The whole machinery is durable, and easily kept in repair. It thrashes and cleans all kinds of grain in the best manner, performing the work at the rate of from 25 to 50 bushels per hour. Four hands are required to tend the machine when in operation, viz.—one to forward the bundles, one to feed, one to measure and put the grain into bags, and one to pitch the straw away as it comes from the machine. It can be easily moved from place to place, and attached to any horse power, and can be used in the field as well as on the thrashing-floor, there being no loss or scattering of grain after it is once fed into the machine. The late Judge Buel considered this machine as the best adapted to the purpose of any he had ever seen.

**Horse Power.**—The power almost universally employed to propel thrashing-machines in the United States is that adapted to horses. These are generally of a description which admits of transportation along with the machine from place to place. They are of two kinds, one called the sweep power, in which the horses attached pass round in a circle; the other called the endless chain or tread power, where the horse or horses move as if walking or trotting, but in consequence of the rotation of the endless chain of bars on which they are placed, always remain in the same place. \textit{Mixe's cast iron portable sweep power} is generally considered the best now in use, in the Middle States at least. Its weight is from 700 to 1000 lbs., and the price $80 for a two-horse, and $90 for a four-horse power.

The \textit{endless chain or tread power} is coming into very general use, being specially adapted to farms where there is much barn or shed-room, admitting of the thrashing being done under shelter; whereas, with the sweep power, the operations require the open yard.

The tread power, called Pitts's, is now in high repute. These, as well as all other kinds of machines used in the thrashing, are very extensively manufactured in Wilmington, Delaware, by Hollinsworth & Co., and may also be had of Mr. Chandler, manufacturer of agricultural implements, 196 Market street, Philadelphia, as also at most of the numerous depots for agricultural implements in that and other cities in the United States. The price of the one-horse endless chain power is $75; of the two-horse do., $85. It is said that a two-horse tread power is equal to a four-horse sweep power.

**THRAVE.** A quantity of grain, consisting of 24 sheaves. It is sometimes written thrave.

**THRIFT.** \textit{(Statice, from statize, to stand)}; in allusion to the powerful astringency of some of the species. The species of thrift ought to be in every garden, on account of their lively little flowers. There are three indigenous species of thrift or sea-lavender, all perennial, viz.—

1. The \textit{common thrift}, or sea-gilliflower \textit{(S. Armeria)}, which is a common ornament of rustic gardens, where it serves for edgings of flower-beds; nor does this plant suffer much
THRIPS.

The Thrips, or vine-fretter, as it is often called, is a very minute, light-colored or spotted fly, exceedingly active in all its motions, and appearing to leap rather than fly. They live on the buds, leaves, and flowers of plants, being so small as readily to escape notice, unless particular attention is directed to them. They are generally found by observing the effects of their apparently poisonous bites which produce deformities in the leaves or blossoms, causing these often to swell or curl up. The peach tree occasionally suffers severely from their attacks, as well as from those of plant-lice, to which family of insects they are allied. (Harris on Destructive Insects.) A remedy for thrips will be found, with the mode of using it, under the head of Aphis.

A new disease of the plum tree, occasioned by thrips, is described by Dr. Harris, in Hovey's Horticultural Magazine.

THYME, GARDEN (Thymus vulgaris, from Svis, courage, being considered a reviver of the spirits; or from Svis, to sacrifice, being employed as incense). The varieties are,—the broad-leaved green, narrow-leaved green, variegated, and lemon-scented. The variegated is grown almost solely on account of its ornamental value. A good large, and dry soil is best suited to it. In moist or rich ones, it becomes luxuriant, but deficient in its aromatic qualities, and generally perishes during the winter. The situation cannot be too open.

Thyme is propagated both by seed and rooted slips. Sowing may be performed from the middle of March until about the beginning of May. Slips may be planted from the beginning of February until the close of May.

The seed must be sown neither thin, nor raked in more than half an inch below the surface. It is sometimes sown in drills of a similar depth apart, or as an edging to a bed or border. The seedlings must be kept clear of weeds, and, if the season is dry, watered moderately twice a week. When of about six weeks' growth, or when 3 or 4 inches high, they require to be thinned to 6 inches apart, unless grown as an edging, when they must be left thick. Those removed may be pricked out to a similar distance, if required. Water is required occasionally until they have taken root. The plants may be left in the situations they are placed in at this season, or be finally planted out in September or October, or in the early spring of the following year. To obtain slips, some old stools may be divided into as many rooted portions as possible, or layers may be obtained by loosening the soil around them, and pegging the lateral shoots beneath the surface. They must be planted out at distances similar to those raised from seed, water and weeding being similarly required.

In autumn the decayed stalks should be cleared, and a little fresh earth scattered and turned in among the stools.

Although this herb is perennial, yet after 3 or 4 years it becomes stunted and unproductive, consequently requiring to be raised periodically from seed. For the production of seed, some plants should be allowed to run up without being gathered from in early summer. The seed is ripe during July, and must be cut immediately it is so, and laid on a cloth to dry, otherwise the first rain will wash it out of the seed-vessels.

THYME, WILD (Thymus). A genus of aromatic, pungent, branched, somewhat shrubby plants, belonging to the natural order Labiatea. They are often diffuse in England, and of humble growth: in some instances annual. The common wild thyme (T. serpyllum) is plentiful almost everywhere, particularly on heaths and dry mountainous ground. The odour of the plant is gratefully aromatic. Bees are fond of the flowers. Whether, as alleged, the quality of the thyme is improved by the sheep feeding on this plant, or on fine, short grasses which usually accompany it, is still a matter of great doubt. See Basil, Calamin, and Thyme.

TICKS. See Sheep, Diseases of.

TILLER. A term applied to the branching of the stems of wheat, &c., from the roots.

TILTH. The condition of the earth after ploughing, &c.; or the state of the soil in respect to tillage as relating to manuring.

TIMBER (Germ. zimmcr; Dn. timmerhout). The term used to express every large, tree squared, or capable of being squared, and fit for being employed in house or ship-building.

TIMBER TREES. See Trees, Plantations, and the several indigenous trees, under their alphabetical heads.

TIMOTHY GRASS (Phleum pratense). See Cat's-Tail Grass.

TINE. A tooth or spike placed in any implement, but especially in the harrow kind. See Harrow.

TOAD (Rana bufo). A well-known and much dreaded, though perfectly innocuous reptile of the frog genus, which feeds on insects, flies, ants, &c. It is preyed upon by owls, buzzards, snakes, &c.; otherwise the toad attains to an age, which in some species is remarkable instances of which have been recorded.

Dr. H. Storer, in some remarks upon reptiles furnished by him to Professor Hitchcock, and published in the Zoological Survey of Massachusetts, observes:—Great errors also exist with regard to the order Batrachia. The acrid secretion found upon the skin of the Hyla versicolor, the toad, and several species of efts and newts, has caused them to be considered venomous—which is incorrect. Every species of this order is inoffensive, and, when better known, will undoubtedly be found beneficial to man.

In some countries, the flesh of the different Rana, frogs, is an article of food. With us,
TOAD-FLAX.

TOAD-FLAX. A name applied to two per-ennial species of Antirrhinum. 1. The creeping, pale blue toad-flax (A. reptens) is a rare species, growing on chalky banks or rocks near the sea. The herbage is smooth and glaucous, stem panielle, leaves linear, scattered, partly whorled; flowers sweet-scented.

2. Common yellow toad-flax (A. linaria), which is common about hedges and the borders of fields. The leaves are linear-lanceolate, crowded; stems erect; spikes terminal; flowers terminal, inodorous. (Pl. 10, x.x.) See Fluellin and Snap-Dragon.

Common linaria is found in the Middle States, where it bears the names of toad-flax, butter-and-eggs, and Ramstead-weed. It is a foreigner, frequenting fence-rows and pastures, where it is a showy but very obnoxious weed. (Flora Cestrica.)

TOAD-FLAX, BASTARD. See Bastard TOAD-FLAX.

TOBACCO. Botanists have given this well-known American plant the generic name of Nicotiana, from John Nicot, of Nmes, in Languedoc, ambassador from the King of France to Portugal, where he procured the seeds from a Dutchman who had derived them from Florida. The first plant was said to have been presented by Nicot to Catharine de Medicis, whence the former French name, Herbe à la Reine, or the queen's plant. The name tobacco, which has superseded all others, is an appellation acquired from the place from whence it was originally most generally derived, namely, the island of Tobago, in the West Indies. According to Linnaeus, tobacco was known in England as early as 1586, but only the herb for smoking, a practice introduced into England by Sir Walter Raleigh, who acquired it from Captain Lane. In the house in which he lived at Islington are his arms on a shield, with a tobacco plant on the top. Smoking has consequently been common in Europe for upwards of two centuries. It is a powerful narcotic, and also a strong stimulant with respect to the whole system, but especially to the stomach and intestines, to which, in small doses, it provokes emetic and purgative. The smoke thrown up from the aromatic tobacco, and the infusion of the leaves forms a powerful lotion for obstinate ulcers. The decoction, powder, and smoke of tobacco are used in gardening to destroy insects, and in agriculture for the same purpose, and to cure cutaneous eruptions in domestic animals.

Botanists have identified many different species of tobacco, and Loudon, in his Encyclopaedia of Plants, makes the following list of those enumerated under the generic head of Nicotiana, with the places from which they were derived—

In the 4th plate there are representations of the species known as Virginia tobacco (Nicotiana tabacum, f), common green tobacco (N. rustica, g), Havana repanda (h), of which the fine and fragrant cigars are made; the Quodriavialis, or four-leaved tobacco (i), and the Nana, or dwarf species (k), both of which last are used by the Indians of the Rocky Mountains.

Tobacco is cultivated in Europe as far north as Sweden, and is also grown in China, Japan, and other eastern and hot countries. The sort most generally preferred is the Virginia species, a very beautiful plant. The common green kind (N. rustica), is also frequently cultivated, especially in Europe, it being considered harder than the Virginia sort. Parkinson says he has known Sir Walter Raleigh, when prisoner in the Tower, prefer it to make good tobacco, "which he knew so rightly to cure." Tobacco has been successfully cultivated and cured in England, but its growth is prohibited as a crop, and it is now only grown for curiosity as a border flower, or by gardeners for the destruction of insects. In Germany and other northern countries, most families who have gardens grow enough of N. rustica for their own use; but as they do not know how to cure it properly, it is not much valued, and is never made into chewing tobacco or snuff, but used for smoking.

Although tobacco, an annual plant, may be brought to maturity in almost every country, even in Russia and Sweden, with their temperate summers, still will the plants, under such unfavourable circumstances, be small, and their flavour weak. In long, moist, and not very warm summers, such as those of Ireland, the plants may attain a very large size, but they will not have that superior flavour which can only be derived from abundance of clear sunshine, and free, dry air. The fragrant tobacco of Havana and Lucania may retain pre-eminence for smoking, but for all other purposes the peculiarly high and rich flavour of the tobacco of Maryland, Virginia, and neighbouring states must always give it preference, both at home and abroad.

It will be seen from an estimate furnished Congress by Mr. Ellsworth, Commissioner of Patents, of the agricultural products of the United States in 1842, that tobacco, though cultivated in every State of the Union, constitutes a staple crop in comparatively few, namely, Virginia, Maryland, North Carolina, Kentucky, Tennessee and Missouri. The crop of the year mentioned, was below the average, and in Virginia not over two-thirds of the regular crop, being both light and of bad quality. It was distributed as follows:

The remainder of the 100,000 hogsheads is distributed through the German States, Sardinia, Hungary, &c. &c. We have been unable to ascertain the precise duties paid in all cases, but the enormous rates of those ascertained, and the fact that the tobacco import is in most of the countries of Europe carried out for a stipulated sum, renders it certain, that while none are below what is here named, some of the highest much exceed the almost prohibitory imposts of Great Britain. A duty of 800 per cent., such as England imposes on our tobacco, is an anomaly in the history of trade; and which, under all circumstances, may be deemed positively unjust. This excessive duty, however, is imposed merely for revenue purposes, not for protection to agriculture, like the duty on wheat; as, excepting a few plants for private use, for medicinal purposes, &c., it is prohibited to be grown.

"The culture of tobacco is every year extending itself in the Western States, and promises to become a most important article of export from the rich districts north and south of the Ohio. In fact, a variety or other particulars, it is stated that the whole amount supplied elsewhere than in the United States, is about 150,000,000 pounds; the amount of possible consumption of American tobacco is put at not less than 1,000,000,000 pounds. So that were only one-half of this quantity actually consumed, it would be four times more than our present export, which, in value, is only second to that of cotton.

In almost every country in Europe the most vexatious restrictions in the forms of excessive duties and imposts are levied upon tobacco. In general, the governments, such as France, Spain, Italy, &c., take possession of all the tobacco imported or raised, and farm or let out to great capitalists for immense sums, the privileges of vending to manufacturers and retailers. In this way the cost of tobacco in Europe is usually extremely high, and governments manage to derive from their subjects vast sums of money by exactions in the shape of imposts upon the tobacco they consume. In France, the revenue thus annually derived, is $10,000,000, and all this from a reduced importation of some 6000 or 7000 hogsheads. It would indeed seem to be a favourite object for excessive taxation in nearly every government. At a great meeting of tobacco planters held in May, 1840, it was shown from authentic documents, that on an export of 100,000 hogsheads, valued here at $7,000,000, a duty was paid by the consumers in the various countries of Europe, of more than $30,000,000. As a matter of interest to many of our readers," says the editor of the Cultivator, "we copy or condense

1044

Increased attention has been lately paid to the culture of tobacco in Illinois and even in some of the New England States. The following statement would seem to show, that, notwithstanding the vast amount of tobacco raised in the Union for home consumption and exportation, there is yet no reasonable ground for apprehending an over-stock of the market. In a letter of the Secretary of the Treasury relative to the amount of home consumption and exports of tobacco, with a view to other particulars, it is stated that the whole amount supplied elsewhere than in the United States, is about 150,000,000 pounds; the amount of possible consumption of American tobacco is put at not less than 1,000,000,000 pounds. So that were only one-half of this quantity actually consumed, it would be four times more than our present export, which, in value, is only second to that of cotton.

In almost every country in Europe the most vexatious restrictions in the forms of excessive duties and imposts are levied upon tobacco. In general, the governments, such as France, Spain, Italy, &c., take possession of all the tobacco imported or raised, and farm or let out to great capitalists for immense sums, the privileges of vending to manufacturers and retailers. In this way the cost of tobacco in Europe is usually extremely high, and governments manage to derive from their subjects vast sums of money by exactions in the shape of imposts upon the tobacco they consume. In France, the revenue thus annually derived, is $10,000,000, and all this from a reduced importation of some 6000 or 7000 hogsheads. It would indeed seem to be a favourite object for excessive taxation in nearly every government. At a great meeting of tobacco planters held in May, 1840, it was shown from authentic documents, that on an export of 100,000 hogsheads, valued here at $7,000,000, a duty was paid by the consumers in the various countries of Europe, of more than $30,000,000. As a matter of interest to many of our readers," says the editor of the Cultivator, "we copy or condense

Rice, Sugar Tobacco, etc.

planters were compelled to "accept and receive 40 lbs. of tobacco so stripped and smoothed, in full satisfaction of every 100 lbs. now due them." It is not important to ascertain whether this law was re-enacted at the end of the 3 years named in it; for we find in an official report to the commissioners, that the yearly exports of tobacco for ten years ending in 1709, were 28,888,666 lbs., of which 11,260,659 lbs. were annually consumed in Great Britain, and 17,598,007 lbs. in other countries of Europe. In 1744—1776, the average annual exportation was 40,000,000 lbs., of which 7,000,000 lbs. were consumed in Great Britain, and 33,000,000 lbs. in other European countries. The average annual exportation from 1678 to 1770, both inclusive, was 67,780 hhd.s. of about 100 lbs. each, or 67,780,000 lbs. As we have now approached the period when the exportation of tobacco arrived at a point from which it has vibrated, (sometimes a little above or below it,) we subjoin a statement of the exportation for the years 1772—1775, inclusive, which will furnish the remarkable fact that (compared with any succeeding four years since that period) the annual exportation of tobacco just before the Revolution, was about the same that it has been at any time since, in our most prosperous periods. For although 1790—1792 were three years of very heavy exportations, they fell off in 1793 nearly one-half, making the annual average exportation not materially different from 1772—1775:

It may be proper to remark, that the weight of a hogshead of tobacco is much greater now than formerly. Originally, tobacco being less compactly pressed, the hogsheads averaged only 600 lbs., but they gradually increased, and in 1770, reached 1000 lbs. average. At this time Kentucky averages about 1300 lbs. per hogshead, and the average of all kinds (Kentucky, Virginia, Maryland, and Ohio) we have estimated at 1200 lbs. per hogshead, which we believe to be very nearly right. The annual average exportation for the last 21 years, from 1815 to 1835, inclusive, is within a fraction of 8,276,000 hogsheads. Taking our estimate of 1200 lbs. per hogshead to be the true weight, we shall thus have 99,313,000 lbs. as the annual average for the last 21 years; and we have seen that the annual average exportation for the four years ending in and including 1775, was 99,374,785 lbs., which establishes the remarkable fact, that the exportation of leaf tobacco has remained stationary for a period of 60 years.

On a careful examination of the foregoing statements, it appears, that when our exports of leaf tobacco, for two or three successive years, much exceeded 100,000,000 lbs.; for some succeeding years they are proportionately reduced below that standard. It is also evident that the revolutionary war gave a check to the exportation of leaf tobacco from which it has never recovered; for until that period, as may be seen by reference to the preceding statements, the annual average exportation increased regularly and steadily. It was 37,780,000 lbs. greater for the years 1763 to 1770, than for the years 1744 to 1746; and for the years 1772 to 1775, it was 31,594,785 lbs. more than the annual average for the years 1763 to 1770. In other words, for the 31 years immediately preceding the revolution, our exports of leaf tobacco annually increased very nearly 3,328,000 lbs., and for the 60 years since that period, it has remained stationary, except when interrupted by wars or other commercial embarrassments. The reason is apparent. Before the revolution, all Europe depended on us for supplies of the article; but, being cut off from the supplies by the war, Europeans turned their attention to growing it for themselves, and

This shows an increased production of nearly double in the 3 years.

It will strike you with surprise, as it did us, that the consumption of tobacco has increased so much in our own country as to carry off the very large surplus grown beyond the foreign demand. Formerly, when all the tobacco was grown in Virginia and Maryland, we exported much as we do now; and now, in addition to those states, which produce nearly, or quite as much as they did then, Ohio, Kentucky, and Tennessee, together with Connecticut, Pennsylvania, Indiana, and Missouri, produce as much more. We must, therefore, consume more than the quantity required for exportation.

Remarks.—If the preceding statements may be relied on as correct, it appears that there
TOBACCO.

has been a very surprising increase of the use of tobacco in this country, and that the annual consumption now amounts to upwards of 100,000,000 lbs.—giving about 7 lbs. to every man, woman, and child. The amount initially paid by the consumers of this quantity of tobacco in its manufactured state, has been computed by a writer in The Portsmouth Journal, at $20,000,000. (National Gazette, Philadelphia, Oct. 6, 1836. Republished in Farmer's Register, vol. vi. 1838.)

Culture of Tobacco.—The following concise directions for the cultivation and management of tobacco are chiefly taken from a communication drawn up by Mr. J. F. Edmunds, of Mecklenburg, Virginia, and originally published in the Farmer's Register.

Raising the Plants.—The land for the planted bed is usually selected in a warm exposure on the south or southeastern side of a hill in a wood, new ground being always preferred. From this the roots should be grubbed, the rubbish cleared away and the old leaves raked off. Brush of pine or other wood is then to be piled on until from 2 to 3 feet thick all over the bed, and this is to be set on fire. As the beds should be prepared for seeding immediately after the frost is out of the ground, the brush should be collected and put in place some time during the winter. Instead of burning over the whole bed at once, a part may be fired for an hour or so at a time proceeding thus over the entire bed. The place is then to be broken up with hoes, and sometimes with coulters drawn by horses or oxen, and the work repeated until the earth is made perfectly fine, being careful to avoid turning under the surface. All the roots should then be extracted, and the land laid off in beds (slightly elevated if dry, and more if moist or wet) 4 feet wide. And to 16 square yards, a common pipe-bowl of seed is sown. The bed is then trodden or pressed with hoes, and well covered with brush to protect the plants from frosts. When the shoots are some fully out, they should be slightly manured with strong manure made fine; this should be repeated frequently, and in larger quantity, as the plants increase in size and are able to bear it.

When the plants have attained a good size, and there is no longer danger of frost, the covering of brush is removed, and the bed weeded with the hand, those employed in this duty taking great care to avoid bruising the tender plants. The beds require frequent picking to keep down the weeds.

Preparation and Planting.—The plants will be generally ready for removal about the last of May or first of June. They are to be drawn out after a rain and transplanted in good ground previously well prepared for their reception.

Soil and Season.—In Virginia and the other states, the best tobacco is grown in rich, light, alluvial, loamy land, or such as has been recently cleared and brought into cultivation. Tobacco requires a mild and warm season, and can never be worth growing in situations elevated much above the level of the sea, in northern exposures, or in wet and springy land.

Field Culture.—The land for tobacco should be of the best quality, either newly cleared and virgin soil, or old ground highly manured and well pulverized, or good clover fallow, ploughed in the fall, manured and cross-ploughed in the spring, just before planting, when harrowed, and then laid off with a plough in rows 3, 3½, or 4 feet apart each way. Every square thus made is to be scarped with the hoe so as to form a hill in which one plant is to be set. In case the plants die from drought, or are destroyed by worms, a very common occurrence, others must be set in their places.

Cultivation.—The culture is very much like that usually adopted for Indian corn, the plough, cultivator and hand-hoe being freely used to keep down weeds and loosen the earth. It is important to the early growth of the plants to plough and work deep once or twice so that when it is ripening, the ground will be broken deep and fine. (The coulter is preferred for this operation.) This should be effected without much interference with the roots, as that would check the growth, and prevent the plant from attaining its proper size. And hence the advantage of greater distance between the rows than the common distance of 3½ feet—because the wide rows can be ploughed, and worked with less damage to the roots. In this, as in all other crops, if we wish a good return, "we must speed the plough" and hoe, before the roots run out. On our high lands we should endeavour, by deep and horizontal ploughing, to counteract the bad effects of drought. On our flats, we should aim to prevent the collection of water by drains discharged at the lowest point.

The bed is best for high land, because it retains more moisture where it is generally needed. The hill, retaining less moisture, is best for flat land, where there is commonly a superabundance.

Priming, Topping, Suckering, and Warming.—As the tobacco plant grows and develops, a blossom-bud puts out from the top, which is termed bottoming. This top must be pulled off, along with some of the upper leaves, as too small to be of any value. The plants are thus left usually about 2 or 3 feet high. The plants also shoot out suckers from every leaf, which must be broken off, care being taken not to break the leaf from the main stem. This causes the leaves to spread.

The most regular topping is performed by measure. The topper carries in his hand a measure 6 inches long, by occasionally applying which, he can regulate the priming with great accuracy; and as the remaining leaves are numbered, this governs the operation, and gains the object of even topping. The topper should always carry this measure in his hand, as it serves to prevent excuses for negligence and uneven topping. Prime six inches, and top to eight leaves. We have found, by experience, that this is the best average height. We sometimes, but seldom, vary from this general rule. If the land is poorer than common, or if, from the backwardness of the plant, and the advanced state of the season, we apprehend frost, we do not prime as high; (say 4 inches.) If we have an uncommonly rich spot, and there is danger that the top upper leaves are too small to be of any value.
leaves will come to the ground, we should rise in the same proportion. The crop should be wormed and snickered, at least once a week.

Cutting and Housing.—In about 3 months after setting out, the plants assume a spotted and yellowish appearance, indicating that they have attained sufficient maturity for cutting and housing. This stage of the tobacco culture is generally reckoned the most difficult and delicate part of the whole business, and the planter, if he wishes to be successful, must give it all his attention, as the profit of a whole plantation, for the year, greatly depends upon the diligence and skillful management exercised during the few days of cutting. He should therefore be well prepared for this state of the crop, by having the barns close, carts and wagons in good order, and every thing arranged to despatch business as much as possible, since it is hard work he has to encounter. To save a heavy crop in the best manner requires both energy and activity. The most judicious hands should be selected for cutters. The plants are cut with a knife near the ground, and suffered to lie in the sun for a few hours, to dry them, or a little longer.

When the field is a pretty large one, a medium or average hand should count the whole number of plants he cuts, so that, allowing each cutter the same number, we may arrive at nearly the whole quantity cut. We should never cut more nor less than will fill the contemplated barn; otherwise there is labour lost in attending to a barn not full, or the overplus is injured for want of firing. The tobacco, after it has "fallen," or becomes sufficiently limber, is carried to the barn in carts or wagons, being from 6 to 10 plants on a stick, and stowed away for firing. It is also of great importance to be particular in the arrangement of the sticks. The equal and general circulation of heat throughout the house depends on the manner in which this is done. Our barns commonly have three firing tiers above, and three below the joists. We commence arranging the sticks on the most elevated tier in the roof, to which we give five inches distance; and on each tier, as we descend, we gain one inch; so that on the lowest tier, nearest the fire, the sticks are placed eleven inches apart. This disposition of the sticks, I have ascertained by late experiment, is important. The sticks of tobacco being wider apart, next to the fires, gives a freer circulation, and, consequently, a more equal temperature, than the usual way of equal distance from bottom to top. The heat having more space to ascend, must be more equal and generally diffused, and will give a more uniform house of tobacco. I esteem this a considerable improvement; and if we have house-room, and make a greater difference in the proportionate distance between the sticks, it will be a still better arrangement.

Curing.—We commence our warming or preparing fires, says Mr. Edmunds, the day after housing. We prefer what is commonly called the "bed logs" of green, and the "feeding" of dry or seasoned wood. By this arrangement the fires are rendered more governable. The bed logs should be nicely fitted to the barn floor, two lengths to reach across, the large ends placed outwards, to guard against the tendency of heat to the centre. We keep up our warming fires from 36 to 48 hours, the mercury ranging from 100° to 115°. This will generally bring the leaf to the drying state; the tail, or end of the leaf, now begins to curl handsomely, and then the planter must be on the alert. If he is careless, and his fires are made too hot, the aromatic oil passes off with the sap and smoke, and he has a house of red or dark inferior tobacco. If his fires are kept too low, his tobacco will be a clammy sweat, and the oil escapes. There is much more danger of the former than of the latter evil. There is more tobacco injured by too much heat than by the want of a sufficiency. The fires should now be kept steady and regular, with a gradual increase of heat, so that in 48 hours the mercury will stand 150° to 160°. It must be kept at or about that temperature until the tobacco is cured.

Stripping, Prizing, &c.—After the plants become sufficiently dried, known by the stems getting hard, which will be in about 2 months after housing, the leaves are stripped from the stalks. This operation is a most important one. In the spring or late in winter is chosen, to prevent the leaves from crumbling. They are divided by select hands into three classes for stripping: 1st, that which is of the best colour and quality; 2dly, that which is somewhat inferior, comprising the balance of the leaf; 3dly, lugs, or ground leaves. Some planters make still more classes, but this requires more attention and discrimination than can be generally bestowed, at least by ordinary hands. After sorting, the leaves are neatly tied up in bundles called "hands," consisting of 4 leaves in each bundle of the first class, or 6 of the second and third classes. The hands are next put down to condition," as the process is commonly termed. This consists in putting it in large bulks and subjecting it to pressure from weights, in which state it undergoes a sweat. It must be watched during this process, and as soon as it is observed beginning to heat, taken out and hung up to dry. After drying thoroughly, it must be again taken down and put into bulk, a damp spell being chosen so as to prevent the leaves from breaking or crumbling. In Mr. Edmunds' instructions he observes, that, "at the close of each day's stripping, and oftener if the weather is drying, we bulk down what has been stripped, being careful to pack straight. It is left in this situation until we wish to commence prizing, and then hung, from 12 to 15 bundles on a smooth stick, and hoisted in the barn, the sticks placed 6 inches apart, the hoister carrying a measure in his hand. It is important to measure, as the order will be more uniform. It should remain until the stems are perfectly dry; after which it should be taken down for prizing, as dry as it can be handled without breaking. It remains in this state a few days until the leaves are pressed together, and we have the soft weather for packing. Each bundle is then carefully straightened, repacked, and heavily weighted. It is then ready for prizing. We should prize in weather when the order of the tobacco will.
TOBACCO.
not change. Each bundle should be straight, and closely packed in hogsheads in the usual way."
Some very excellent views upon the culture and subsequent management of tobacco will
be found dispersed through the different southern
ern agricultural periodicals, and especially the
first volume of the Farmer's Register. One of the communications in this last work, signed
Frederick Oronoko, is very full of information
upon every branch of the subject. The writer
states that two great errors are generally com-
mited in topping and pruning. On rich land the
plants are topped too low, which, with plants in the young state, causes the leaves to
grow too large, coarse, and curly. On such
lands, instead of making 10 leaves, at least 12
should be made by topping to about 16, and
not finishing priming with the topping, but
commencing again when the four top leaves
get about half-grown. If the seasons be fa-
ourable to a rapid growth, some of the high
top suckers should be indulged a while, which
in a wet summer will prevent the leaves from
growing coarse. Nothing, he says, is easier
than to keep down the size of the leaves, and
prevent them from getting too large, if you will
only be watchful to thin them out in the proper
extent in the early part of the summer, when the seasons are favourable to rapid
growth. Sucker and prime judiciously, as the
rains subside and dry weather sets in. By
turning out a superabundance of leaves, it en-
able one to speculate on the weather in this
crop with more certainty than can be done
with any other. The four top leaves are al-
ways the richest, if ripe, and of much the best
and most useful shape. In a plant of 10 leaves,
it thinks, in general, they are worth more than
the other six, although the four are not so
large, and do not usually weigh more than half
as much as the six. The same rules, he thinks,
are also applicable to the culture of tobacco on
thin land, such as can just barely produce a
crop, although he is opposed to the culture of
such poor land. One-third to one-half of the
Virginia crop is made upon such land as does
not pay for the labour. It is a general im-
pression that much of the fine, high-priced
tobacco has been made on poor land. It will,
he says, "be well to correct this error, as it has
caused much injury, and great loss of labour,
and final destruction and death to a great deal
of thin land, either poor originally, or in the
last stage of consumption by the Virginia-kill-
ing mode of cultivation. It is true, however,
to a notorious degree, that several poor coun-
ties have of late been very conspicuous, and,
perhaps, meritously celebrated, for making
fine, high-priced tobacco; but the fine tobacco
was not made on poor land, when the land was
actually poor; it was made on the richest,
liveliest spots that could be picked out in those
poor counties. Many of those who have not rich
land, have resorted to the necessity of picking
the best spots of thin land with only a meager
cloth of soil, and that cloth nearly all composed
of vegetable matter, scattered in the hills, which
causes them to be tolerably rich, active, and
productive for one or two years, as this is
generally new ground. In this way a part of
the fine, high-priced tobacco has been made,
but much the greater part has been produced
by the rich land, with the aid of the art of high
curing, with but little or no fire."
Another great error dwelt upon by the same
writer is that of cutting before the plant gets
entirely ripe, which is the chief cause why so
much is defective in flavour, colour, and sub-
stance; and why so much feels rich and thick
without being so. The odoriferous qualities
of most aromatic plants are acquired in great-
est perfection during the last stages of their
growth, and some are never fully developed
till they get through the period which is by far
the earliest case with tea, coffee, and tobacco.
Much of the substance as well as weight are therefore sacrificed by premature
cutting, which also prevents the plant from
curing with a good, lively, healthy colour.
A dull, dingy hue will inevitably be the aspect
of all that is cut green, cure it as you may. Any
bright colour given to it artificially by the pro-
cess of curing will fade away. "I hazard no-
thing in the declaration that every rich plant
which is cut in perfection, fully ripe, whether
on rich or thin land, bottom or high land, may be cured of good colour and flavour, that will be lasting
longer than that furnished by the dullest, and
that none but the rich plant will give you that
colour, that flavour, that growing and vital feel,
and a more beautiful and durable appearance.
And although good colour and flavour constitute
the chief value, yet no more than about one-tenth
of the Virginia crop has ever come to market
with these great advantages.
"Many incorrect and erroneous opinions have
gone into circulation respecting colour.
Impressions have been extensively made in
the country that yellow is a favourite hue. A
bright, lively colour is invariably admired by
the purchasers who give the highest prices.
But neither brown, red, nor yellow will do. A
rich mixture of red and yellow on the under
side of the leaf is desirable; such a mixture
as is to be found in fat lightwood, and brilliant,
rich, bright mahogany. The dull brown and
dark, dingy colours are very objectionable.
The next best colour to the favourite one just
described, is a rich, deep yellowish-green, or
rather the fat lightwood colour, with a slight
admixture or tinge of green, but it is so much
the worse of the green, in the ratio that it con-
tains that shade, which lessens the fine flavour,
and detracts from the value.
"A similar colour, in a faint and feeble
degree, can be given to the poor, thin tobacco,
and is certainly a handsome dressing for it in
the new state, and is well calculated to take
with superficial judges. But as such a dress-
ing injures the stamina, and increases the fad-
ing in going through the sweat, either on land
or at sea, it should never be attempted, as it is
an injury, and will never take with any com-
petent judge."
The dapple, or pieball, is very much admired
by many purchasers who are esteemed good
judges, but the writer thinks those variegated
colours a disadvantage, and the results of either
too rapid curing, or bruising in pressing. A
competent judge, he says, had rather have the
coat of one, or another, leaf, stem, and fibres, all of
one colour, of the fat lightwood appearance; and
this uniformity in colour proves the maximum,
and is the best evidence of rich, well-cured
tobacco, in its highest perfection.
Tobacco.

The same writer thinks that firing has been carried to great excess, very much to the injury of tobacco, of late years, both in smoking it too much, and parching and curing it too rapidly. The smoke is a very objectionable flavour, and the excessive parching makes the leaf too crisp, and destroys the valuable elasticity. It should be well cured, with as little fire as possible. Some cure it very well without fire.

Several years ago, a great number of planters took up the impression, that the purchasers were fond of hard-fired tobacco, from the erroneous opinion of some of them, who said they liked to smell the effects of fire, because it was an evidence that it was well cured; but they have since discovered their error, and no one is now fond of the smell of smoke, which is a great objection in every market in Europe as well as in America.

The following additional observations relative to curing tobacco, are furnished by the same authority.

Sunning the tobacco is very necessary after cutting; but it should not be kept in the field any longer than to kill and make it sufficiently limber for removal to hang on sticks upon a scaffold at the tobacco-house, where it should hang in open airy order, at first letting in the sun well upon the sticks. In this way the butt-end of the sticks and big ends of the leaves and stems will get a great deal of the sun's heat, which they require in curing. And as fast as the leaves contract and draw up from heat, and in drying, the plants should be moved up nearer to each other, in closer and closer order, to prevent the lower parts of the leaves from being exposed to the sun.

It would be a great advantage to split the stalks, as it facilitates the curing very much. They should be split from the top down within 2 or 3 inches of the cutting point. The plants thus split should straddle the sticks, and the sticks should range north and south, so that the morning's sun will shine on one side of the stalk, which they require in curing. And in this manner it should take the sun and open air night and day, until it becomes well cured, and until the stalks, and stems, and leaves get dry. Showers of rain, and even heavy showers, in this situation, while the leaf continues green, are of little disadvantage; because they only wet a small part, viz.: the under side of the leaves, which are now uppermost. Nearly all of the rich ingredients are concentrated on the upper side of the plants as they stand growing.

But, hot, sultry spells of rainy or very damp weather, or long days of continuance, will mould, mildew, rot, or wash it to destruction, particularly after a considerable progress in curing. And when the winds come from the eastward, preceded by several damp, cloudy days, you may count upon a long spell, and then you should commence housing before the rain sets in, or much falls; and use fire as the weather may require.

The firing should be in close houses; the closer the better. And the more windows, the better, all with tight shutters, to shut out the damp in long wet spells, and let it in when wanted to bring the tobacco in order. No tobacco can be finally well cured without coming and going frequently. You cannot have any command of your tobacco as regards weather, without close, tight houses, which are of very great importance.

Five fires discovered are enough for a room 20 feet square; and they should not be large, but burn free, steady, and gradual, and would be the better of never going entirely out, if you intend curing by this destructive mode. But why make fires in the house at all? As smoke is now so very objectionable, why not do the little firing that may be necessary in very long wet or damp spells, to prevent mould, mildews, &c., in the manner that planks is steamed and dried at saw-mills?—by stoves, or by running a ditch or two through the house, and covering this with flat slabs of rock, or arching it over with brick, and making the fire at one end, out of doors. The heat and smoke thus procured will be enough in a close house, with the windows all shut, to prevent mould, mildew, &c.

Those who cure without firing, or with as little as possible, let it remain after it turns yellow until the stalks and stems as well as the leaves get dry, in the open air and sun, if the weather permits, or in the house by the aid of fire, if necessary. But if the stalks, stems, and leaves get dry before the leaves get sufficiently yellow, let the tobacco hang until it becomes very high indeed, and from wet or damp weather, and bulk it in this damp, soft, high order, in very large bulks, in a very close room, and cover well with straw, &c., with heavy weights on the top, and let it remain till it gets warm; examine it every three to four hours night and day, and as soon as it yellows sufficiently, hang it up in the house, if the weather be wet or very damp, and fire it moderately and gradually until dry.

The best kinds of woods to use are those which make the most heat and weakest smoke. The kinds best for smoking bacon are the worst for firing; but since the smoke flavour has become objectionable.

Another correspondent of the Farmer's Register shows, by observations of the thermometer, the precise degrees of heat to which the tobacco is subjected in the different stages of firing. He has also furnished valuable information in relation to other points connected with the curing process. In warm weather, says this writer, we hang from 8 large plants to 10 small ones on each stick; the sticks should be carried immediately into the house, and placed 8 or 9 inches apart. The sticks having been regularly arranged throughout the house, the process of curing then comes on.

My practice for several years, with but little variation, has been to regulate the sticks, the day after cutting and next morning. Commence with small fires, so as to raise the thermometer to 90°; this heat should be continued from 36 to 48 hours, which we call the warming or preparatory fire: (the small yellow tobacco, when cut, requiring a shorter preparation than large, thick, green tobacco;) the heat should then be raised gradually 10°, and continued 4 or 5 hours—thus continuing to raise
TOBACCO.

the heat throughout the whole process 16° every 4 or 5 hours, until the thermometer reaches 150°, which is called a curing heat. The continuation of this heat depends much on the state of the atmosphere, as well as on the size of the plant: it should, however, be continued until the whole plant is thoroughly cured. As soon, then, as the tobacco comes in order, it is hung up on sticks, either in some other house, hanging it as thick as you can conveniently press the sticks together, where it will remain in perfect security until you are ready for stripping.

In the month of November you may safely begin to strip; and much care should be used in making the different qualities, as well as tying the different bundles; the "tie leaf" should be stemmed, which looks much better than to have one-half of the leaf hanging down the bundle. A good hand will tie from 700 to 1000 bundles in the day. The tobacco straw and binder rope, are easily packed down in bulk at night, and a platform or 20 inches from the floor, where it may remain until winter is nearly over, when it must be rehung in order to get it in pruning order.

Much depends on the order for pruning. The stem must be perfectly dry: never strike or take down tobacco for pruning, unless the wind is at some southern point; and it should be taken down as dry as you can possibly handle without very much breaking it. When down, it should be well covered with fodder or leaves; if the "season" continues, you may pack it in bulk as straight as possible for pruning; the hoghead weighing from 160 lbs., to 1 cwt. The following are a few extracts from notes taken last summer during the curing season.

15th Sept. 1833. First barn—tobacco very ripe—weather hot and dry—cut Friday—commenced firing Monday morning—thermometer 90° at 9 o'clock—12 o'clock 106°—process too rapid—half past 3 o'clock, 110°—fired all night—Tuesday 9 o'clock, 120°—3 o'clock 150°—fired all night—Wednesday 150°—fired all night—Thursday 150°—Friday 150°—fires kept up irregularly, and stopped in the evening, High wind each day—thermometer at back side of the house. When this tobacco came in order to be examined, I discovered that a small portion was somewhat injured by the fires being too strong in the commencement, as seen above.

16th Sept. 1833. Second barn—tobacco very ripe—but not very ripe—weather hot and dry—cut Saturday—commenced firing Monday—smoked all day at 90°—Tuesday the same half day—Tuesday evening thermometer 100°—Wednesday morning leaf half cured on the lower tier—heat 140°—fired half night—Thursday day 145°—Friday 146°—fired half night—handsomely cured—thermometer 3 feet from the fire and nearly 2 feet high, every day.

22d Sept. Third barn—dry weather—cut Saturday—not very ripe—commenced firing Monday morning 90°—continued all night same—Tuesday 9 o'clock 110°—tails curling—tobacco looks very well—Wednesday 120° at 9 o'clock—lower tier leaf nearly cured—Thursday day 150°—fired all night—Friday 160°—fired

till bedtime." This house, on examination, was very well cured.

I forgot to mention in the proper place that my barns are made as tight and close as possible. I do not, however, think that the roof should be very close; my barns are covered with oak boards, and are generally open enough to let off the smoke and vapour as fast as they are formed. Some of my neighbours have windows made just under the comb of the house.

As the essential properties of the tobacco plant are very volatile, the writer maintains that the sooner it is well cured and pressed into hogheads the better, and the hoghead cannot be too tight. If the crop comes in early, so as to admit of being cured in autumn, it will be all the better. It should not, if possible, be allowed to remain out of the hogheads all winter. He tells the planters of Virginia not to fear that they will ever overstock the world with fine tobacco, and thereby reduce the price. The better it is made, the less will be made in Europe and sold. Tobacco is not the result of the perfection of its qualities. The low, dull state of the markets for common and inferior tobacco, is not the result of too much, but a consequence of its indifferent quality, which causes it to be little if any better than that which is made on the continent of Europe, with which it comes in competition.

In Maryland and Virginia it is estimated that one good hand can manage 6000 plants, which, allowing a yard to each, would cover about an acre and a quarter. A hoghead weighing 1350 lbs. (some weigh 1800 lbs.) is considered a good size. On the rich lands of Kentucky, from 1000 to 1500 lbs. are raised per acre. In Virginia the leaves of 4 good plants are estimated to make 1 lb. of cured tobacco.

Some of the diseases, accidents, and enemies to which tobacco is exposed, are, in the language of the planter, worm-holes, ripeshot or sun-burnt, moon-burnt, stunted, torn by storms of hail and wind, injured or killed by frost, house-burnt.

TOBACCO. Chemistry of. Under the head of Ammonia it has been observed that the juice of fresh tobacco leaves contains ammoniacal salts. The existence of the volatile alkaline in cured tobacco, is shown by the action of the smoke of a cigar upon blue vegetable flowers, or vegetable colours, turning the reds to purple, and the purples to green.

When the leaves of the tobacco plant are subjected to distillation with water, a weak ammoniacal liquid is obtained, upon which a white, fatty, crystallizable substance swims, which does not contain nitrogen, and is quite destitute of smell. But when the same plant, after being dried, is moistened with water, tied together in small bundles, and placed in heaps, a peculiar process of decomposition takes place. Fermentation commences, and is accompanied by the absorption of oxygen; the leaves now become warm and emit the characteristic smell of prepared tobacco and snuff. When the fermentation is carefully promoted and too high a heat avoided, this smell increases and becomes more delicate; and after...
TOMATO.

the fermentation is completed, an oily, azoized, volatile matter called *nicotine* is found in the leaves. This substance, *nicotine*, which possesses all the properties of a base, was not present before the fermentation. The different kinds of tobacco are distinguished from one another, like wines, by having very different odorous substances, which are generated along with the *nicotine*.

On a soil which contains potash, both wheat and tobacco may be reared in succession, because the latter plant does not require phosphates, salts which are invariably present in wheat, but requires only alkalis, and food containing nitrogen.

According to the analysis of Posselt and Reimann, 16,000 parts of the leaves of the tobacco plant contain 16 parts of phosphate of lime, 8 parts of silica, and no magnesia; whilst an equal quantity of wheat straw contains 47 parts, and the same quantity of the grain of wheat 99:45 parts of phosphates.

Now, if we suppose that the grain of wheat is equal to half the weight of its straw, then the quantity of phosphates extracted from a soil by the same weights of wheat and tobacco must be as 97:7:16. This difference is very considerable. The roots of tobacco, as well as those of wheat, extract the phosphates contained in the soil, but they restore them again, because they are not essentially necessary to the development of the plant. (*Liebig's Organic Chemistry.*)

**TOMATO, or LOVE-APPLE** (*Solanum lycopersicum; Lycopersicum esculentum*). There are two species of the tomato present in cultivation in England: the red-fruited and the yellow-fruited. Of each of these there are several sub-varieties, chiefly differing in the size and shape of their fruit. The most esteemed is the common large red, though for pickling some of the smaller-fruited varieties are preferable.

Of the red there are—

Of the yellow there are—
1. The large yellow. 2. Small, or cherry-yellow.

The soil best suited for the love-apple is rich, light, and moulzy, in a dry subsoil; for, although a regular supply of moisture is a chief requisite, yet stagnant water is very injurious. Sea-weed may be applied with advantage to the border on which it is grown, as may kelp or common salt in small quantities. The situation must be sheltered. It is propagated by seed, which may be sown at the close of March or early in April, in a hot-bed or stove, which latter is to be preferred. The hot-bed must be of a moderate durability, earthed about 6 inches deep. The sowing must not be performed until the requisite time has elapsed for guarding against the danger of a violent, heat arising. If a hot-house be employed as the nursery of the seedlings, the seed must be sown in pots or boxes set on the flues or round the edges of the pits.

In whatever situation sown, the seed must be scattered thin, and not buried more than half an inch below the surface. The plants are not long in appearing; when of two or three weeks' growth, in which time they acquire a height of as many inches, they must be thinned to 3 inches apart, and those removed, if wanted, pricked at the same distances, in a similar bed to that from which they may be removed; shade and water being afforded as necessary appear necessary. Air and light must be afforded freely in every stage of their growth.

This annual trailing plant is a native of South America, and is now most extensively used in Europe, but still more so in the United States, where they flourish most luxuriantly and mature in the open air, the fruit of some species growing to a very large size, sometimes a single one weighing a pound, and even 1½ lbs. It is used in the preparation of soups, and when stewed it forms a fine vegetable sauce, of a rich and pleasant acid flavour. In its preparation the ripe fruit is cut in halves, and squeezed sufficiently to extract the water and seeds, and, being put in a pan, with a pod of pepper or capsicum, and a small portion of beef-gravy or butter, it is stewed over a slow fire for an hour; it is afterwards rubbed through a sieve into a clean stew-pan and simmered a few minutes, salt and other seasoning having been added. When well prepared, it constitutes a superior vegetable. The tomato is reputed to be possessed of highly valuable medicinal virtues, and forms a most wholesome article of food. With sugar it makes a very valuable preserve.

In the Middle or Northern States, the seed may be sown in April, in a hot-bed; or in May, in a warm situation, and transplanted as soon as the season will admit. A middling soil produces more fruit and less vines than a very rich soil.

Tomatoes remaining on the vines late in the season, and which, if left out, would be destroyed by frost, may be preserved for many weeks by simply pulling up the vines and hanging them up, with the fruit upon them, in some house or sheltered situation. Those not ripe when the vines are pulled mature afterwards.

Cows are said to thrive well and give an increased quantity of milk of improved quality when fed upon tomatoes. They may not take them kindly at first, but are said to grow fond of them soon.

**TOMENTOSE.** In botany, covered with dense, close, white hairs, or down.

**TOP-DRESSING.** A term applied to such manures as are laid upon land without being turned in: and also to the practice of dressing the surface of grass land, or other crops, with some kinds of highly reduced manure, that can be evenly spread out or sown equally over them by the hand.

A great variety of substances are in use for this purpose, such as soot, ashes, the dung of pigeons and other birds, rape dust, lime, gypsum, &c., the benefits of which are noticed under their respective heads.

**TORMENTIL** (*Tomentilla*, alluding to a supposed efficacy in toothache, as well as to a belief that it could cure diseases of the bowels). The British species are two; both perennial. They are now regarded as belonging to the genus *Potentilla*, and the natural order *Rosaceae*.

1. In England common tormentil or sept-foil (*P. officinalis* or *tomentilla*) grows in barren pas-
TREES.

Youalt's Travelling Tower-Mustard (Erysimum, from turris, a tower; the foliage is so disposed on the stems as to give them a pyramidal form, and for the same reason the plants are called tower-mustards). The smooth tower-mustard (T. globra), is indigens, and grows wild on banks and by roadsides, in a dry gravelly soil. The flowers are numerous, closely corymbose, pale sulphur-coloured. Pods very long and slender, on short stalks. Seeds about 60 in each cell, very small.

TRACTION. See Carts, Horse, Road, Strength, &c. The reader may also consult a very able essay "On Draught" in Professor Youatt's work on The Horse, of which our space will not allow us to give even an outline.

TRANSPLANTING. The act of removing either cuttings, layers, roots, or entire plants, from one soil to another. See Planting and Propagation.

TRAPA NATANS. This plant grows in ponds, and is eaten like the chestnut. The canal of Versailles is covered with the plant, and the root is sometimes served up at table.

TRAVELLER'S JOY. See Clematis.

TREACLE-MUSTARD (Erysimum, from erion, to draw and cure; it is popularly reckoned a cure for a sore throat, and is also said to draw and produce blisters). An extensive genus of plants, possessing warm and pungent qualities. The leaves are simple, often lanceolate, and nearly erect. From a corymbose, yellow, sulphur-coloured, or white. Pods in very long upright clusters. There are in England three indigenous annual species. 1. The worm-seed treacle-mustard (E. cherionthoides); 2. The garlic treacle-mustard (E. allaria), known also under the local names of Jack-by-the-hedge, or sauce-alone. 3. Hare's-ear treacle-mustard (E. orientale). The second is the most common. The whole herb is smooth, shining, deep green, and exhalas, when bruised, the smell of garlic; and the seeds are stronger than the other parts of the plant. The stem is a foot high, and bears the flowers in one, stalked, cordonate, acute, veiny, and broadly serrated. The flowers are white. The pods erect, smooth, on a spreading stalk. The peasantry eat the young leaves with bread and butter. See Hedge Mustard.

TREES are divided naturally into two principal classes, namely, fruit and timber trees: the former includes all such as are raised chiefly, or entirely, for their edible fruit, an account of which, together with their modes of cultivation, the reader will find in alphabetical order, and also in the articles Fruit, Orchard, Pruning, &c.

The second division comprehends those trees, the wood of which is employed in ship-building, machinery, or for other useful purposes, such as the oak, elm, larch, &c., the culture of which has been discussed under those respective heads. For the diseases of trees, see American Blight, Canker, Mildew, &c.

By timber, in English law, is intended only such trees as are considered fit and proper by the custom of the country to be employed in building or repairing houses; and timber trees are those which are of 20 years' growth. The custom of the country naturally varies with regard to the kind of trees which are considered to be timber. The oak, the elm, and the ash are universally deemed to be such; but beech is considered so in Buckinghamshire, birch in Yorkshire, because it is generally used for buildings of an inferior kind. Thus the chestnut, walnut, lime, and others may, under similar customs, be considered timber. If pollards are sound, it seems that they must be considered as timber: this was the opinion of Chancellor King.

According to English common law, the property of the tree is in the owner of the soil on which it grows; and though its roots may extend into two estates, yet it belongs to the owner of the land on which it was originally planted or sown. Nurseries of young fruit trees, raised for filling up orchards, cannot be removed by the tenant, but a nurseryman may do so.

The tenant for life, without impeachment of waste, of an estate, may cut down timber in a husbandlike manner. But the Court of Chancery will restrain such tenant from cutting down underwood of an insufficient growth, or ornamental or sheltering trees. But this shelter or ornament is not to be construed to mean extensive woods.

By custom, but not by common law, the trees growing on a copyhold estate may belong to the lord. The copyholder is not guilty of waste if he cut timber merely for necessary repairs. Timber trees growing on the estates of ecclesiastical corporations are to be devoted to the repair of the church. And consequently neither they nor their lessee can fell timber for their own use. Neither can a mortgagor cut down timber if the land without it is a scanty security. But the Court of Chancery will not restrain a mortgagor from cutting timber, unless the security is insufficient without it. Though the timber of the estate belongs to the landlord, and also such trees as are likely to grow in and around any waste of bushes and trees not timber is in the tenant; and, therefore, the landlord cannot maintain an action of trespass against a stranger, for cut-

1053
TUCKAHOE.

TRUFFLE. (Tuber Cyrilium). A round fungus growing under ground in many parts of Southern Europe, destitute of roots and leafy appendages. It absorbs nutriment at every point on its surface. The truffle is composed of globular vesicles, destined for the reproduction of the vegetable, and short, barren filaments, called by Tarpin tigellides; and the reproductive bodies, trifinelles. Each globular vesicle is fitted to give origin to a multitude of reproductive bodies, but a few of them only perfect the young vegetable. The parent dies; the trifinelles are nourished by its dissolving substance, and the cavity it originally filled becomes the abode of a multitude of young truffles; but many of them die, the stronger starving the weaker. As truffles spread over a large space, it is difficult to say by what means they progress. The truffle is one of the most wholesome and nutritious of the esculent fungi, and is generally discovered by means of dogs, which are taught to scent it; so that, on smelling the truffle, they bark and scratch it up. Truffles are highly esteemed at the tables of the luxurious, where they are served up, either roasted in a fresh state like potatoes, or they are dried, shed, and dressed as ingredients in soups and ragouts. See Tuckahoe.

TRUSS. A bundle of hay, straw, &c. It may be observed that in England a truss of hay must contain 66 lbs. or half a cwt.; a truss of straw 36 lbs.; 96 trusses make a load. In June, July, and August, a truss of new hay must weigh 60 lbs. See Hay and Straw.

TUCKAHOE. This curious vegetable is sometimes known by the name of Indian bread, or Indian loaf. It is found in the Southern States of the Atlantic, and even as far north as Kent county, Del. It is a natural production, the origin of which has greatly perplexed naturalists, as it is commonly found several feet under the surface, and, like the truffle of Europe, has apparently no stem or leafy appendage connecting it with the external atmosphere. They are generally found through the masses of humus, whose acuteness of smelling enables them to fix upon the spot where they lie buried. They are usually of a globular or flattened oval shape, and rather regular surface, the large ones resembling somewhat a brown loaf of coarse bread. The size varies from that of an acorn to the bigness of a man's head. Clayton, the celebrated botanist, was the first naturalist who has mentioned the Tuckahoe. He gave it the Latin name of Lycoperdon solidum. (See his Flora Virginica.) In May, 1817, Dr. Macbride, of Charleson, S. C., communicated his discovery on the subject to the New York Philosophical Society. Although the tuckahoe is quite common in the Southern and one or two of the Middle States, its natural history is still involved in much obscurity. Its name in the Indian language is said to designate bread, and is applied to certain edible roots. Though sometimes found emerging from the earth and exposing a small part of the surface, it is generally met with 2 or 3 feet below the soil. When first dug up, it is soft enough to be easily cut with a knife, and of an acrid taste. Its colour internally is white, like that of the most of the common roots, and its texture compact and homogeneous. It is covered with a tough substance, strongly adhering to the white parerechyma, of a dark brown colour, and somewhat wrinkled. When dried, the internal substance becomes hard and loses its acrimony, possessing very little taste or smell, and capable of being reduced to powder without difficulty. When examined by the microscope, the tuckahoe exhibits no fibres or pores or any other indications of organization, so easily detected in roots and other vegetable productions of ordinary growth. Its substance breaks as easily in one way as another, like a lump of starch or chalk. From these characteristics, together with the peculiar nature of the bark or external covering, it has been classed among the fungus tribe. In those parts of the country, however, where the tuckahoe most abounds, it is generally supposed to be the root of a species of Convolvulus (Pandurata), called "the man of the earth." But both
TULL, JETHRO.

Dr. Macbride and Mr. La Conte, after much attentive examination in its native state, are decidedly of the contrary opinion, the roots of the Convulvulus being unlike those of the tueka-hoe. Most of the southern botanists regard it as a fungus. (See Medical Repository, vol. vi.) See Fungi.

TULIP (Tulipa). A genus of celebrated and much-prized florists' flowers. They succeed well in rich loam and sand, and are increased by offsets; new varieties are obtained from seed. The choicer kinds require to be taken up and dried after they have ceased flowering, and planted again in the autumn. They should be slightly protected in very rainy or frosty weather, as they are very liable to rot. One species, the wild tulip (T. sylvestris), is indigenous to England, growing about old chalk-pits. It bears sweet-scented, bright-yellow, somewhat drooping flowers in April. Although the Tulipomania, which rose to such an absurd height in Holland in the 17th century, is long since extinct, yet the rage for producing fine tulips still exists. The finest tulips are reared at Haarlem. The principal florists have their favourite breeders. A breeder is a seedling tulip, 8 or 9 years from the seed, but still vigorous. If the stem be tall; the petals of the flower blunter at the apex; if the flower be self-coloured, or of an equal, uniform colour on both surfaces of the petals; if the base be pure white or bright yellow; and the anthers and stigmas forked or broad, it is highly esteemed as a breeder. The bulb is planted deep in a sheltered, sunny place, and care is taken to prevent the leaves being injured by wind or hail; the stem is propped, and the flower carefully secured from the hot rays of the sun, as well as from wind and violent rain. The seed is carefully collected, and from it many fine tulips are anticipated. The varieties at Haarlem are very numerous; they are chiefly varieties of the Tulipa Gesneriana and T. Suaveolens.

TULIP POPLAR (Liriodendron tulipifera). This tree, the only one of its genus, is found in great abundance on the Delaware in the United States, where it forms the rich woods in the alluvials bordering the Delaware and other bays, it attains a growth which makes it the most majestic tree of the American forest. Trees are frequently found from 100 to 140 or 150 feet in height, and 6 or 8 feet in diameter, the trunk being sometimes 60 or 80 feet perfectly straight and without a knot or branch. This stately tree, when its wide-spread branches extend from the ground to the summit, loaded in May with its tulip flowers, has been referred to in the article on the Bee, as the most magnificent of floral productions. The wood, which is very soft, is highly valued for building, and also for many purposes to which it is applied by the cabinet-maker and other mechanic artists. The variety called yellow poplar is generally preferred. It is known by its thicker and more deeply furrowed bark. The bark, which is very thick and spongy, is also a valuable aromatic bitter; and has been successfully used in intermittents.

TULL, JETHRO. The science of agriculture, although the first in importance to mankind, is yet remarkable for the few great names whose discoveries or general abilities adorn its history. For an explanation of this fact, we must in some measure be contented with the common observation that its advances, its improvements, are so slow; as to be almost imperceptible; and dependent upon much more tedious experiments than any other science. In all instances, it is true that many, very many of the processes, daily witnessed and carried on by the cultivator, are based upon chemical principles, and may be illustrated, and very materially assisted, by chemical experiments; but those who have studied the science the most carefully are fully aware that no experiments upon the laws of dead matter ever nearly equal in difficulty those upon living substances, for these last, in many instances, seem endowed with powers which completely neutralize and overcome the very principle of chemical attraction and repulsion. Such experiments, too, are not, like those made in the philosopher's laboratory, secure from interruption, and carefully and readily guarded from every source of error; on the contrary, those of even the most scientific, the most careful cultivators, are of necessity liable to many accidents, are ever the sport of the winds and the weather, require months to complete, and often the duration of a life to repeat and firmly establish. Then, again, to add to the difficulty of such investigations, there are hardly two soils to be found, in England or elsewhere, whose composition and conditions are even nearly the same. All differ either in the proportion of some ingredient, in climate, in declination, or in the nature of their substrata; the variations in their treatment, therefore, must often be as different as their numerous varieties. Thus, encircled with difficulties, requiring for the attainment of considerable eminence the union of both practical experience, patient and long-continued research, and scientific knowledge, we need hardly feel surprised that those who have made important improvements in agriculture have been but few in number, and that these illustrious exceptions to the general rule have appeared at a very distant period. The illustrious Jethro Tull, how skilful and successful in his business, however industrious and talented, is but rarely induced to describe the improvements he has caused, or the implements he has improved or invented; he is too often content with the profit derived from his own ingenuity, and too frequently lets others reap all the honours of discoveries to which he is more justly entitled.

In the list, however, of distinguished English farmers, Jethro Tull presents us with a highly honourable exception to the general rule; for, utterly regardless of all selfish considerations, he not only made great and successful efforts for the promotion of agriculture and made those valuable researches, publicly known in a work entitled the Horse-hoing Husbandry, which will hand him down to all after-ages as one of the chief of English farmers; as a patriot who, undaunted by the natural difficulties of the attempt, attained great and important advances in the cultivating and increasing the fertility of the land, and in enlarging the resources of the followers of a business to which he was not originally bred; for, as we shall
TULL, JETHRO.

presently see, Tull became a farmer not from inclination, but from the effects of a sickly constitution and diseased frame.

The life of Jethro Tull will, indeed, well repay the careful and often-repeated study of the English farmer in more ways than one; will afford not only instruction, but encouragement to him, who has to contend against the poorest soils, the most adverse of circumstances; for, if such a cultivator holds a poor, thin, hungry soil, so did Jethro Tull;—if he farms in a remote and desolate district; if he has ignorant and obstinate labourers; if he is visited by sickness; if he is almost driven from his profession by even incurable diseases, so, let him be assured, was that great farmer whose labours are the subject of this memoir. The dauntless intrepidity and perseverance, too, of Tull, should always be remembered to his honour. Knowing, as he did, the correctness of the principles for which he so nobly contend-ed, he never relaxed in his endeavours to induce their general adoption; and if it was only after the lapse of many years, when Tull had long been in his grave, that those principles and those mechanical inventions for which he so energetically contended were commonly adopted, the fault was not Tull's, but must be attributed to the ignorance and the apathy of the age in which he made his important, his ill-requited discoveries.

The debt of gratitude which all modern farmers owe to Tull is, indeed, a large one; he was the first who boldly and zealously contended for the adoption of improved machinery in all agricultural operations; the ploughs which he depicts in the engravings which accompany his _Horse-hoe Husbandry_, have not been very materially improved in the last century. He invented several varieties of hand and horse-hoes. He was very nearly, if not quite, the first who produced a practically useful thrashing-machine; he was one of the first that, as discoverers, have the temerity to disturb old systems. He was regarded by the bulk of his contemporaries as an idle, restless innovator. He was ridiculed, thwarted, and opposed in every way, not, as might have been reasonably expected, by the most ignorant, but by those who either did know, or ought to have known, better things. His neighbours regarded him as almost a lunatic; and the tradition of the neighbourhood of Shalborn still is, that he was even wicked enough to attempt to banish the flail from his farm, and that he had a machine intended to replace it; a frame, with a number of round, iron, horse-shoe shaped, nails driven in, which, when turned round, would strike the corn as the assistance of the labourer.

This, there is little doubt, was an attempt to construct a thrashing-machine; and that it was, in those quiet days for agriculture, regarded as a wonder, is proved by the existence of the tradition. When thus located in a remote rural parish, on the borders of the counties of Berks, Hants, and Wilts, Tull wrote his _Husbandry_, a book which is not nearly so well known as it ought to be; for, though the progress of science has rendered a considerable portion of Tull's writings obsolete, yet much, very much, remains unaltered by the progress of discovery, to amply repay the farmer for a careful and often-repeated perusal.

Tull wrote with all the modern and delicacy of genius; he tells us, in the preface to his _Husbandry_, that he knew that he had undertaken a task of which he was incapable, and that it was produced during a long confinement within the limits of a lonely farm, in a county where he was a stranger. And when we remember that he was, through life, an invalid,—obliged to abandon his sedentary profession of the law, and seek for health by foreign travel and by country pursuits,—when we think of these things, we cannot but still more admire the energy of mind he betrayed, and the difficulties he overcame. He feelingly alludes to some of these, when he says, with regard to his great work—"'Tis no wonder that the style is low as the author, or as the dust that is here treated of, since the whole was written in pains of the stone, and other diseases as incurable and almost as cruel; but fine language will not fill a farmer's barn." Every thing connected with the history of this great benefactor of agriculture must be interesting to the cultivators of this and all other countries. I regret that, with some industry, I have not been able to obtain for the farmer more information with regard to him. He was born in Oxfordshire, on his paternal estate, near Oxford. He was educated for the legal profession, became a member of Staple Inn, and was called to the bar on the 11th December, 1693, by the benches of Gray's Inn, and not at the Temple, as is commonly asserted in the biographical dictionaries. He was afflicted soon after his call to the bar with a pulmonary disorder, and, in consequence, abandoned his Oxfordshire farm, and for some time travelled on the Continent. He was for a considerable period at Montpellier, in the south of France. Returning to England, he took into his own hands the farm which he had in Hampshire, where, after resuming those agricultural efforts which he had commenced in Berkshire, he wrote his _Horse-hoe Husbandry_.

During his tour on the Continent, Tull carefully compared the agriculture of France and Italy with that of his own country, and omitted no occasion to observe and note every thing which supported his own views and discoveries. He particularly, on more than one occasion, in his work, alludes to the similarity of the practice followed by the vine-dressers of the south of Europe, in constantly hoeing or otherwise subduing their vines, and his own horse-hoe husbandry. Finding that they did not approve of dunging their vineyards, Tull readily added the fact in favour of his own favourite theory, that manuring a soil is an unnecessary operation.

After Tull's decease, his lands in Berkshire found their way into Chancery, and were sold, by order of the court, in 1784, to Mr. Blandy, the father of the present owner. It consists of about 70 acres of freehold land, but Tull held about 130 acres in addition, by a different tenure. The house in which he dwelt has been modernized, but the old-fashioned brew-house yet remains as Tull had it; and when I visited
Prosperous, in July, 1840, was still in very good condition. Of the out-houses, Tull’s granary and his stables are yet in existence, though fast verging to destruction; and at the end of this granary, which Tull built, is an old well in which, when cleared out some years since, was found, deeply buried in the accumulated mud of nearly a century, a three-pronged hoe, which there is no doubt belonged to Tull, and is now in the museum of the Royal Agricultural Society of England. Into this well it was most likely thrown by his men, who, adopting the use of his new tools with the utmost reluctance, annoyed him in many ways. After much discussion, he told them they “did not know what "Tis," he says, "the most formidable objection against our agriculture, that the defection of servants and labourers is such, that few gentlemen can keep their lands in their own hands, but, rather than make nothing of them, they let them for a little to tenants who can bear to be insulted, assaulted, kicked, cursed, and bridelled, with more patience than gentlemen are endowed with." This burst of feeling would very clearly intimate the probable truth of the case—that Tull was energetic and irritable—that his servants pillaged and annoyed him, and that he did not submit to them in positions without the struggle against them in a way which his legal education should have taught him to avoid.

Such was the spirit of enterprise, and such was the genius of Tull, that no difficulties, however formidable, stopped him in his researches. His experiments, carried on in his garden and in his house, with regard to the food and the habits of plants, some of which he gives in the first pages of his work, betray the thirst for knowledge, the industry, and tact, which he possessed.

The tradition of his neighbours is, that, when confined to his room and to his couch by his incurable maladies, he yet managed to carry on his experiments on vegetation, by having large boxes and garden-pots of earth placed in his room, and before his windows, where he sowed his seeds, and watched their progress under different modes of cultivation, with all the zeal of a martyr, and the enthusiasm of an inventor. He is still spoken of by the old labourers of that district, as being a man whom it was impossible to oppose, in any of his plans, with eventual success. He was evidently the wonder of his neighbours, who would, perhaps, have regarded him as a magician, if the age of witchcraft had not then been nearly, if not quite, over. It would seem, from what Tull says (p. 50), that it was in 1701 that he constructed his first drill for planting sainfoin. And the occasion of his doing so he thus describes in his preface: "It was very difficult to find a man that could sow clover tolerably; they had a habit (from which they could not be driven) to throw it once with the hand to two large strides, and go twice on each cast; thus, with 9 or 10 pounds of seed to the acre, two-thirds of the ground was unplanted; and on the rest was so thick that it did not prosper. To remedy this, I made a hopper, to be drawn by a boy, that planted an acre sufficiently with 6 pounds of seed; but when I added to this hopper an exceedingly light plough, that made 6 channels 8 inches asunder, into which 2 pounds of seed to an acre being drilled, the ground was as well planted. This drill was easily drawn by a man, and sometimes by a boy."

Tull's great improvements in tillage consisted in the use of his drill, and in the adoption of such wide intervals between his rows of turnips (several feet, 3 to 6), that the horsehoe could be easily and constantly employed. He ridiculed, very justly, the delusions under which the farmers then laboured with regard to the unvaried advantages of thick sowing. He told them that "did not the "Tis" show them, that every row of vegetables to be horse-hoed ought to have an empty space of 3 or 4 inches in front and behind, and the least, and of nearly 5 feet in all sorts of corn," and he was very justly suspicious that what he was going to advance "would seem shocking to them before they have made trials."

Tull was the first English farmer who advocated to its fullest extent the decided advantages of constantly pulverizing and stirring the soil, to illustrate which almost all his experiments were directed. His explanations, however, of his own discoveries were not always so good as the object he had in view, although there is little to find fault with in his theory of the advantages of tillage. "I have had," he says (p. 24), "the experience of a multitude of instances, which confirm it so far, that I am in no doubt that any soil, be it rich or poor, can ever be made too fine by tillage; for one cubical foot of this minute powder may have more internal superficies than a thousand cubical feet of the same or any other earth tilled in the common manner; and I believe no two arable earths in the world do exceed one another in their natural riches twenty times; that is, one cubical foot of the richest is not able to produce an equal quantity of vegetables, *caetera paribus*, to 20 cubical feet of the poorest; therefore, it is not strange that the poorest, where, by pulverizing, it has obtained 100 times the internal superficies of the rich, untilled land, should exceed it in fertility; or, if a foot of the poorest was made to have 20 times the superficies of such rich land, the poorest might produce an equal quantity of vegetables with the rich. Besides, there is another extraordinary advantage when a soil has a large internal superficies in a very little compass; for then the roots of the plants in it are better supplied with nourishment, being nearer to them on all sides within reach than it can be when the soil is less fine, as in case of tillage, and the roots in the latter extend much farther than in the other to reach an equal quantity of nourishment; they must range and fill perhaps..."
above 20 times more space to collect the same quantity of food. But, in this fine soil, the most weak and tender roots have a free passage to the utmost of their extent, and have also an easy, due, and equal pressure everywhere, as in water.

He did not confine his attention to the advantages of thoroughly pulverizing the land: he was also an advocate for much deeper ploughing than was usual in his time, and in one or two places laments the supineness of the farmers in this respect, and the idleness of the ploughmen, in only half-penetrating the soil, for fear of injuring the appearance of their horses; and he illustrated the advantages of his proposed mode of ploughing by the best means in his power, not only by general observation, but by also appealing to several very ingeniously-contrived little experiments upon the habits of plants.

Tull saw very clearly that this theory of the advantages of pulverizing and deepening soils would be strongly supported if it could be shown that the roots of the commonly cultivated grasses would, under favourable circumstances, penetrate to more considerable depths than the ordinary shallow soils of the farmer allowed them. He paid, therefore, considerable attention to the roots of plants, not only in his small experimental glasses and pots, but in his fields. He found, by some observations on the roots of some wheat plants growing in a deeply loosened soil, that their roots had penetrated to more than double the depth of the commonly ploughed land of the farmer; and all this I can support from my own observations on the roots of the crops growing on the edge of chalk and loam pits, and in other situations where the soil has been loosen to great depths. Tull, too, noticed the very considerable and rapid extension of the roots of trees growing near to old dunes, sewers, &c., and he hence added another argument in favour of the advantages which are derived from assisting, in the best way they may know, the roots of plants to penetrate deeper into the soil. Had Tull lived in our days, he would have been an ardent advocate for the subsoil and subterraneous ploughs; he would not then have confined his efforts to the increased use of the common plough and the trenching-spade.

A century has now elapsed since Jethro Tull thus earnestly endeavoured to draw the attention of the farmers of England to the importance of deepening, pulverizing, and mixing their soils. Tull, unfortunately for himself, lived a long time too soon: had he encountered the ignorance and the obstinacy of his workmen, the apathy of his neighbours, the ridicule of those who understood him not, and the anger of the indolent. The principles, however, which he inculcated have survived and overcome all these obstacles; are yearly more prized, because better understood. Tull thought that the earth, and the earth alone, did every thing for vegetation; astonished at the effects which were produced by merely deepening and pulverizing, he allowed his enthusiasm to carry him too far. “Every plant,” he tells us, “is earth, and the growth and true increase of a plant is the addition of more earth;” and in another place he adds, “too much nitre corrodes a plant, too much water drowns it, too much air dries the roots of it, too much heat burns it; but too much earth a plant never can have.” Thus impressed with the value and the all-sufficient powers of earth to support vegetation, it need hardly surprise us that Tull soon came to the conclusion that, under a proper management of the plough and the scariifer (for a rude instrument of this kind was known in Tull's days), the land might be so pulverized and deepened as to bear its crops without the addition of any decomposing manures.

Tull deceived himself, in this instance, by not attending to the quantity of finely-divided, slowly decomposing substances, which all cultivated soils contain in some shape or other. By ploughing and pulverizing, the progress of the putrefaction of these organic matters was accelerated, they were rendered more soluble, and then the succeeding crop was, by their decomposition, sufficiently nourished. But these operations could not be long continued; at each repetition of the experiment the amount of the stubborn, slowly decomposing matters of the soil became reduced, and, in consequence, the crops produced under the system became less. Tull's farm at Shalborn was well adapted to try the effect of this theory; it is situated on the crown of a rising ground, whose thin-skinned soil is a light loam mixed with gravel, resting on chalk; of such a soil, the organic matters, of necessity, are speedily exhausted by cropping and pulverizing. Tull soon found this out; he struggled hard against the necessity, but he finally had recourse to the employment of manures; he found at last, that, however valuable good tillage is to the application of fertilizers, it is utterly incapable of supplying their place. The failure of Jethro Tull, therefore, in this great effort was complete; but it was the failure of a man of genius. He tardily admitted the value of dunging the land; but Tull tells us, by way of explanation, such a way as to refer all the benefit to the earth, when he told the farmers of those days, “its use is not to nourish, but to dissolve, that is, divide the terrestrial matter which affords nutriment to the mouths of vegetable roots.” To a very considerable extent Tull was correct in this explanation of the mode in which common manure operates in rendering the soil more fertile; for it renders the land more pervious to the atmospheric gases and vapour, and, in consequence, all vegetation growing upon the land is better nourished. But the benefit thus obtained is an effect, and the organic matters of the compost, as they slowly dissolve in the soil, gradually give out a considerable proportion of various gases, such as carburetted hydrogen and carbonic acid gas, all of which are absorbed by the plant at the moment of their extrication, enter into new combinations, and promote its vigorous growth. That this is not a merely mechanical advantage is proved in several ways; for instance, the benefit of the application of the decomposing compost is proved to be just as advantageous in some instances to the crop, where it is not even mixed with the soil. This is shown by the effect (known to every gar-
TULL, JETHRO.

gardener) which is produced by placing the manure in a chamber beneath the soil, so that the roots of the plants neither mix with, nor does the soil even touch the compost. The gases of putrefaction, however, arise and mix with the soil, and the dung is for the most part reduced without any division of "the terrestrial matter," which Tull imagined to be so essential to the explanation of the phenomenon. We need not search in the works of Tull for any attempts to use the drill for the application of fertilizers, for all Tull's efforts were directed to cultivate the earth without manure of any kind. He admitted the necessity of using it at all only with extreme reluctance; he told his readers, 7 years before his death, that "the particular scheme of raising constant annual crops of wheat without dung or fallow is as yet only upon probation; but, by six crops I have had in that manner, I see nothing against their being continued. This, it is true, requires greater care in their management than any other branch of the husbandry; but he who can do this without dung or fallow, may easily do it with one or both of them; and there may be such wet, clayey land which the plough cannot well pulverize without help of the ferment or dung."

Tull, in fact, let no opportunity escape him to decry the ill effects of employing manure. Modern gardeners would be astonished at his zeal when he contends for its banishment from the kitchen garden. "There is," he says (p. 18), "much more reason to prohibit the use of dung in the kitchen garden, on account of the ill taste it gives to excellent roots and plants, especially such dung as is made in great towns. It is a wonder how delicate palates can dispense with eating their own and their beasts' ordure, but a little more putrefied and evaporated, together with all sorts of filthy and nastiness, a tincture of which those roots must unavoidably receive that grow amongst it. Indeed, I do not admire, that learned palates, accustomed to the gout of silphium, garlic, and mortified venison, equaling the stench and rankness of this sort of city muck, should relish a land peopled with flies fattened by its immediate contact. People who are so vulgarly nice as to nauseate the modish dainties, and whose squeamish stomachs even abhor to receive the food of nobles, so little different from that wherewith they regale their richest gardens, say, that even the very water wherein a rich garden cabbage is boiled stinks; but that the water wherein a cabbage from a poor undug field is boiled has no manner of unpleasant savour; and that a carrot bred in a dunghill has none of that sweet relish which a field carrot affords. Dung not only spoils the fine flavour of these our eatables, but it spoils good liquor. The dunged vineyards in Languedoc produce nauseous wine; from whence there is a proverb in that country, that poor people's wine is best, because they carry no dung to their vineyards."

Our author, however, had a better opinion of vegetable manures than those of animals, for he says, "Vegetable dung, unless the vegetable be buried alive in the soil, makes a much less ferment in it, and, consequently, divides it less than animal dung does. But the dung of vege-
tables is much more wholesome for the use of edible roots and plants than that of animals."

Jethro Tull, according to Chalmers, died at his house at Prosperous, January 3, 1740. Of his works and inventions of agricultural machinery I have already spoken. Five years of his only work that I am acquainted with, The Horse-hoe Husbandry, were published in folio in 1731, the chief volume in 1733; and in the same year some additions were printed which are not found in many of the copies of that year, or even in that of 1751. Cobbett, however, was careful to add it to an octavo edition which he printed in 1829. In this, he omitted only the plates of the ploughs and other agricultural implements; but he added an introduction, in which he did little except land Tull, and vituperate those who had adopted Tull's plans, without acknowledging the source of their obligation; not remembering that many a Tullian improvement has been often made since our author's time, by plain, practical farmers, who never even heard the name of Tull mentioned.

Tull, as I have before remarked, published his "addenda" to his Husbandry in the same year that the first edition appeared; in these he takes more notice than was perhaps necessary of certain attacks which had been made upon his book, by the members of a certain "equi-vocal society," amongst whom was the celebrated Stephen Switzer, the most talented seedsmen, gardener, and horticultural author of his day. It appears, too, that a society of gentlemen in Dublin had, without his leave, reprinted for distribution his five "specimen chapters," all of which annoying circumstances evidently irritated him; besides these controversial notices, and certain corrections of the errors made by the printer, the long addenda do not contain any thing very valuable. Time has settled pretty well the respective merits of the contending parties; the name of Tull is steadily increasing, while the name and works of even the classical, the elegant Switzer, are much too little known amongst modern cultivators.

Twenty-four years after the death of Jethro Tull, a paper appeared in the Gentleman's Magazine, vol. xxxiv. p. 522, dated at Hungerford, about 4 miles from the farm where he lived and died, and signed with the initials D. Y., which details almost all that is known of the life of the great introducer of the drill system. It was written by one of his neighbours, who had known and associated with him, and valued very properly his services in the cause of agriculture. He describes in that essay the sensation produced by the unheard-of attempts of Tull. He says, "Novelty, always excites some curiosity—many gentlemen came from different parts on the fame of this new method of farming, some of whom were persuaded by the weight of Mr. Tull's arguments, to go hand in hand with him in the course of his experiments, while others, who thought themselves more wise and more discerning, took every occasion of ridiculing the practice, and of representing it as a fanciful project, that, after a great expense, would end in nothing but the ruin of the proprietor. In general, the whole
body of farmers and husbandmen pronounced the man as a conjurer, who, by sowing a third part of his land, would make it produce a quantity equal to that of sowing the whole."

The farm of Jethro Tull will ever be an object of interest to the lover of agriculture. Arthur Young made a pilgrimage to Prosperous (Annals of Agr. vol. xxiii. p. 173), and William Cobbett did the same. More persons would visit it if they knew where it was to be found. To such it will be interesting to know that the rural parish of Shalbourn is situated under the Coomb Hills, about 4 miles south of Hungerford; that the roads are tolerable, and the present holder of the farm obliging, and not insensible of Tull's great merits. If Tull was deceived in his belief of the powers of the plough to render the soil fertile without the assistance of manure, he was yet fully justified in almost every thing that he predicted, with regard to the advantages of thoroughly pulverizing and increasing the depth of the soil.

"The difference betwixt the operation of the spade and that of the common plough," he observes, "is only this, that the former commonly divides the soil into smaller pieces, and goes deeper;" and he adds, "how easy and natural it is to contrive a plough that may equal the spade, if not exceed it, by going deeper, and cutting into smaller pieces than the spade commonly does." The explanation, too, which Jethro Tull gave to the advantages or theory of deep ploughing was excellent, considering the chemical knowledge of his days; for the modern cultivator must remember, that, in his time, the composition of the atmosphere was almost entirely unknown. Tull could not have known any thing of the three gases,—nitrogen, oxygen, and carbonic acid,—of which it is now found to be constituted; and of the existence of its insensible aqueous vapour he was equally unacquainted; he did not know how important these are to the roots of plants, and the mode of furnishing them naturally, by means of promoting by pulverizing the land on which they vegetate. But though Tull did not know these things, yet it is certain that he had carefully observed many facts which proved that vapour was absorbed by the soil, and that this absorption was promoted by pulverization. "To demonstrate," he says (pp. 27, 28), "that dews moisten the land when fine, dig a hole in the hard, dry ground, in the driest weather, as deep as the plough ought to reach; beat the earth very fine, and fill the hole therewith; and after a few nights' dews, you will find this fine earth become like powder on the bottom, and the bottom ground all round will become dry. Till a field in lands: make one land very fine by frequent deep ploughing, let another be rough by insufficient tillage alternately; then plough the whole field crosswise in the driest weather, which has continued long, and you will perceive, by the colour of the earth, that every fine land will be turned up moist, but every rough land will be dry as powder from top to bottom. In the driest weather, good hoeing procures moisture to roots; though the ignorant and inquisitive fancy it lets in the drought, and therefore are afraid to hoe their plants at such times."

These enlightened observations of Tull have been verified and illustrated by the progress of agricultural discovery, by the improved modes of practice adopted by modern farmers, and by the march of chemical philosophy. Evelyn had observed the advantages of continually keeping the ground of fruit orchards hoed or dug. Sir Henry Steuart attests, with Sir Walter Scott, Withers, and a hundred others, the same fact, as applicable to timber plantations. The farmers of even the most sandy soils of Norfolk, on the very same principle, keep the ground between their rows of turnips constantly stirred, just as Tull proposed and practised a century since. And when, long after Tull was in his grave, Dr. Priestley discovered the oxygen gas of the atmosphere, it was soon found that its presence was essential to the growth of plants; that it was highly grateful to the roots of plants, either when applied to them in its simple state, or when combined with the aqueous matters of the atmosphere; and that this application was very sensibly indeed promoted, in either form, by increasing the finely divided state of the soil; and, further, that without this division of its particles, the earth was totally incapable of absorbing either the necessary gases or the watery vapour.

The subsoil-plough of Mr. Smith of Deanston, and the surfir-plough of Sir Edward Stracey, which have both proved so successful in our days, only illustrate the truth of Tull's principles and Tull's sagacious observations. Tull was an advocate for deep ploughing, and for internal pulverizations: he did not, it is true, see the necessary limits, on ordinary soils, and with common ploughs, to the realization of this theory: he forgot that the inert nature of many substrata would render it impossible to bring them at once to the surface; but though he omitted to take this into his calculation, yet still he argued correctly enough, when he urged the importance of pulverizing to increase the depth of their soils by every practicable means, to let in the air to the roots of their plants, and to give every facility possible to the growth of the roots of the plants; for, by so doing, he very plainly told them they derived benefits which exclusively belong to the vegetable world. "There is yet," he said (p. 28), "one more benefit hoeing gives to plants, which by no art can possibly be given to animals; for all that can be done in feeding an animal is, to give it sufficient food at the time it has occasion for it; if you give an animal any more, it is to the injury of its health. If you could give it more months, which is impossible; but, in hoeing a plant, the additional nourishment thereby given enables it to send out innumerable additional fibres and roots; so that hoeing, by the new pasturage it raises, furnishes both food and mouths to plants."

To every agricultural operation, in fact, of a mechanical nature, Tull's genius was admirably adapted; his ploughs, his hoes, his drills, were all of a description far superior to those of the rest of the farmers of those days. It was only where he attempted to reason upon the habits and food of plants, involving chemical truths, that Tull made great blunders. Thus,
believing, as he did, that earth, and earth alone, was the sole food of plants of all kinds, he ridiculed the opinion of Dr. Woodward, that all the food was more derived from the earth than from them through the agency of water. Woodward thought, very justly, "that water is only the agent that conveys the vegetable matter to the bodies of plants, that introduces and distributes it to their several parts for their nourishment." This theory seemed absurd to Jethro Tull, who believed that all plants fed upon the same kind of food, and that that food was earth, and only earth. It is true that Tull had a very indistinct idea that something else was requisite for the food of plants, and that "certain materials contribute in some manner to the increase of plants." And he then specifies five substances, at the head of which it is not a little singular, that he places saltpetre or nitre. But how this salt operated as a fertilizer was not at all more clear to Tull than to any who have succeeded him in the investigation. "Nitre," he says, (p. 10), "is useful to divide and prepare the food, and may be said to nourish vegetables, in much the same manner as my knife nourishes me, by cutting and dividing my meat; but when nitre is applied to the root of a plant, it will kill it as certainly as a knife misapplied will kill a man. Nitre is, in respect of nourishment, just as much the food of plants, as white arsenic is the food of rats." Tull, however, had a high opinion of the powers of common salt, when used as a steep for seed-corn, to prevent the smut in wheat; and he gives (p. 66) this account of the origin of the practice.

"Brining of wheat, to cure or prevent smutiness, was accidentally discovered about 70 years since, in the following manner: A shipload of wheat was sunk near Bristol in autumn, and afterwards at the ebb-tide all taken up, after it had been soaked in sea-water; but it being unfit for making of bread, a farmer sowed some of it in a field, and when it was found conduct and gave very well, the wheat was bought at a low price by many farmers, and all of it sown in different places. At the following harvest, all the wheat in that part of England happened to be smutty, except the produce of the brined seed, and that was all clean from smutiness." He then gives the farmer directions for drying the brined seed, by rolling it in quicklime, just as is now commonly practised by the farmer.

Water, Tull thought, was not a food for plants, because it commonly contains earth, to which he attributed the origin of the common opinion that plants do not grow by water. And as to their being their food, which is certain, Tull considered this as a complete phantasm,—quite an airy hypothesis. In common with many of the learned of his days, Tull here strangely confused himself, by not attending to observations and experiments with regard to plants, and to these only. The merit, however, of Tull, amid his occasional mistakes, was enhanced by his modesty; and it is impossible for us, when we reflect upon the difficulties he had to encounter in the prosecution of his researches, and in the production of his book, to be insensible to his appeal, where he tells us, at the conclusion of his preface, "One cause that made the three parts of this book (that is to say, the theory, or speculative part, the practical part, and the description of the tools), the more defective, was, that it was too much for me to make perfect at once, and two would have been useless without the third: therefore, it was better to give but a sketch of all than to have made any two of them never so full and perfect, leaving out the other."

Such was the modesty, such were the merits of this great father of the drill and the horse-hoe husbandry, to whose memory something, I hope, will one day be erected—some memorial to indicate the agriculturist's gratitude, worthy of the English farmer. Tull lies buried without even a stone to indicate that such a benefactor of agriculture rests beneath it. His grave is even doubtfully placed. If Tull died at Shalborn, as Chalmers asserts, he was not buried there. There is no trace of him in the parish register; the tradition of the old people of the neighbourhood is, that he died and was buried in Italy. His deeds, his triumphs, it is true, were of the quiet, peaceable kind, with which the world in general is little enamoured; but their results, their value to the land of his birth, were of no mean order. His drill, his horse-hoe, have saved his country, in seed alone, the food of millions; and when used as a distributor of manure, it has done, and it will hereafter to a considerable, still greater things. It has brought into cultivation thousands of acres of the barren craig, the wolds of Lincolnshire, of the deep sands of Norfolk; and its powers are not yet nearly exhausted, for, as fresh fertilizers are discovered, the drill evenly and economically distributes them; and as improvements in its construction are continually taking place, there is evidently much yet to be achieved by its use. The same remarks apply, in a great measure, to his hoe, and to his system of attempted cultivation without manure; for, although the last was a complete failure, yet even this bold attempt was not unattended with benefit; and as Tull taught, and hence taught, that, although by deep ploughing and complete pulverization of the soil the use of manure could not be entirely avoided, yet that by these means a much smaller quantity was sufficient than under the old and indolent mode of tilling the land. The efforts, too, of Tull were productive of advantage in other and in indirect ways:—his researches, his successes, his example, excited a spirit of inquiry, which since his days has hardly ever entirely slumbered. He was certainly the first who dared to boldly quit the beaten track, which had been trod for ages and ages, and follow a way of his own. And although he has been well followed and imitated by succeeding cultivators, who have availed themselves of new discoveries and machinery of which Tull had not the assistance, yet there have been none who have since excelled, or perhaps equalled him, in the boldness and originality of his conceptions, or in the energy with which he realized them. (Quart. Journ. of Agr. vol. xi. p. 342.)

TUMBREL. A sort of dung-cart, convenient for many purposes.
hay to sheep during the winter. It resembles the basket fish-pots used by fishermen, and consists of a circular cage or crib, which may be made of osiers, willows, or other pliant brushwood of any kind. The whole is about 10 feet in circumference, and closely walled to the height of about one foot, above which it is left open for the space of 18 inches; it is then walled again to the height of 8 or 10 inches, and an opening about 18 inches in breadth, is left at the top, for putting in the roots or other food, whether green or dry. The staves which form the skeleton of it are 10 inches asunder, so that 12 sheep may feed at the same time in each tumbril.

 TUPELO. Under this name Michaux describes three species of the genus Nyssa found in the United States. One of these, the Nyssa aquatica, has already been described with the Black gum, with which it is commonly confused where both grow together. (Michaux, vol. iii. p. 40.)

 TURF. The term often applied to the green surface or sward of grass lands. Also the name given to peat, which is used in several parts as fuel. It varies much in its nature in different places, being sometimes hard and of a dark or black colour, while in others it is soft and spongy. It is a substance very useful in burning calcareous stones into lime. See Lime, Moss, Peat.

 TURKEY (Melagris gallo-pavo). A wild fowl, originally introduced into Europe from America. They require care in their infancy. The black turkey is the best sort, both for size and delicacy. Turkeys are particularly clean birds, loving sweet food and delighting in air. They prefer roosting in trees, for which reason an evergreen, such as a yew tree, spruce fir, &c., is a great advantage, planted in the centre of a poultry-yard. Turkeys and pea-fowl hop up gradually from the low branches, and are sheltered from frost. But where this is not the case, the turkey-house must be dry and warm in winter, and cool in summer; it must be kept free from vermin, and the dung and litter of feathers, &c., should be often swept away. The perches must be large for their talons to grasp; and there should be plenty of ventilation, by gratings or holes bored in the floor.

 Turkeys seek quiet places to lay in, and often stray far from home. Their nest must be watched, and the newly laid egg exchanged for one made out of chalk every day. The turkey-hen lays from 12 to 20 eggs; and when she desires to sit, place her in the turkey-house on her eggs, and coop her up with them, if she is unwilling to remain, till she becomes settled. Do not disturb the hen while sitting, or attempt to assist the chick in piercing the shell. When the young ones are born, keep them in the nest for some time, as they love warmth, but do not handle them. Keep them warm and dry. When the red colour of the head appears, they are considered safe from the diseases of their infancy. Do not allow a turkey to sit twice in a season; the young ones never succeed unless they are full feathered before Michaelmas. Feed young turkeys three or four times a day, and let the food be a thickish paste, made of fine barley-meal, mixed with finely chopped onions, nettles, and pot-herbs. The French give their turkeys plentiful supplies of nettles, of which they are very fond; it is a warming and nutritious herb. Let the food be given fresh every day, and place it on a board with a shallow pan of water. Coop the hen while the young ones feed, or she will eat it herself. When the chicks begin to follow the turkey into the poultry-yard, do not let them out till the dew is off the ground. Vetch and marrow-fat peas are poisonous to young turkeys; lettuce brings on looseness; and henlock and henbane should be destroyed near all poultry-yards.

 Turkeys love oats, boiled potatoes mashed with the meal of buckwheat, barley, or beans; or plain barley, like other fowls. Let the water always be sweet and clean. A turkey is six weeks fattening; if possible, feed two or three together, as they do not love solitary confinement. Let them eat as much as they like, but let not the food be fresh every day, and let it be the paste above mentioned, softened with water. Cramming turkeys is a cruel practice, and is not often done. They will feed well enough and fast enough if plenty of sweet food is placed before them, and if they are allowed some little space to move about in. It is a curious fact, that turkeys in America feed on the caterpillars that are found on the tobacco plant with impunity.

 Turkeys eggs are very good in pastry, and mixed with hen eggs they improve omelets. Turkey's dung, properly mixed with other comports, makes a valuable manure.

 TURNIP (Brassica rapa). No vegetable has had such influence in advancing the husbandry of Great Britain as the turnip. By whom and at what period turnips were first used in England as the food of cattle, however, does not appear; but from various accounts, their culture and uses were known in the Low Countries as far back as there are any records. The ancients appear to have been well acquainted with the value of this root; Columella, speaking of the several kinds of vegetables adapted for the farm, recommends the cultivating of rapa in plenty, because, says he, those roots that are not wanted for the table will be eaten by the cattle. Worledge, in his Mystery of Husbandry, &c., printed in 1669-81, says, that "although turnips be usually nourished in gardens, and be properly a garden plant, yet are they, to the very great advantage of the husbandman, sown in his fields in several places in England, not only for culinary uses, as about London and other great cities, but also for the food of cattle." Again, he says, "that in Holland they slice their turnips with the tops, and rape-seed cakes and grains, &c., and therewith make mashers for the cows and give it them warm, which the cows eat like hogs." He likewise complains of the very great neglect and deficiency of English husbandry in this particular. Some time since, a very excellent paper "On the Cultivation of the Turnip Crop on Light Soils," by Mr. M. Milburn, appeared in the Transactions of the Yorkshire Agricultural Society, from which this paper is chiefly extracted.

 It is generally supposed that the cultivation
of turnips as a field crop was introduced into Norfolk by Lord Townshend; but there is still further evidence that they were known as such some time before, for in 1684, when the patent or hinge harrows were in use, and subsequently with the loose harrows, which separate the rubbish more effectually from the soil; and then the weeds should be raked off, which is generally performed by women.

As soon as the couch-root, &c., are cleared off, either by carting into large, or burning in small heaps, the land may be ploughed with Finlayson's or any approved dray; and the same course followed alternately, so long as any roots remain. When they are unable to rake them off, they should be hand-gathered, and no manure whatever should be placed on the destruction of any by the sun's rays, until the 25th of June, a time when, on most soils, the sowing shall be concluded. It is desirable that the land should lie a week or ten days before the last ploughing is given to it, as it admits of the germination of such seeds of weeds as may be lying dormant in the soil, and is likewise favourable to the accumulation of moisture in a dry season. The turnip-seed should be sown immediately, however, after the last ploughing.

**Manure.**—In treating of the manures with which the turnips should be dressed, farm-yard manure stands the foremost, because it is what every farmer possesses, and, with the exception of that which is not burnt, it is the only manure of the East Riding of Yorkshire, is almost invariably employed in the cultivation of turnips. In general, it never will, and never can be superseded; and, though every deference is due to the practical knowledge of the East Riding farmers, there can be no doubt that, if their straw were more carefully made into manure, and applied to the turnip crop in conjunction with bones, it would be decidedly advantageous. It is unnecessary to say that house-made manure, and by fattening cattle, especially such as are consuming artificial food, is the best; and that of horses, cows, pigs, &c., should be mixed as intimately as possible, the larger the better. By neutralizing the coldness of that of the cow, and vice versa. It is desirable to cart this mixture to the fields intended for turnips in January and February, during the frost, or at such other times as convenience may dictate; but the earlier the better. About three weeks before used, it should be turned over, the sides of the mixen being carefully turned into the middle. Without entering in particular into the much disputed question of the fermentation of dung being useful or otherwise, thus much every farmer will know well the truth of, that on light soils, and for turnips, it is the most beneficial, where it is used at all. When fermentation is progressing so fast as to induce destructive heat, or mouldiness, it may be checked by treading the mixen and covering it with soil; and when it is sluggish, it may be excited by turning and watering.

For sandy or gravelly soils, farm-yard manure is an almost necessary ingredient in producing a crop of turnips. The rapid decomposition of vegetable matter which takes place on such soils requires that there should be a supply for that succulent crop; and, as before stated, there can be no doubt of its utility to calcareous soils; but for peaty descriptions, the land should be harrowed across; first with the patent or hinge harrows, and subsequently with the loose harrows, which separate the rubbish more effectually from the soil; and then the weeds should be raked off, which is generally performed by women.

When the dryness admits of it, usually in two or three days, the land should be harrowed across; first with the patent or hinge harrows, and subsequently with the loose harrows, which separate the rubbish more effectually from the soil; and then the weeds should be raked off, which is generally performed by women.
where there is abundance of vegetable matter, it is less useful.

The time for laying on the manure depends on the method of sowing adopted, and clearness of the land from weeds. If the plough-drill be used, it is desirable to immediately precede the plough; if the Norfolk, or large drill, it is better to lay it on a week or two before sowing, to allow it to mix intimately with the soil, especially if other manure is intended to be used, and the soil pretty free from weeds. The quantity to be applied will vary with circumstances: 12 to 14 tons per acre may be stated as an average, and more if the soil be poor and no other manure intended; while less may be used in proportion as other manures are applied.

Lime stands next in importance, as a dressing. The object of all manure is to supply some deficiency, remedy some mechanical inconvenience, or correct some detrimental agent in the soil. When dung, for instance, has been applied for several successive crops, a quantity of undecomposed vegetable matter accumulates, which the natural soluble properties of the soil cannot dissolve, and it remains inert. A dose of lime will correct this, and bring every particle of such inert matter, with which it comes in contact, available as food to the plants. It also assists in the intimate pulverization of the soil, as well as corrects any acidity which may exist in it, from causes which the agriculturist can seldom foresee, nor correct, except by its use. It is also destructive to weeds in the soil, and hence exceedingly valuable; for every farmer knows that weeds, being indigenous, are much more ready to grow in the soil than his crops, which are artificial, and often exotic. For peaty soils, an occasional dressing of quick lime is invaluable, especially if there is an addition of clay, road scrapings, &c., to give the requisite firmness to the soil. It should be laid on as soon as convenient after bringing from the stall, and as hot as possible. The time for laying on lime is a few weeks before the sowing, in order that the subsequent ploughings may mix it thoroughly with the soil, and thus its effects be more immediate after the sowing. The quantity per acre entirely depends upon the character of the lime in the locality. Two to four chaldrons per acre are used; but as it is applied for turnips generally in conjunction with other fertilizers, the former may be stated as the better quantity. If dung is also applied, they should be used at as great a distance of time between each other as circumstances will admit of, and the latter not long before the sowing.

Bones form one of the most valuable manures for turnips on all light soils, on account of their portable and stimulating character; they are least useful on a gravelly or loamy soil. They have converted barren moor lands into rich, fertile, and productive farms, luxuriating in every valuable product of the earth. Their value is beyond all praise. The East Riding of Yorkshire affords a specimen of what they have effected; and they require only to be known to be extensively applied. In many cases they are used alone; in others, in conjunction with farm-yard manure, with ashes, and with lime. Ashes are sometimes drilled with them as a substitute, by diminishing the quantity of the bones. Lime is a valuable auxiliary, on "old going land," or soil which has been long under cultivation. On peaty soils, having a substratum of sand, they have produced wonderful crops, by supplying them with the necessary animal matter. The quantity varies from 12 to 30 bushels per acre. Sixteen bushels per acre will produce a fair crop, on average soils; and some farmers say that more than that quantity is waste. It is desirable to mix them with a quantity of ashes, when they are drilled in the above quantity. This facilitates the early progress of the plants, and supports them until the bones become available. English bones are generally preferred to foreign; but from experiments made by the writer, he prefers foreign to English, and also to recent bones; for, although the latter have more of their juices than the former, the former sooner decompose; and the fat and animal juices require considerable chemical changes before they are available as food for the plants. A mixture might be judicious, but he has not tried it, nor is he aware of the trial having been made.

Other manures of a miscellaneous character are used for turnips. Pigeon's dung is most valuable; rape dust has been used successfully; and animalized carbon has also been advantageously employed. Sixteen bushels per acre, when drilled, is the quantity generally applied. Malt culms are useful as a top-dressing. (Trans. York. Agr. Soc.)

A machine for sowing turnip-seed with bone-dust is described in the second volume of Trans. High. Soc. p. 205; and the results of some experiments with different manures is given, Trans. High. Soc. vol. i. p. 66, 72, vol. iv. p. 232.

Weir's Manuring one-row Turnip Drill, is described and figured by Loudon, and said to be a remarkable improvement on the Northumberland implement. It has a manure hopper, and a seed hopper, the same as the others; but the manure, in place of being dropped along with the seed, is deposited in a deep gutter made by the coulter which goes before; this manure is covered by a pronged coulter which follows the other; next comes the coulter which forms the gutter for the seed, which are deposited 1 inch above the manure. (See Loud. Ency. of Agr.)

Varieties.—There are numberless varieties and sub-varieties of turnips, which arrange themselves under four heads:—1. Swedish turnips, or Ruta baya; 2. Yellow and white turnips; 3. Yellow turnips; and 4. White turnips. Professor Low has divided them into three classes, distinguished by their form:—1. The round, or globular; 2. The depressed; and 3. The fusiform. These may be considered as types, to which the different cultivated kinds more or less approach. Many varieties are cultivated which are more fanciful than useful. For the main particulars of the following list I am chiefly indebted to an interesting Essay on the 1064

TURNIP.

TURNIP.
**TURNIP.**

*Turnips* published by Dr. William Ellis of Caistor, Lincolnshire, and to Messrs. Lawson’s excellent *Agriculture’s Manual.*

**Swedish Turnips.**—The Ruta Baga, or Swedish turnip is harder and more nutritious than any of the common sorts, and in addition to its being more esteemed as food for horses throughout the turnip season, is better adapted for spring feeding generally. It, however, requires a somewhat deeper and superior class of soils, together with a greater allowance of manure. Swedish turnips are generally sown from about the middle to the end of May, and 2 to 2½ lbs. of seed per imperial acre are, under ordinary circumstances, considered sufficient. They possess an advantage over the others in being easily transplanted, so that the blanks in the rows, either of the Swedes or other sorts (when they occur), are by that means easily filled up.

**Skirving’s new improved Purple-topped Swede.**—Mr. William Skirving of Walton Nursery, near Liverpool, who has for many years directed his attention to the improvement of agricultural roots and plants, introduced last season for the first time the above variety. From comparison with every known variety of turnip, which Mr. Skirving has been at pains to collect from all quarters of the British isles and many other countries, it appears to have shown itself to possess all the good qualities of a turnip, and gives a greater weight per acre of sound nutritious bulb: it is also harder, and keeps longer than any other variety. The leaves of Mr. Skirving’s Swede appear to participate considerably of the character of those of the common turnips, being less smooth and more serrated at the edges, and deficient in that glaucous bloom which distinguishes the leaves of the genuine Swedish turnip, which leads me to suspect that he has attained the size by hybridizing with some of the larger varieties of yellow turnips. 

**Ballantyne’s new improved Purple-topped Swede.**—This improved variety for symmetry of shape, equality of size, and for the uniform deep purple colour of its top, is unsurpassed by any other variety which has come under our notice. 

**Scott’s Prize Purple-topped Swede.**—This is a heart-shaped, purple above ground, and yellow fleshed, with a small top.

**Letting’s new Purple-topped Swede** is a decidedly distinct variety. It has a leaf something like that of a lettuce. The leaves are so inserted in the top of the turnip as to give it much the appearance of that of a pine-apple. It grows to a good size, keeps well, and bears a very high character among the agriculturists of Berwickshire and Northumberland, where it is extensively cultivated. The crop has a most beautiful appearance when in full leaf.

**Green-topped Yellow Swede.**—This variety is of longer standing than the purple-topped, since the introduction of which less attention has been bestowed by cultivators in procuring improved stocks of the green-topped Swede, which has on that account fallen somewhat in the estimation of growers; but, where the same care is taken in selecting the roots grown for seed, the green-topped may be considered as being equal in merit to the purple.

**Scott’s Prize Green-topped Yellow Swede** is an improved variety of the above. The purple-topped Swedes are at present more popular, as we before mentioned; but where, as is the case with Mr. Scott’s, equal care has been bestowed on the selection of stocks, and in the subsequent management, the green is in no way inferior to the purple-topped variety.

**Hillyard’s Thorpeland Swede.**—This has the appearance of a true Swedish turnip, and is said to be more nutritious, bulk for bulk, than some of the larger varieties, which may or may not be the case. Its dwarfish size, and the impossibility of raising any great weight of food per acre from it, must, notwithstanding its other good merits, be considered sufficient. They possess an advantage over the others in being easily transplanted, so that the blanks in the rows, either of the Swedes or other sorts (when they occur), are by that means easily filled up.

**Coz’s new Imperial Swede.**—This variety may be considered as intermediate in colour between the purple and green-topped sorts; its roots often attain a large size, but are rather irregular, and of a somewhat coarse-like quality.

**White Swede.**—The roots of this turnip are very irregularly shaped, with numberless fangs: they are white under the surface of the ground, and greenish above. It is impossible to say what improvement may be of any use, and, perhaps, the white root is acquired, rather than superior to the white Swede worthy of cultivation.

**Yellow and White Turnips.**—Common turnips are divided into two important classes, viz. the white and yellow-rooted; the former comprehending those which are most tender and arrive soonest at maturity, and which are best fitted for using during the earlier part of the season; and the latter, with trifling exceptions, such as from their hardness and period of arriving at perfection, are intermediate between the white sorts and the Swedes, and, like the latter, require a somewhat superior soil and an additional allowance of manure. The period of sowing common turnips should be regulated according to the length of time that the variety to be grown requires to arrive at maturity; for when allowed to remain in the ground in what may be termed growing weather, or before winter sets in, after they attain to a full size, they become soft, spongy, and of inferior quality. A general rule, however, is, to commence with the yellow sorts about a fortnight after the Swedes, and about the beginning of June, and to follow with the white sorts from the middle till towards the end of that month.

**Yellow Turnips.**—**Aberdeen Sugar Yellow.**—This turnip—alone we are from its being rather below the medium size attained by yellow turnips in general, it is more particularly suited for garden culture—is also in good repute in some quarters as a field turnip. It is recommended for its fine globular shape, and the superior solidity of its flesh. It has a light greenish top, very small neck, and tap-root.

**Aberdeenshire Sugar Yellow.**—This is a very hardy turnip; it buries itself considerably in the ground, is highly nutritious, and one of the most approved of the varieties lately introduced.

**Elgin Imperial Purple-topped Yellow.**—The following particulars, respecting this variety, are given by Mr. Hogg:—“This turnip possesses all the qualities of the Swedish, with the advantage of being a much freer grower.
It produces a larger crop than the white globe, a good feeder, and stands the winter better than any of the common yellows. It is in full perfection for using in February, and continues for as long a period as the Swedes; and should the latter fail, the border imperial being sown as late as the month of June, will yield a crop equal, if not superior, to what might have been expected from the Swedes, had they succeeded."

Green-topped Bullock Yellow.—This turnip attains a medium size. Its shape is globular, or somewhat flattened, with a very small tap-root; it is an old variety, and is held in deserved estimation.

Purple-topped Bullock Yellow.—This variety differs from the former chiefly in the colour of the top, a small size, shape, and quality of the roots being pretty nearly the same. It is also highly esteemed, and is considered by some to come nearest to the Swedes in hardiness and solidity of texture.

Skirving’s Improved Purple-topped Bullock Yellow.—This improved variety of the above obtained for its introducer.—Mr. William Skirving, of Liverpool—the medal of the Highland Society of Scotland. It has been generally grown for a number of years by the first agriculturists in Lancashire and the northwestern counties.

Green and Purple-topped Yellow Scotch differ but little in any of their essential properties from green and purple-topped bullock yellow. The roots are flatter, and grow more in the ground.

Ox-heart Yellow is an excellent turnip; although it comes early to maturity, and attains a considerable size, it is by no means deficient in hardness.

Yellow Globe.—This is a superior turnip, both for field and garden culture. Its roots are of medium size, globular, and always nearly under the surface of the ground; top greenish, leaves rather small and spreading.

This variety differs from the last in growing more out of the ground, and having a greener top; in other respects it is pretty similar.

Brown-topped Tankard Yellow.—Root bright yellow, with a purple or brownish top, of a somewhat irregular long or tankard shape. This variety is in great repute in Aberdeen-shire. A sub-variety of not so very long a shape, is preferred by some growers. They are both excellent turnips.

Green-topped Tankard Yellow differs from the above chiefly in the colour of the top. Of this the latter is a variety of a flatter shape.

Large Laurencekirk Yellow Tankard, introduced by Mr. Robert Scott, of Laurencekirk, resembles Dale’s hybrid in many particulars, like which it grows a good deal out of the ground, but is distinguished by its more oblong and more uniformly shaped roots. It arrives early at maturity, but is generally considered as rather less hardy, although it yields an equally bulky crop.

Dale’s Hybrid.—This highly esteemed variety is a cross between the green-topped Swede and white globe, procured by repeated impregnations. Its most distinguishing characteristics are as follow:—foliage strong and luxuriant, roots of a large size, oblong shape, and of a lightish yellow colour, with light green top, having also a small neck and tap-root. The form of the root, however, although generally oblong, is rather apt to vary, being sometimes almost globular; but its more material characteristics, of large size and luxuriance of growth, are always the same. Compared with any other of the yellow field sorts, it is found to arrive sooner at maturity, and consequently may be sown at a later period of the season; while at the same time it is equally hardy, or at least has been found sufficiently so, to withstand the severest winters which have occurred since its introduction.

Gordon’s Yellow.—This very superior variety is of a rather oblong shape, deep green colour on the top, which is generally very slightly tinged with red. It is very nearly allied to Dale’s hybrid, being a cross between the Aberdeenshire bullock yellow and the Swede. Sir F. A. Mackenzie, Bart., upon whose extreme accuracy as an experimentalist the utmost reliance may be placed, grew last year a considerable number of the most approved kinds of turnips, on his farm at Conan Mains, near Dingwall, in Ross-shire, with the view of selecting such as might be found most worthy of being kept in cultivation as best suited to the soil and climate of Ross-shire. The result of these experiments was, that of Swedes, Skirving’s is decidedly the best; Gordon’s yellow the best of the yellow-deshed, and Scott’s purple-topped hybrid and the old white globe, of the white-deshed kinds.

Hood’s New Large Yellow is a very superior, large, globular-shaped, hardy turnip, remarkably perfect in symmetry, with rather a lightish green top.

Pollexfen Yellow.—This turnip derives its name from its introducer, Thomas Pollexfen, Esq., of Cairston. From his peculiar method of selecting and transplaning the bulbs, as well as of transplanting the turnip-seed of Mr. Pollexfen’s growth has long been held in deserved estimation in Scotland, and has commanded the highest prices. The insular situation of Orkney, although in latitude 59° north, renders its climate less exposed to the extremes of heat and cold than in more continental situations farther south, the winters being mild, and the frost so gentle that the ice is seldom sufficiently strong to sustain the weight of a man. Its climate is on that account peculiarly favourable to the growth of turnips, and turnip-seed grown in Orkney is accordingly highly prized by the Scotch farmers. The Pollexfen yellow is a green-topped turnip of a large size, rather flatterish in shape, skin very smooth and thin; the flesh is firm and nutritions, being slightly impregnated with the green topped Swedish. It is adapted for winter and spring feeding, and is not liable to injury from frost. This turnip obtained the prize at the meeting of the Highland and Agricultural Society of Scotland, held at Inverness in 1836, in the report of which it is highly commended.

White Turnips.—White Globe.—Roots globular; skin smooth, and perfectly white; neck
and tap-root small. Although the above description embraces the principal characteristics of the white globe turnip, yet there is a considerable variety in those to which the name is applied, arising from the degree of care and attention bestowed by growers in selecting their seed-roots; and the shape is often not a little affected by the kind and state of the soil in which they are grown. Thus globes of any kind, and particularly the variety here mentioned, when grown on a very superior rich soil, may be seen forced beyond their natural size, and thereby acquire somewhat of a monstrous or overgrown appearance, losing in a great measure their natural symmetry of shape.

Pomeranian Globe.—This variety was introduced some years since from Pomerania, and may be considered the most perfect globe turnip in shape, as well as the most regular or uniform grower. Its skin is of a smooth white, and somewhat shining or transparent-like in appearance; leaves smoothish, of a dark green colour, with whitish nerves.

Green Globe.—Roots of a globular shape, with round neck and tap-root; very white beneath, and green above the surface of the ground, of medium size, hardy and firm of texture, but scarcely so much so as the green round, although it arrives at maturity rather earlier.

Stone Globe.—This is considered to be the hardiest of all the entire white globe turnips. It grows naturally deeper in the soil than the others, and has stronger and darker green foliage.

Red Globe.—Roots medium-sized, globularly shaped, and firm in texture. This is an old, and, in some districts, a pretty extensively cultivated variety. It is medium early, and generally allowed to be particularly well suited for light soils and exposed elevated situations.

White Round is known in Lincoln by the name of spring white. It is the largest of the round turnips, and, at the same time, the softest and most irregular in shape. It is generally hollowed towards the neck, and, being so, is apt to be injured by retaining moisture, which renders it unfit for using, except in the beginning of the winter season.

Green Round.—The round turnips are all of a peculiar flattish shape, rather hollowed towards their neck, as also on their under side; and, when grown to a large size, they become more or less of an irregular round, or somewhat cornered shape. The green-topped variety possesses these characters in a less degree than the former, and is generally of a pretty, regular, round shape, flattened, but not much hollowed, on the upper and under surface, the former of which is of a green colour, and the latter white. It is also the hardiest of the round turnips.

Red Round.—This sort is inferior in size to the two former, but rather firmer in texture, and more regular in shape. It should also be used in the early part of the season.

The tankard, like the three preceding kinds, are unsuitable for winter feeding, not so much on account of their softness, as from their standing mostly above ground, and being thereby much exposed to frost. They are generally earlier in arriving at maturity than the others. The white tankard has its roots more than half out of the ground, oblong, or tankard-shaped, but often bent or crooked. It is the largest of the tankards, but is also softer in texture than either red or green; its leaves are large and luxuriant: it is the earliest in maturing of any, but will not stand the frost.

Green Tankard.—The roots of this species are also more than half above ground; of a greenish colour, except on the under surface, which is white.

Red Tankard.—In size, form, and texture, this variety may be considered as occupying an intermediate place between the white and green tankard. It is of a bright red colour on the upper surface, and white on the under.

Lawson Hybrid.—This variety, which was raised by James Wright, Esq., of Lawton, near Perth, may be considered as bearing the same relation to the Swede as Dale's hybrid. Its leaves are darkish green, rather small and smoothish, roots roundish, or somewhat heart-shaped, being often tapered on the under side; white below and green above the surface of the ground: they are hardy, and possessed of more solidity and firmness of texture than most of the white sorts.

Scott's improved Purple-topped Hybrid.—This variety obtained the prize of the Highland Society of Scotland at the meeting at Glasgow in 1839. For a white-fleshed turnip it is remarkably solid, and attains a great size. This turnip was decidedly the best in point of size, symmetry of shape, uniformity of growth, and quality of flesh, of all the white-fleshed varieties grown by us last season in our experimental ground. It occupied the same preeminent place among those made trial of by Sir F. A. Mackenzie, Bart.

Chesham Green-topped Ox-heart.—This is an excellent variety, grown in some of the southern districts of England, and in Scotland. It acquired this name from having been first introduced by Messrs. Willmot & Co. of Lewisham.

Autumn, Stubble, or Six Weeks.—Roots much above ground, rather large, of an irregular globular shape, or in form between the white globe and white round, and rather soft. This sort arrives sooner at maturity than any of the others, the tankard turnips perhaps excepted; and from its natural softness of texture should always be sown late, and used before the severe frosts set in. As descriptive of its forwardness, it has received the above names, being suited for sowing in early situations in autumn after the corn crop has been removed, and it is also valuable for making up blanks in turnip fields, where the first sowing may have partially failed.

The comparative nutritive powers of the different varieties of turnips appear to be as follow:

(Sinclair's Hort. Gram. p. 406.)

1067
Methods of sowing.—The modes of sowing are various; but the general principle to be attended to is, to get the seed into the nearest possible connection with the manure used, so that it may have all the advantage of its fertilizing influence in the earliest stage. This is forestalling, because, it decides the drill method to be the most valuable, before we describe the others; but it is a principle so necessary and obvious as to strike every reflecting person at the outset. The old broadcast plan was, to spread on the manure, plough it in, and then very carefully sow the seed with the hand. This practice is almost everywhere abandoned, nor can it be justified or recommended in any case.

The plough drill is used where farm-yard manure only is employed. The manure is spread on the ground, and the plough follows with the drill, being fixed to the right-hand side of the plough, and thus deposits the seed immediately on the manure made by the plough, and directly upon the manure just covered by the plough. The plough-drill is only useful where very bulky manure alone is applied. See Drill.

The ridge or Scotch method is used with success, especially on inferior and thin soils, and has its decided advantages. The ridges are made either with a single cast of the double mould-board plough, or a double one of the common or ribbing plough, and from 20 to 28 inches apart. A cart with manure follows, and women are generally employed to drop the manure into the seams made by the plough. This process follows, and closes the ridges, covering the manure; and the drill succeeds, drawn by one horse, and sows one ridge at a time. A light roller goes over the sown ridges to cover the seed, and sometimes the ridges are rolled before the sowing. This plan takes more time and labour to effect it, but the turnips generally succeed; and if they should be destroyed by the flea-beetle, they can be resown with more probability of success than by any other method.

The general and most expeditious way is by the large drill. This is constructed to deposit the bones, ashes, &c., with the seed, upon the level and sideways. A ridge or 7 rows of seed is drawn by 3 horses, and will drill 12 acres per day. The seed does not run down the same funnel as the bones, but has a separate apparatus immediately behind the latter, and the coulters of the drill generally cover the whole. A pair of light harrows are usually passed over once after the sowing; and should much heavy rain succeed, it is desirable to give it another turn with the harrows immediately before it is dry, to prevent it from scaring. The quantity of seed sown by each of these methods, is from 2 to 3 pounds per acre.

After Culture.—When the turnip plants are of about 3 weeks' growth, they require to be thinned, and the weeds destroyed. This is usually performed by hand-hoeing; but in some cases Swedes are hand-thinned by women, and subsequently horse-hoed, which can be done in all cases where they are sown in ridges, and is a considerable saving of labour. No two plants should be left together at the first hoeing, but they should be thoroughly singled; and a second hoeing must take place about 2 or 3 weeks afterwards, to destroy the weeds. For ordinary crops, they should be left 7 to 12 inches distant, according to the richness or poverty of the soil; if the latter is the case, they should be at shorter distances, as they will grow to a smaller size. The whole of the ground should be gone over, as it loosens the earth, and promotes the growth of the plants. The double operation is usually performed for from 6s. to 7s. per acre. Sometimes the crop requires hand-weeding in the autumn, especially if the soil is infested with charcoal.

Diseases.—The extensive and repeated culture of the turnip has fostered the rapid increase of its natural enemies; and after all the pains, labour, and expense of the cultivator, he often sees his crop entirely destroyed, or seriously injured. The remedies he can apply for many of these can only be termed palliative; but since he is now endowed with a knowledge of natural history and field-entomology advances, he may expect more and more assistance. See Insects.

The turnip flea-beetle (Haltica nemorum) is one of the worst enemies which attack the turnip plant, which it does when in its seedleaf state, and often destroys a crop, and even the second and third sowings. Various steps have been taken in order to prevent its attacks, and several steps for the seed used, but without success; top-dressings of a saline and astringent character have been applied, but have failed; machines have been invented, but none of these have succeeded. The only directions which can be given are: sow plenty of seed; use stimulating manure, to excite the plants to vigorous growth in their first stages, and secure a sufficiency of moisture in the soil at the time of sowing; especially keeping seedlings in turnip fields clear of charcoal, which nurses the flea. See Fly in Turnips.

The black caterpillar, larva of the Athalia centrifolia, also preys upon the leaves in a more advanced stage, appearing on the plants when they are about 3 weeks old. See Saw-flies.

Another disease to which the turnip is liable, is vulgarly called “fingers and toes.” See Anthrax.

The wire-worm is a sad enemy. (See Wire-worm.) The swarms of aphides, or plant lice, severely injure the turnips; and, from the smallness of their size, are often unobserved. In 1836 they committed terrific ravages. They suck the juices of the plant, and appear in countless numbers. They are both oviparous and viviparous, and increase with amazing rapidity. Happily they are always followed by swarms of lady-cows, which feed on them, as well as insectivorous birds, which destroy vast numbers. No remedy can be applied with any probability of success. Every farmer should carefully protect swallows, red-breasts, &c., which are great destroyers of the aphides.

Slugs are, especially on newly ploughed soils, great devourers of the turnip plant in all its stages. Ducks will devour them, but always injure the plants. Three bushels of quick
lime per acre, scattered over the plants early in the morning, when the slugs are active, is a certain method of destroying them. Perhaps the very best preservative from all the above diseases may be stated to be—liberal manuring, adapted to the soil; thorough clearing of the land from weeds; and, in short, pursuing the steps above detailed for securing a full crop. The vigour of the plants in such cases, and their rapid vegetation, often enable them to overcome many serious attacks.

Storing.—There are different modes of performing this useful practice. The common way is to take up the turnips, choosing dry weather, cutting off the leaves and taproots (provincially called topping and tailing), which operation should be performed with as much exactness as possible, so as not to wound the bulb, as this would cause the turnip to rot; nor yet to leave much of the leaves, as this would make the turnip vegetate on receiving a slight degree of heat; after this the turnips are placed on straw, and left close together, on the feeding byre, in a narrow tapering ridge, similar to potato pits, and this is covered with straw and secured with ropes. The situation chosen for the store should be as dry as possible. The heaps must not be covered with earth, like potatoes; for this would cause the turnips to heat and completely destroy them.

But as this practice of storing is only adapted for the Swedish and yellow varieties, the white globe variety possessing too much water to be preserved for any length of time, another method is often practised by what is called ploughing the clover. The turnips are placed down the furrow, with the leaves, are placed close together in the position they grew, upon some dry place near to where they are to be consumed. In this way they will keep longer than if they had been left in the field, as they are not so apt to run to seed.

But even the placing system has its objections; for if a tract of dry weather set in, the turnips, from being merely on the surface, become soft and shrivelled, and not so palatable to the cattle, and will even continue so for a considerable time, although the weather should be rainy, until the fibres begin to take hold of the soil; and another objection is, that if the turnips are not placed near the standing, the destruction from game, hares, wood-pigeons, &c. is very great, particularly if the turnip be Swedish.

In order, therefore, to remedy these objections, another method has been adopted, which has been found to answer every purpose intended. The turnips are brought from the field, without either “topping or tailing,” to a piece of dry ground near the straw-yard; then a man with one horse in a plough makes a straight furrow; the turnips are then placed in the furrow quite close together, till the whole is filled from end to end; then the man with the plough moves round to where he commenced, drawing another furrow just as close to the turnips as to enable him to cover them, and so on alternately, the men making the furrow and covering the turnips, while the women and girls lay in the turnips. By this method the turnips keep as fresh, preserving all their natural juice and are as well relished by the cattle as though they were taken from the field; thus allowing the land to be sown with wheat.

The report of the Harleston Farmers’ Club for 1839, affirms that the best method of preserving roots during the winter, is by clamping them, both as regards protection from frost and maintaining their quality; and that the following is a very effectual method of making the clamps: Select a convenient and dry situation, and pack the roots carefully, with their crowns outside, in a row about 6 feet wide at the bottom, and terminating in a narrow ridge at the top; then dig a trench, commencing immediately at the edge of the roots, 2 feet wide and 1 deep, turning the mould from the heap; thatch the latter carefully with straw, commencing in the trench, so that all the rain may drain off the heap into it. The clamp may be left two or three weeks in this state, that the evaporation from the roots may escape; the mould already taken out of the trench is then to be laid on the straw, commencing at the bottom of the clamp, and at even distances as above the roots; 8 to 10 inches thick throughout, finishing with a sharp edge. Half the trench originally made will, of course, by this plan be filled up with straw and mould; the other half will remain as a channel for the water falling off the heap; and, as sufficient mould will not have been raised from the original excavation, it will be advisable, in procuring more, to make the channel left round the heap a few inches deeper, as well as wider. If the roots are stored late in the season, and the probability of frost setting in renders it necessary to cover the heap with clamps, it is necessary to leave the top uncovered for a week or ten days longer, that the heat may escape. There is no objection to the roots being wet and dirty when they are clamped: the tops should be cut off, but not too close to the crown; the roots and fibres should be left on.

In England, the turnip crops cultivated with so much care and at so much cost, yield a most abundant supply of vegetable matter, most of which, owing to the comparatively mild winters, is left on and in the ground to be eaten off by sheep. This adds great fertility to the soil and prepares it for producing those astonishingly luxuriant crops of wheat of 40, 50 and 60 bushels to the acre. The profits of the turnip crop, either direct or indirect, must be very great, to authorize a tenant on land loaded with taxes, to go to an expense of nearly $50 per acre in putting in his root crop, as may be seen in the article APPRAISEMENT, where the details of expenditures in putting in only 17 acres of Swedish turnips are estimated at £117 15s. sterling, equal to nearly $900, of federal money, a sum actually paid for the crop in the ground by an incoming tenant. The root crops of Britain which form the basis of her agricultural prosperity, can only be partially carried on in the United States, owing to the severity of the winter, by which every thing on or near the surface of the ground is bound in early and enduring frost. But then, where cold thus opposes a barrier, a high summer heat opens a new resource, and where nature obstructs the way in one direction, she opens others to agricultural thrift. One of these is
the Indian corn crop, denied Europe, except in a small space on or near the Mediterranean. The turnip crop, far transcending that of any other staple, is referred to under the head of MAIZE. In reference to the agricultural value of the turnip and other roots, Mr. Nicholas Biddle in an address before the Philadelphia Agricultural Society in 1842, made the following interesting observations:—

"It is strange how things so slowly acquire national importance. The best farming is that which will give the greatest mass of sustenance to animals—since the less land required for animals, the more can be given for the maintenance of human beings. The farming region, England, had reached the limit of its power of supporting animals—since it turned to the root culture it more than doubled or quadrupled its power—and now, odd as the mingling of such dissimilar notions may seem, it is scarcely an exaggeration to say, that England's power is based upon its iron, its coal, and its turnips. Then, that beet, which the commercial jealousy of Napoleon endeavoured to raise to the dignity of the sugar-cane, which at this moment yields to France more than 60 millions of pounds of good sugar, and has now become so incorporated with the French agriculture, is the government of France between the encouragement of the foreign sugar-cane and the domestic sugar beet. To us the question is unimportant, since sugar is so cheap in this country as to leave to us the sugar beet as an excellent food for our cattle."

Although the excessive frosts in the United States interfere with the English plan of feeding the turnips from the ground during winter, still there is no question that great advantages may be derived by the American farmer from the cultivation of the turnip, the Swedish especially, to lay up as green and succulent food for stock, to be used conjointly with hay and other kinds of provender. Very satisfactory experiments have demonstrated the value of turnips appropriated in this way, for an account of which the reader may consult Buel's Farmer's Instructor, Coleman's Reports, the Cultivator, and other Am. agricultural periodicals.

The insects which attack turnips in America will be found described under the heads CATERPILLAR, FLEA-BEETLE, FLY in TURNIPS, &c.

TURNIP CART. This is an ingenious adaptation of the disc turnip cutter to the turnip cart. The disc is in motion by a cog-wheel fixed upon the nave of the cart-wheel, which, as it revolves communicates by means of cog-wheels with the axis of the cutting-plate. It offers a very convenient mode of feeding sheep on pastures or lawns, and was introduced about the year 1834, by Arthur Biddell, farmer, of Playford, the inventor of the well-known scarifier, which bears his name.

TURNIP CUTTERS. Although there are several kinds of turnip cutters, the principles upon which they are constructed do not embrace much variety: setting aside the simple application of the knife with a lever handle, the others may be divided into two classes; first, those which have their knives placed on a disc; and secondly, those with their cutting edges arranged on a cylinder.

TUSSER, THOMAS.

As the object to be effected is simple, and involves little mechanical contrivance, a short description will suffice. Gardner's Patent Turnip Cutter, is pronounced the best known in England. In Ransome's Barrow Turnip Cutter, Gardner's machine is used, the disc of which is attached to the side of a barrow, which serves as a hopper; the knife is nearly the length of the radius, and when required to cut the turnip in slices is alone used; if it be necessary to cut small slices for sheep, the small cross-knives are, by a simple contrivance, adjusted to disect the slice; and in this case the barrow is useful, as it is easily moved from trough to trough into which the small slices may be made to fall.

It is intended to cut into small slices for sheep, and is generally acknowledged to be the best implement for the purpose that is at present in use in England.

TURPENTINE. A transparent, oleo-resinous substance, which exudes naturally, but is chiefly obtained by incision, from various species of pine. There are several kinds of turpentine, namely, common, Bordeaux, Canadian, Strasburg, Venice, and American white. The Chian turpentine is the preparation of the resin of the Pistacia Lentiscus tree. All of them possess the same general and chemical properties.

TUSSER, THOMAS, a celebrated agricultural writer. Five-and-twenty years after the publication of the first English work upon agriculture (Fitzherbert's Boke of Husbandry), appeared (in 1557) the One Hundred Points of Good Husbandry, by Thomas Tusser. This celebrated work must be regarded more as a series of poetical good farming, and domestic directions and axioms, than as a regular treatise upon agriculture. All that is known of the author of this curious production has been collected by Dr. Mavor, in his able edition of Tusser's book, and by my brother, Mr. George W. Johnson, in his History of English Gardening; and both these authors have been obliged to content themselves chiefly with Tusser's own account of himself; for Tusser did what few men ever attempt—he wrote his own life, and in a manner still more rare, in verse. His life was full of adventure; for he evidently had all the restlessness of genius, with the unsettled habits too commonly confirmed by continued change of occupation.

He was born about the year 1515, at Rivenhall, a village on the high-road between the towns of Witham and Kelvedon, in Essex, of a family allied by marriage to the higher ranks of society.

He was buried in the church of St. Mildred in the Poultry, according to Stowe, with this epitaph:

"Here, Thomas Tusser, clad in earth, doth lie, That sometime made the Points of Husbandry: By him they learn them may; yet; here learn we must, When all is done, why sleep, and turn to dust: And yet, through Christ, to heaven we hope to go; Who reads his books, shall find his faith was so."

In whatever capacity he at various times lived he acted with ability, yet never so as to benefit his fortune. That he excelled as a chorister,—to which he was originally educated, though strongly against his inclination,
TUSSER, THOMAS.

is certain; for none but those of more than ordinary powers are admitted into the royal choir. As a courtier he was unfriended upon till the disgrace of his patron. As a farmer it is evident he possessed a correct knowledge, from his work upon the subject. The same book testifies that, as an author and a poet, he was far above mediocrity. Fuller, in his Worthies of Essex, describes him, in his usual quaint manner, as "a musician, schoolmaster, serving-man, husbandman, grazier, poet; more skilful in all than thriving in any vocation. He spread," he adds, "his bread with all sorts of butter, yet none would stick thereon." The testimony of Fuller to the excellent private character of Tusser is valuable as coming from one who must have been the contemporary of many persons who well remembered our author. "I hear," says Fuller, "no man to charge him with any vicious extravagancy or visible carelessness." The true reason of his ill success in life is to be found, perhaps, in the verses of a poet almost his contemporary. Peacham, in his Minerva, a book of emblems, published in 1612, has a device of a whetstone and a scythe, with this beneath:

"They tell me, Tusser, when thou wast alive, And hated for profit turned every stone, Where'er thou causest thou couldst never thrive, Though hereto best couldst counsel every one; As it may in thy Husbandry appear, Wherein afresh thou livest among us here. So, like thyself, a number more are wont To sharpen others with advice of wit, When they themselves are like the whetstone blunt."

Tusser's work first appeared in 1557, entitled "A Hundred Good Points of Husbandrie:" 

"A hundred good points of husbandry" is contained in the household, with household, with wisdom. Housekeeping and husbandry, if it be good, Must love one another like cousines in blood. The wife, too, must husband as well as the man, Or farewell thy husbandry do what thou can. Imprinted at London, in Pletre strete, within Temple barre, at the sygne of the hand and starre, by Richard Totell, the third day of February, An. 1557. Cum privilegio ad imprimumdolum solem."

A copy of this edition, which Dr. Mavor considers to be unique, is in the British Museum. It consists of only 13 quarto leaves. The Book of Husbandry, it is supposed, was at first printed by itself; it was afterwards added to the editions of the Husbandry. Editions of this work appeared in 1561, 1562; and another, "newly corrected and amplified," 1570, 1571 (Watts). To these succeeded an enlarged edition and several reprints, the last of which is that edited by Dr. W. Mavor in 1812, 4to and 8vo, with many notes and additions.

To this Book of Husbandry, says Weston, is often joined The Book of Regards, containing the Castle of Delight, the Garden of Unchrittinesse, the Arbour of Virtue, and the Castle of Repentance. Another work is ascribed by Haller to the pen of Tusser, viz. Tractatus de Agricultura Versibus Anglis. London, 1638—72. Both these last-mentioned works are extremely rare.

Tusser dedicated his book first to Lord William Paget, in an acrostic, and after his death to "the Lord Paget of Beaudesert," his son and heir. From this we find that Tusser shared an author's very common fate, for he tells us—

"By practice and ill spending, These lessons had their breeding, And not by hearesay or reading. As some abroad have blown; Who will not thus believe me, So much the more they grieve me, Because they grudge to give me, What is of right mine own?"

Its price, when first published, as described in his prefatory address to the reader, was only 4d. or 6d. He says, "What is a groat Or twain to note, Once in the life, For man or wife?"

The style in which Tusser wrote his book is plain, and sometimes rather hobbling; but at the same time it is a metre easily remembered; and verse is well adapted to impress upon the memory the mass of useful truths and rural directions contained in the work. In the rhyming preface, "to the buyer of this book" (for Tusser seemed to do every thing in verse), he says—

"What look ye, I pray you shew what? Terms pointed with rhetoric fine? Good husbandry seeketh not that, Nor is't any meaning of mine."

His tenth chapter consists of a series of 63 excellent "Good Husbandry Lessons, worthy to be followed of such as will thrive." He omitted no opportunity to give occasion for reasonable reflections:

"As bud, by appearing, betok' neth the spring, And leaf, by her falling, the contrary thing; So youths bids us labour to get as we can, For age is a burden to labouring man."

He comments the system of moderate cor rents, and was evidently no enemy to the sports of the field:

"To hunters and hawkers take heed what ye say, Mild answer with courtesy, drives them away; So where a man's better will open a gap, Resist not with rudeness, for fear of mishap."

He begins his monthly husbandry with September, for that was then the period, as now in England, when arable land was commonly entered upon by the farmer. He says, in his opening stanza,—

"At Michaelmas lightly, new farmer comes in, New husbandry forceth him; new to begin; Old farmer, still theking, the time to him given, Makes August to last until Michaelmas even."

In furtherance of his object, that of giving some very minute directions to the incoming tenant, he even gives a catalogue of farming implements in verse, in which he manages with some adroitness to include several apparently impracticable names, such as,—

"A hand-barrow, wheel-barrow, shovel, and spade, A curry-comb, mane-comb, and whip for a jade."

It was the approved practice in Tusser's days to "sow it timely thy white wheat, sow rey in the dust." They were used also to put rye meal into their wheat-flour:

"But sow it not mixed to grow so on land, Least rye tarry wheat till it shed as it stand."

Thick and thin sowing had even then their respective advocates:
TUSSER, THOMAS.

"Though beans be in sowing; but scattered in, Yet wheat, rye, and peason, I love not too thin; Sow barley and drudge with a plentiful hand, Let wheat, stend of seed, overgrows thy land.

It is evident that in those days the farmers were not able to grow their grain on many soils where the modern holders find no obstacles. Thus he speaks of the difficulty they found in producing barley in the parish of Branham, in Essex, where he farmed some land; and, again, he tells us, what will surprise the modern skilful Suffolk farmers,—

"In Suffolk, again, whereas wheat never grew, Good husbandry, used, good wheat land I knew."

And he adds,—

"As gravel and sand is for rye and not wheat." He mentions several varieties of wheat then grown by the farmers of the reign of good Queen Bess, such as white and red rivet, white and red pollard, Turkey and gray. But of this last he says,—

"Oats, rye, or else barley, and wheat that is grey, Brings land out of comfort, and soon to decay.

The land, however, was evidently farmed with little skill:

"Two crops of a fallow, enricheth the plough, Though one be of peace, it is land good enough: One crop and a fallow some soil will abide, Where, if ye go further, lay profit aside."

He warns the farmers to beware of corn-stealers, and to keep their soil in good heart; to manure their land with the earth from headlands and old banks; he commends the use of night-soil for gardens; and recommends the manure of the farm-yard to be laid up "round on a hill." And he had the wisdom to perceive the advantages of shed-feeding live-stock:

"The housing of cattle, while winter doth hold, It is good for all such as are feeble and old; It saveth much compass and many a sleep, And spareth the pasture for walk of thy sheep."

Grazing has, since Tusser's days, been more and more on the decline, as soiling has been better appreciated. A distinguished modern, witty divine, in a letter to a friend, thus zealously denounces the grazing system: "Grazing is an absolute barbarism; it is just the same as if you desired your servants to trample and roll over your bread and butter."

For faint cattle he recommends the use of bay-salt; and in his February's husbandry gives some directions for the management of their dung, which betrays a deplorable want of knowledge in its economy:

"Who layeth on dung, ere he layeth on plow, Such husbandry useth, as thrift doth allow: One month ere ye spread it, so still let it stand, Ere ever to plow it, ye take it in hand.

Place dung-beap slaw, by the furrow along, Where water, all winter-time did it such wrong: So make ye the land to be lusty and fat, And corn the sooner grown, to be better for that."

In another place, however, he recommends the farmer to use the mud from ditches and ponds as a dressing for their land.

They harvested their corn, it seems, then, much after the same manner as at the present day. They reaped their wheat and mowed their stubbles; and this they carried as we do now, as soon as possible after harvest:

1072

TUSSER, THOMAS.

"For fear of destroying with cattle or rain, The sooner ye load it more profit ye gain." And as to barley, Tusser says,—

"The mowing of barley, if barley do stand, Is cheapest and best, for to rid out of hand: Some mow it, and rake it, and set it on cocks; Some mow it, and bind it, and set it in shocks.

They let out, at the period when Tusser wrote, it seems, the harvest-work either by the day or by the week, or at the will of the worker, of getting in the corn he seems to prefer the latter:

"By great will deceive thee, with ling'ring it out, By day will despatch, and put all out of doubt."

His directions to the farmer with regard to the treatment of his harvestmen and the poor gleaners, and his warm hopes for the farmer's success, betray the excellent benevolent spirit with which he was actuated. He says,—

"Corn carried, let such as be poor go and glean, And after thy cattle, to mount it up clean; Then spare it for rowen till Michel be past, To lengthen thy dairy, no better thou hast.

In harvest-time, harvest-folk, servants and all, Should make altogether, good cheer in the hall; And fill out the black bowl of blythe to their song, And let them be merry all harvest-time long. Once ended thy harvest, let none be beguil'd; Please such as did help thee—man, woman, and child. Thus doing, with alway, such help as they can; Thou winnest the praise of the labouring man.

Now look up to God-ward, let tongue never cease In thanking of Him for his mighty increase Accept my good will,—for a proof go and try; The better thou livest the gladder am I."

Having commenced his directions with the outgoing tenant, his last stanza concludes with a reference to the incoming:

"New farmer he thinketh each hour a day, Until the old farmer be packing away.

"Thou endest and holdeth out August's Husbandry till Michaelmas Eve. Tho. Tusser."

The Book of Husbandry of Tusser is also interesting from the information it gives us with regard to the customs and habits of the farmers of more than two centuries and a half since. It is evident that they then lived very much upon salt fish, for in his directions for the farmer's diet, he mentions for Lent herring and salt fish—at Easter they had veal and bacon—at Martinmas, beef—before the feast of St. John, mackerel—fresh herrings at Michaelmas—at Hallowtide, sprats and spurdlings—for Christmas fare they seemed to have all the modern standing dishes,—

"Good bread and good drink, a good fire in the hall, Brandy and a good house, and good mustard withal; Beef, mutton, and pork, shred pies of the best, Pig, veal, goose, and capon, and turkey well drest."

They evidently, however, lived generally very frugally:

"Where fish is scant, and fruit of trees, Supply that want with butter and cheese, Quoth Tusser."

They bought, in Tusser's time, such stocks of salt fish as would amaze a modern farmer in these protestant days, when by the increase of green weeds not only cattle and sheep are kept easily through the winter, and fresh meat is always to be had. Few farmers would now think of undertaking a journey to buy fish; yet he directed the farmer of the sixteenth century,—
"When harvest is ended, take shipping or ride, 
Lio, salt fish, and herring for Lent to provide;
Get home that is bought, and go stack it up dry, 
With peas, straw between it, the safer to lie."

They had a rude way of measuring time, it seems:
"As hours are teached, instead of a clock,
How winter nights pass by by crowing of cock."

The care of the garden evidently fell to the wife’s share, who had also to see to the feeding of the household. It seems that the labourers had then a great fondness for porridge, for Tusser tells us,—

"No spoon-meat, no bellyfull, labourers think."

In other days, too, it is evident that spinning was no mean part of the mistress’s avocation, for it is here said,—

"Wife, pluck fro thy seed hemp the finible hemp clean; 
This looketh more yellow, the other more green. 
Use t’one for thy spinning, Michell the other, 
For shoe-thread and hatter, for rope and such other: 
Now pluck up thy flax for the maidens to spin."

Tusser never seems to have forgotten, on any occasion, to recommend to the landholder the payment of his just dues; even the question of the tithes, once so obnoxious to the farmer, was not overlooked by him. He advised his farming brethren to

"Tithe duly and truly, with hearty good will, 
That God and his blessing may dwell with thee still; 
Though parson neglecteth his duty for this, 
Thank thou thy Lord God, and give ev’ry man his."

The Points of Husbandry, united to the Comfort of Husbandry, by Thomas Tusser, Gentleman, was, it is concluded, first published with The Husbandry in 1561 or 1562. It is written in a rather more lively style than the former, and has an epistle dedicatory, "to the right honourable, and my especiall good lady and mistress, the Lady Paget," which he thus commences:

"Though danger be mickle, 
And hafavour so fickle; 
Yet duty doth tickle 
My fancy to write: 
Concerning how pretty, 
How fine and how netty, 
Good huswife should Jetty 
From morning to night."

This work contains an abundance of directions, in his usual style of versification, for the conduct of household duties. He directs the servants, before breakfast, to be set to work:

"Let some to peel hemp, or else rushes to twine, 
To spin, or to card, or to seething of brine."

At breakfast time the wife was, in those days, the carver for the farm servants:

"Let huswife be carver, let pottage be heat, 
A mess to each one with a morsell of meat."

In the cookery department the now nearly extinct race of turnspits were indispensable attendants upon the cook:

"Good diligent turnbroche, and trusely wishal."

In his washing section he is rather more terse than gentle in his conclusion:

"Maids, wash well, and wring well, but beat, ye wot how."

If any lack beating, I fear it be you.

In his directions for malt-making he alludes to the use of straw and wood, but does not mention the modern fuel, coke, or cinders. They used, it seems to dine at noon:

"By noon, see your dinner be ready and neat; 
Let meat tarry servant, not servant his meat."

The mistress of the house then made, as now in some parts of England, her own candles, it seems:

"Provide for thy tallow, ere frost cometh in, 
And make thine own candly, ere winter begin."

Twice a week, Sundays and Thursdays, the ploughmen were entitled to roast meat for supper; and to a harvest goose when the corn was gathered in. At harvest-home the mistress was enjoined,—

"Remember thou, therefore, though I do it not, 
The seed-cake and pasties, and furney pol."

In Tusser’s time a very unwholesome custom prevailed, in the absence of carpets, of strewing the citizens’ houses with rushes, and those of the country with flowers. He gives, therefore, a list of “strewing flowers of all sorts,” in which we find only the common sorts of flowers now cultivated, such as cowslips, daisies, lavender, roses, sage, tansy, violets, &c.

Such were the works of Tusser, writings which were long in the hand-book of the English country gentleman. That they were popular is evidenced by the rapid succession of copious editions which fell to their lot; that they were read with delight is shown by the way in which he is commonly quoted by the farmer of all grades. If he had spoken in prose, as has been sometimes suggested, he might certainly have been more instructive to the few, but he would not have been read by the many.

The popular details and histories of all nations escaping from rudeness are commonly written in prose; and multitudes can learn these by heart who never were taught to read. Tusser, therefore, is deserving of the gratitude of the English farmer, for his labours tended to improve, to refine, to elevate the profession he celebrated in his verses. The attempt at any thing like a systematic treatise on farming had not, when Tusser died, been deemed possible. (Quart. Journ. Agr. vol. xii. p. 69.)

TWAYBLADE (Listera ; named in honour of Martin Lister, M.D., a famous English physician and naturalist; best known as a conchologist and entomologist). A genus of curious little native plants, growing wild in shady places. They may be grown in a mixture of peat and loam, and are increased by divisions of the roots.

TWIG-RUSH (Cladium, from klados, a branch or twig, referring to the appearance of the plant). This is a genus of hard, harsh, rushy, often prickly-edged plants, whose stems, whether round or triangular, are more or less clothed with alternate sheathing leaves or scales.

Twitch. See Cucumber.

U.

UDDER. The glandular organ of a cow, mare, ewe, or other animal which is destined for the secretion of milk. There are four teats, each of which consists of two granular lobated glands, comprehending bloodvessels, nerve.
and milk ducts, all of which first unite into eight or ten principal ducts, and these again into one, which perforates the skin of the teat at its apex. The granular part is the secreting organ.

UMBEL. In botany, a particular arrangement of the flowers in certain plants, of which the carrot is a familiar example; the peduncles and pedicels spring from a common centre, and rise till they form a somewhat flat tuft. The umbel is a loose inflorescence, the primary axis of which is short, and the secondary long; and the umbel becomes compound when the secondary axes are developed, in the same manner as the primary. Both the primary and the secondary umbel is generally furnished with bractes at the point of its divergence. The secondary umbel is termed umbelulate. The difference between an umbel and a corymb is, that in the latter the flowers form a flat head, the secondary axes arising alternately from different points of the primary, not, as in the former, springing from a common centre. See Inflorescence.

UMBELLIFEROUS PLANTS (Umbelliferae). An extensive group of useful plants, including those well-known garden vegetables: parsley, celery, carrots, fennel, caraway, coriander, dills, anise, lovage, angelica, eryngo, saumure, hemlock. The name of the class was given from a fanciful resemblance to some waking an umbrella or parasol. The flower-stem divides at the top into a number of short, slender branches, which all run from a common point or centre like the rays of an umbrella from the ring sliding up and down the stick. The class, though containing so many useful plants, has many possessed of extremely poisonous qualities, such as hemlock, the fool's parsley (Aethusa cynapium, Pl. 19, e), dropwort, &c. The blossom of the elder resembles at first sight those of umbelliferous plants, to which, however, the elder does not belong, because the rays of the flower do not proceed from a common point, some being higher, some lower.

UNDERWOOD. A term applied to coppice, or any wood not accounted timber. See Coppice, Forest, and Plantation.

URINE. A saline fluid secreted from the blood of animals by the kidneys, collected in the urinary bladder, and emitted by the canal of the urethra. Urine differs in different animals, and varies in its characters, according to the kind of food employed. The usual salts contained in it are, sulphates, phosphates, and chlorides, all of which are fertilizing substances. The urine also of oxen and horses is alkaline; it undergoes decomposition less rapidly than that of carnivorous animals: it contains hippurates, but no lithic acid, that substance which forms red gravel in man. Hippuric acid contains 7 per cent. of nitrogen. Urine, therefore, is of much use as a manure, improving most kinds of soil. Columella has asserted that, stale, it is excellent for the roots of trees. And Hartlib commends the Dutch for preserving the urine of cows as carefully as they do the dung, to enrich their lands.

It is a fluid capable of being employed with great benefit both on vineyards and on arable land. See Liquid Manure and Night-soil.

VALLESNERIA (Spiralis). This plant grows very abundantly from the bottoms of fresh water rivers and lakes over the whole United States, where the flow of water is not very rapid. It goes by the different names of eelgrass, tapegrass, and channelweed. It is upon the roots of this grass, or a native species of vallesneria, that the canavass-back duck feeds, and to which its peculiarly delicate flavour is ascribed, by Wilson, the ornithologist.

VALLEYS. See Depression.

VEGETABLE CHEMISTRY is that branch of the science of chemistry which relates to vegetable substances. Under the heads Analysis, Chemistry, Organic Chemistry, Gases, Earths, Water, Salts, &c., I have endeavoured to include all the facts supplied by this important science for the assistance of the farmer with which I am acquainted; I shall, therefore, merely insert in this place the chemical analysis of the inorganic substances found in several of the commonly cultivated crops of the farmer; and this I take from p. 318, of the valuable Lectures on Agricultural Chemistry and Geology, by J. F. Johnston; see also Liebig's Organic Chemistry.

Besides the elements of the organs of plants, other substances, obtained from inorganic nature, are necessary for certain organs destined to special functions peculiar to each family of plants. In the ashes of the plants left after burning them, these substances are found. Almost all plants contain acids, in combination with soda, potassa, lime, alumina, or magnesia. The quantity of these salts varies at different periods of the growth of the plant: thus unripe grasses contain more bitartrate of potassa than the ripe, and the potato more potassa before it blossoms than afterwards. The nature of a soil, as has already been detailed, alters the quantity of salts found in plants. The Salsola kali, raised from seeds of plants near the sea, in an inland garden, contains both potassa and soda; but the plants from the seed of this contain potassa only. But these facts are detailed under the head Salts, &c.

In examining the results of these analyses, the farmer must remember, that the acids and their bases do not exist in plants in an uncombined state, but in combination with each other; that is, as salts.

1. Of the Ash of Wheat—According to the analysis of Sprengel, 1000 lbs. of wheat leave 11-77 lbs. and of wheat straw 35-18 lbs. of ash, consisting of—
2. Of the Ash of Barley.—A thousand pounds of the grain of barley (two-rowed, *Hordeum distichon*) leave 23 lbs., and of the ripe dry straw 52 lbs. of ash. This ash consists of—

7. Of the Ash of the Grasses and Clovers.—The following table might have been much enlarged. I have thought it necessary, however, to introduce in this place only those species of grass and clover which are in most extensive use. I have also calculated the weights given below for these plants in the state of hay only, as the succulency of the grasses—that is, the quantity of water contained in the green crop—varies so much that no correct estimate
could be made of the quantity of inorganic matter present in hay or grass, from a knowledge of its weight in the green state only. The annexed quantities are contained in 1000 lbs. of the dry hay of each plant:

VEGETABLE PHYSIOLOGY is that science which treats of the vegetable kingdom, its habits, properties, and organization, in the most comprehensive manner. Its objects have been clearly stated by Mrs. Marcet, in her excellent Conversations on Vegetable Physiology, when describing the lectures of M. Decandolle on this science; and what she has so well described, it is needless for me to give in other words. "So far from confining himself to the classification of plants, the physiologist examines the vegetable kingdom in its most comprehensive and philosophical point of view. In describing the structure, he investigates the habits and properties of plants, and shows, not only how wonderfully they have been formed to fulfill the purposes of their own multiplication and preservation, but how admirably they answer the high purpose which nature has assigned to them, of ministering to the welfare of the animal creation, and more especially to that of man. He turns his attention particularly to point out the means by which the science of botany can promote that with which it is most intimately and importantly connected—agriculture. He makes ready the soil and sows the seed for the husbandman; he extracts the healing juices and the salutary poisons for the physician; he prepares materials for the weaver, coals for the dwelling, in a word, as he proceeds, there is scarcely an art on which he does not confer some benefit, either by pointing out a new truth, or warning against an old-established error." From this description of the objects of the science of vegetable physiology, the reader will see that almost all its different branches are treated of separately in articles which are dispersed through this volume. It is only, therefore, a few scattered fragments which I propose to gather together in this place. 

See Acclimation, Botany, Saps, Gases, Light, Putrefaction, Salts, Temperature, Water, &c.

The description of the cambium for the descending sap of plants was omitted in its proper place, and the effect of gravity or attraction upon plants was referred to this head. The sap having ascended into the leaves, and being in its course gradually altered into a fluid suitable for the nourishment of the plant, descends principally through the liber, or inner layer of bark, but a small portion also descends through the young wood, or alburnum. This movement, especially through the plants with pendent branches, is materially facilitated by motion, as by the action of the wind. "Mr. Knight," adds Mrs. Marcet, "has made a variety of interesting experiments on this subject. He confined both the stems and branches of a tree in such a manner that it could not be moved by the wind. The plant became feeble, and its growth much inferior to that of a similar tree growing in its natural state. He confined another tree so that it could be moved only by the north and south winds, and obtained the singular result of an oval stem, the sides accessible to the wind growing more vigorously than those sheltered from its influence. Every species of restraint, and especially such as tend to render plants motionless, impedes their growth. Stakes by which young trees are propped, binding them to walls or trellises, green-houses, or confined situations where the air has not free access, check and injure the vigour of vegetation, and render plants diminutive and weakly. The cambium descends almost entirely through the liber or most internal and youngest layer of the bark; if, therefore, a ring is cut completely through the bark, this fluid is arrested in its course, and, accumulating around the upper edge of the intersected bark, will cause an annular protuberance. The descent of the cambium thus being obstructed, it will accumulate in that part of the tree above the incision, and produce its superabundance of nourishment, creating a prepotential vigour of vegetation, and a corresponding excellence and profusion of produce." This operation, or ringing, is often performed on the non-productive branches of fruit trees.

The effect of gravitation or attraction upon plants is of the highest importance to their germination and their growth. From the very nature, however, of this essentially present power, a principle known only to us by its effects, the research is surrounded with difficulties. Mr. Knight, the late excellent president of the Horticultural Society, described some of the effects of gravity upon plants in his usual happy manner, when, in addressing the fellows of the Royal Society, he observed, "It can scarcely have escaped the notice of the most inattentive observer of vegetation, that in whatever position a seed is placed to germinate, its radicle invariably makes an effort to descend towards the centre of the earth, while the elongated germs take precisely the oppo-
VEGETABLE PHYSIOLOGY.

There are several experiments which tend to prove that the radicles of germinating seeds are capable of operating of their own motion, their points returned and met again at its centre. The motion of the wheel being in this experiment vertical, the radicle and germs of every seed occupied during a minute portion of time in each revolution precisely the same position; and if we have assumed that the plants vegetated at rest; and as gravitation and centrifugal force also acted in lines parallel with the vertical motion and surface of the wheel, I conceived that some slight objections might be urged against the conclusions I felt inclined to draw. I therefore added to the machinery I have described another wheel, which moved horizontally over the vertical wheels; and to this, by means of multiplying wheels of different powers, I was enabled to give many different degrees of velocity. Round the circumference of the horizontal wheel, whose diameter was also 11 inches, seeds of the bean were bound as in the experiment which I have already described, and it was then made to perform 250 revolutions in a minute. By the rapid motion of the water-wheel, much water was thrown upwards on the horizontal wheel, part of which supplied the seeds upon it with moisture, and the remainder was dispersed in a light and constant shower over the seeds in the vertical wheel, and on others placed to vegetate at rest in different parts of the box.

"Every seed on the horizontal wheel, though moving with great rapidity, necessarily retained the same position relative to the motion of the earth, and therefore the operation of gravity could not be suspended, though it might be counteracted in a very considerable degree by centrifugal force, and the difference I had anticipated between the effects of rapid vertical and horizontal motion soon became sufficiently obvious. The radicles pointed downwards about 10 degrees below, and the germens as many degrees above, the horizontal line of the wheel's motion, centrifugal force having made both to deviate 80 degrees from the perpendicular direction each would have taken had they vegetated at rest. Gradually diminishing in the rapidity of the horizontal wheel, the radicles descended more perpendicularly, and the germens grew more upright, and, when it did not perform more than 80 revolutions in a minute, the radicle pointed about 45 degrees below, and the germens as much above, the horizontal line: the one always receding from, and the other approaching to, the axis of the wheel.

"I would not, however, be understood to assert that the velocity of 250 or 80 horizontal revolutions in a minute will always give accurately the degrees of depression and elevation of the radicle and germens which I have mentioned; for the rapidity of the motion of hay wheels was somewhat diminished by the collection of fibres of coniferæ against the wire grate, which obstructed in some degree the passage of the water; and the machinery having been the workmanship of myself and my gardener, cannot be supposed to have moved with all the regularity it might have done, had it been the work of a professed mechanic. But I conceive myself to have fully proved that the radicles of germinating seeds are made to descend, and their germens to ascend, by some.
external cause, and not by any power inherent in vegetable life, and I see little reason to doubt that gravitation is the principal, if not the only, agent employed in this case by nature." Mr. Knight has endeavoured to point out the means by which he conceives the same agent may produce effects so diametrically opposite to each other.

It has, however, been objected by Duhamel (and the greatest deference is always due to his opinions) that gravitation could have but little influence on the direction of the germen, were it, in the first instance, protruded, or were it subsequently inverted, and made to point perpendicularly upwards. To enable myself to answer this objection, I made many experiments on trees of the horse-chestnut and of the bean, in the box I have already described; and as the seeds there were suspended out of the earth, I could regularly watch the progress of every effort made by the radicle and germen to change their positions. The extremity of the radicle of the bean, when made to point perpendicularly upwards, generally formed a considerable curvature within 3 or 4 hours when the weather was warm. The germen was more sluggish; but it rarely or never failed to change its direction in the course of 24 hours; and all my efforts to make it grow downwards by slightly changing its direction were invariably abortive.

As trees possess the power of turning the upper surfaces of their leaves and the points of their shoots to the light, and their tendrils in any direction to attach themselves to contiguous objects, it may be suspected that their lateral roots are by some means directed to any soil in their vicinity which is best calculated to nourish the plant to which they belong; and it is well known that much the greater part of the roots of an aquatic plant which has grown in a dry soil, on the margin of a lake or river, have been found to point to the water, whilst those of another species of tree which thrives best in a dry soil have been ascertained to take an opposite direction: but the result of some experiments I have made is not favourable to this hypothesis; and I am inclined to believe that the roots disperse themselves in every direction, and only become more numerous where they find most employment, and a soil best adapted to the species of plant.

A tree growing upon a wall at some distance from the ground, and all supplied with food and water, has also been observed to adapt itself to the situation, and to make very singular and well-directed efforts to reach the soil beneath by means of its roots. During the period in which it is making such efforts, little addition is made to its branches, and almost the whole powers of the plant appear to be directed to the growth of one or more of its principal roots. To these much in cot. sequence is annually added, and they proceed perpendicularly towards the earth, unless made to deviate by some opposing body; and as soon as the roots have attached themselves to the soil, the branches grow with vigour and rapidity, and the plant assumes the ordinary habit of its species.

In some other experiments of Knight to illust-
VEGETABLE PHYSIOLOGY.

VERJUICE.

instruct and elevate the character of the tiller of the earth in more ways than one. They will teach him, as M. Mirbel long since well remarked, that every operation "is connected in the vast system of the globe, and that order emanates from the equipoise of conflicting phenomena. Animals carry off the oxygen of the atmosphere, replacing it by carbonic acid gas; and are thus at work to adulterate the constitution of the air and render it unfit for respiration. Vegetables take up carbonic acid gas, retain the carbon, and give out oxygen; and are thus purifying the air tainted by animals, and re-establishing the necessary proportions between its elements. In Europe, while our vegetables, stripped by the severity of the season of their foliage, no longer yield the air contributing to life, the salutary gas is borne to us by trade winds from the southernmost regions of America. Breezes from all quarters of the world intermingle thus the various strata of the atmosphere, and keep its constitution uniform in all seasons and at all elevations. The substances which are produced by the dissolution of animal and vegetable matter are absorbed by plants, and constitute a portion of the atmosphere by which they are maintained; plants, in their turn, become the food of animals, and these again the prey of others which subsist on flesh. Yet, in spite of this perpetual state of war and destruction, nothing perishes, for all is regenerated. Nature has ordained that the two great divisions of organized beings should depend the one upon the other for support, and that both the life and death of individuals should be equally serviceable in preserving the harmony of the universe.

If we come to consider vegetation as it regards ourselves, we shall find that this great agent of nature, subjected in a certain degree to the control of man in a state of society, is the main source of his prosperity or of his misery. How many countries have the greedy ambition of princes, and the degradation and ignorance of the people, made barren! Recollect what Asia Minor, Judea, Egypt, the provinces at the foot of Mount Atlas, have been, and behold what they are at this day. Recollect Greece, once the country of science and of liberty, now that of ignorance and slavery; she can be only recognized in her ruins, and her monuments of the dead. Man had denied his labour to the earth, and the earth her treasures to man; all vanished with agriculture. The traveller who passes that country of so great renown, finds, in the place of the fine forests that crowned its mountains, of the rich harvests reaped by twenty busy nations, of the numerous flocks that enriched its fields, only naked rocks and sterile sands, with here and there a miserable village. He seeks in vain for several rivers recorded in history; they are gone! Thus the rage of conquest and of rule not only overturns cities, depopulates whole countries, and brings back barbarism, but it dries up the very springs from which the natural riches of the earth have flowed. To these melancholy results of our passions we might oppose the more cheerful ones of our industry; but they are more properly within the province of the arts of cultivation than of vegetable physiology.

VEGETABLE MARROW (Cucurbita ovifera). This fruit of the cucurbita gourd is uniformly of a pale yellow colour, and of an elliptic-oblung shape, the surface having irregular, longitudinal ribs, uniting into a projecting apex. When full grown it is about 9 inches in length and 4 in diameter, and is by far the best adapted for culinary purposes of any species of the gourd tribe. It is of recent introduction into Europe, having been brought from Persia or northern India for culinary purposes in every stage of its growth; when very young, it is good if fried with butter; when large, or about half-grown, it is excellent either when plain, boiled, or stewed with rich sauce; for either of these purposes it should be cut in slices. The flesh has a peculiar tenderness and softness, from which circumstance it has received its name, much resembling the butter quality of the beurré pear, and this property remains with it till it is full-grown, when it is used for pies. It is in its intermediate state of growth that it is likely to be most approved. Compared with all the other members of the same family, it is the most productive, and, for economy, its superiority is decided. I consider the vegetable marrow without a rival.

"We have grown the true vegetable marrow two seasons," says the editor of the Cultivator, "and although we have not used it in the intermediate state of its growth, as recommended by Mr. Sabine, we esteem it among the best varieties of the cucurbita for boiling and for pies. It is cultivated like the common pumpkin or squash, and will ripen in the U. S. in a high latitude."

VEGETABLES. The observations of vegetable physiologists and the researches of chemists have mutually contributed to establish the fact, that the growth and development of vegetables depend on the rejection of oxygen, which is separated from the other component parts of their nourishment. In contradistinction to vegetable life, the life of animals exhibits itself in the continual absorption of the oxygen of the air, and its combination with certain component parts of the animal body.

While no part of an organized being can serve as food to vegetables, until, by the processes of putrefaction and decay, it has assumed the form of inorganic matter, the animal organism requires, for its support and development, highly organized atoms. The food of all animals, in all circumstances, consists of parts of organisms.

Assimilation, or the process of formation and growth,—in other words, the passage of matter from a state of motion to that of rest,—goes on in the same way in animals and in vegetables. In both, the same cause determines the increase of mass. This constitutes the true vegetable life, which is carried on without consciousness. (Lieng's Animal Chemistry.)

VENISON. The flesh of deer. See Deer and Meat.

VERBENA. See Vervain.

VERJUICE. An acid liquor, prepared from the twigs of the vine, or from grapes or apples that are unfit to be converted into wine or cider. It is also made from the wild crab apples.

1079
VERMIN.

VERMIN. A general name for all birds, animals, insects, &c., which prey upon or prove injurious to the cultivator’s crops, and to his live-stock.

The insects, &c., comprise the most extensive and fearful class of depredators. Among these are the aphides, caterpillars, ants, beetles, and their grubs, wire-worms, slugs, earth-worms, &c.

VERNAL GRASS. See Anthoxanthum.

VERSATILE. In botany, signifies swinging lightly on the stalk, so as to be continually changing direction. It is illustrated in the leaves of the aspen.

VERTICILLATE. Disposed in a whorl.

VERVAIN (Verbena; said to be derived from its Celtic name Ferfæn). This is a genus of extremely beautiful ornamental plants while in flower, either when grown in pots in the green-house or when planted out in the flower garden; and they will all succeed well in the open ground during the summer months. The flowers of V. teucrioides have a delightful jasminelike odour. They all flourish well in a light loamy soil, with careful drainage when kept in pots. The herbaceous perennial kinds increase rapidly by cuttings, planted in sand under a glass; the green-house kinds in a little heat. The annuals and biennials should be raised on a gentle hot-bed.

One species is indigenous to England, the common vervain (V. officinalis), a perennial which grows by road-sides and in dry waste grounds, or pastures about villages. The root is woody, somewhat creeping. Stem ascending, 1½ foot high, leafy, roughish, with minute prickles or bristles. Leaves deeply cut. Spikes slender, several composing a sort of panicle of small, bluish, inodorous flowers. This species has scarcely any aromatic or other sensible quality. The root worn about the neck with a string is an old superstition remedy or charm for the king’s evil.

A great many species of vervain or verbena are found in various parts of the United States. North Carolina enumerates 10 in this country, and altogether 20 American species in the two hemispheres.

VESICLES. In botany, inflated, hollow excrescences, like bladders or blisters.

VETCH (Vicia, from vincio, to bind together, because the species have tendrils by which they encirle other plants). Some of the species of this genus are well worth cultivating in the flower-border for the beauty of their flowers. They are of the easiest culture in any common garden soil. The perennial kinds may be readily increased by dividing the root or by seeds. The seeds of the annual kinds only require to be sown in the open border in spring. V. sativa and its varieties are extensively cultivated, and well known by the common name of vetch or tares; they are used in England as early fodder for all kinds of cattle, and are allowed to be more nutritive and profitable than hay or any other herbage. The seeds also form the food of pigeons. There are in Britain 10 indigenous species of vetch, the principal of which are the tufted vetch, wood vetch, common vetch, and bush vetch. Of all the different vetches (says Sinclair) that were submitted to experiment, the winter tare or common vetch (V. sativa, var.) afforded the most nutritive matter: 64 drachms of the herbage, cut at the time of flowering, afforded 4 drachms 4 grains of nutritious matter; while spring tares only yielded 3 drachms 9 grains, which confirms the justice of that preference which practice has given to the former.

1. The tufted vetch (V. cracca), is a perennials, very common in England in a wild state in hedges, thickets, osier grounds, and bushy, low meadows. The stems are 2 or 3 feet high, furrowed, rather downy, climbing by means of their long, many-branched tendrils, by which they choose and overtop other herbs. Flowers numerous, in dense clusters, beautifully variegated with tints of bright violet-blue, and some purple. Legume scarcely an inch long, smooth, with 4 or 5 dark, globular seeds, the size of a lentil. This vetch is said to be nutritious food for cattle, but it has not come into use, probably from the difficulty of gathering, or of cultivating, so pertinacious a climber. Dr. Plot, in his History of Staffordshire, says that this and the Vicia sylvatica advance starved or weak cattle above any thing yet known; and Dr. Anderson, in his Essays, speaks highly of this plant. It is inferior to the wood vetch, or common tare (V. sativa), in the quantity of nutritious matter it affords, but contains much less superfluous moisture. This must give it a superiority, in regard to nutrient properties, over tares which contain an excess. But it has a strong, creeping root, that will always prevent its admission to arable lands. It might be best cultivated on tenacious soils, and used after the manner of lucern, to which it is much superior in nutritive qualities, though greatly deficient in the weight of crop. Forty-three grains of nutritious matter consisted of—

<td>11</td>
</tr>
</tbody>
</table>

The tufted vetch flowers about the middle of July or the beginning of August, and the seed is ripe at the beginning of September.

2. The wood vetch (F. sylvatica) grows in woods and hedges, chiefly in the more mountainous parts of Britain, and is one of our most elegant wild plants, well worthy to decorate shrubberies, or to be trained over a trellis or bower. The habits of this vetch are similar to those of the species last described, but it seems more impatient of exposure, and thrives best where it has the support of bushes. The root is creeping, perennial; herbage smooth. Stems numerous, much branched, climbing to the height of 6 or 7 feet, and spreading widely, decorating the bushes which support them with a profusion of delicate flowers, elegantly variegated with blue and white, streaked with gray. Legume the size of the last, bright brown, minutely dotted. When transplanted to open situations, the produce is inconsiderable compared with that of the tufted vetch or the bush vetch, though in its natural place of growth the produce is six times that of either of these species; it is likewise superior in the quantity of nutritive matter it affords. Horses, cows, sheep, and the South American llamas, are this vetch
VETCH, THE BITTER.

With more eagerness than they did the other vetches or natural grasses that were on several trials offered to them. The wood vetch flowers in July and August, and the seed is ripe in September.

3. The common vetch or tare (V. sativa, Pl. 7, r) is an annual plant, which is in general cultivation, and therefore too well known to need description; 3000 grains of the green herbage of the common vetch consist of—

Hence 1,135 grains of the woody fibre of tares are combined with 274 grains of saline matter.

In England vetches are very commonly sown upon a wheat stubble, and no crop better repays the addition of any organic fertilizers.

The bush vetch (V. sepium) has been already noticed. See BUS. VETCH.

The other British species of vetch or tare are the narrow-leaved common vetch (V. angustifolius), a spring vetch (V. lathyroides), rough-podded yellow vetch (V. lutea), hairy-flowered yellow vetch (V. hybridus), smooth-podded sea-vetch (V. laviflorea), and rough-podded purple vetch (V. sylvestris). These call for no detailed description. A few species of the vetch family are found in the United States and Territories. The species called tufted vetch (V. cracca), is common on the borders of woods and meadows, and troublesome in some gardens in the southern parts of Pennsylvania and other Middle States. Mr. Nuttall says it is smaller than the European plant described under the same name, but Dr. Darlington does not feel satisfied of its being a native of the United States.

The species enumerated by Mr. Nuttall are,

1. V. pusilla. 2. Sativa. 3. Americana. 4. Sylvatica, inhabiting the alluvial banks of the Missouri as far north as Fort Mandan. Leads a little more obscure than usual. 5. Cracca. 6. Caroliniana. See TARE AND VETCHING.

VETCH, THE BITTER (Orobus, from oro, to excite, and bous, an ox; the word of Theophrastus was the name of a plant used for fattening oxen). The plants of this genus deserve to have a place in every flower garden; on account of their very elegant papilionaceous blossoms. Any soil suits them, and they are readily increased by dividing the plants at the roots in spring, or raised by seeds. There are in England two native species, both perennial.

1. The common bitter vetch, or heath pea (O. tuberosus), grows in elevated or mountainous pastures, thickets, and woods. The root is creeping, externally blackish, swelling here and there into oblong knobs. Herbage smooth, darkish green. Stems simple, erect, a foot high, compressed and winged. Leaves alternate. Flowers in loose, long-stalked, axillary clusters, elegantly variegated and veined, with purplish, crimson, and shades of blue and flesh colour. Legumes pendulous, long, cylindrical, black when ripe. The roots have a sweetish taste, and afford some luxuries and refreshments to the hardy independent Highlander. There is considerable elegance in the flowers, and in the plant altogether.

2. Wood bitter vetch (O. sylvestris). In this species the root is woody and tough, deeply fixed in the ground. The stems are numerous, spreading or recumbent, 1 to 2 feet long, hairy, more or less branched. Clusters of numerous flowers, which have a hairy calyx, are cream coloured, streaked, and tipped with purple. The legumes are ovate-oblong, smooth, compressed, and shorter than usual in the genus.

VETCH, KIDNEY. See KIDNEY-VETCH.

VETCH, MILK. See MILK-VETCH.

VETCHING (Lathyrus). A numerous herbaceous genus of annual or perennial plants. The flowers are stalked, axillary, either solitary, in pairs, or in clusters; either crimson, purplish, blue, or yellow. The herbage commonly affords good fodder; the seeds are scarcely used for any purpose. There are seven indigenous species of vetching, or everlasting pea; the yellow everlasting (L. ophacæa), the crimson everlasting (L. missolita), the rough-podded everlasting (L. hirsutus), the yellow meadow everlasting (L. pratensis), narrow-leaved everlasting pea (L. sylvestris), broad-leaved everlasting pea (L. biennis), and the blue marsh everlasting (L. palustris): most of these species have been already noticed under the heads EVERLASTING PEA AND LATHYRUS. The latifolis is that species usually cultivated in gardens on account of the beauty of the flowers. It has been recommended for field cultivation, but the advice has not been followed. Bees procure much honey from the flowers.

VETERINARY COLLEGE. The Highland Society of Scotland have instituted a veterinary school in connection with their establishment, which is under the management of Professor Dick. By diffusing generally a practical knowledge of veterinary medicine, it cannot fail to be attended with the happiest consequences to the community at large. A veterinary college has long been established in London; and that useful periodical, the Veterinarian, edited by Professor Youatt, has added much valuable information to our stock of knowledge on the diseases of animals. See FARRIERY AND HIPPOPATHOLOGY.

The London Veterinary College was first established in the year 1792, at St. Pancras. Mr. Boerhave in his Dictionary of the Veterinary Art, remarks, that "the public are indebted for this national foundation to the exertions of the Agricultural Society of Odiham, in Hampshire. The first professor was M. St. Bel, a Frenchman, who had previously signalized himself in this country as a veterinary anatomist, by dissecting the famous race-horse Eclipse. This college is supported by public subscription. The annual contribution is £2 guineas, but payment of 20 guineas at once constitutes a subscriber for life.

"The views and objects of the college appear in the following statement, printed by the authority of the governors. The grand object, they observe, is the improvement of veterinary knowledge, in order to remedy the ignorance and incompetency of farriers, so long universally complained of. For this end, a range of stables, a forge, a theatre for dissections and lectures, with other buildings, have been erected: a gentleman of superior abilities has

136

4 Y

1081
been appointed professor, with other requisite

"The anatomical structure of quadrupeds, as horses, cattle, sheep, dogs, &c., the diseases to which they are subject, and the remedies proper to be applied, are investigated and regularly taught; by which means enlightened practitioners of liberal education, whose whole studing has been devoted to the veterinary art in all its branches, may be gradually dispersed over the kingdom, in whose skill and experience confidence may be securely placed.

"Subscribers have the privilege of sending their diseased animals to the college, without further expense than that of their daily food, and these in general form a sufficient number of patients for the practice of the professor and pupils. On fixed days, the professor prescribes for animals belonging to subscribers who find it inconvenient to spare them from home provided the necessary medicines be furnished and compounded at the college; subscribers' horses are also there shod at the ordinary prices."

VILLOUS. A term in botany, signifying covered with soft, close, long, loose hairs, resembling shag.

VINE (Vitis, from the Celtic gued, signifying the best of trees. Vine is derived from the Celtic word gued). A valuable genus of plants. The common grape vine (F. vinifera), with its very numerous garden varieties, is in general cultivation for its much-esteemed fruit. None of the other species are worth cultivating. The acids of grapes are chiefly the tannic and acetic; but malic acid is also present in them. Mr. Loudon, in his Encyclopedia of Gardening, thus botanically describes the vine:

"The grape vine is a trailing, deciduous, hardy shrub, with a twisted irregular stem, and long flexible branches, decumbent, like those of the bramble; or supporting themselves, when near other trees, by means of tendrils, like the pea. The leaves are large, lobed, entire, or serrated and downy, or smooth; green in summer, but when mature, those varieties in which the predominating colour is red constantly change to, or are tinged with, some shade of that colour; and those of white, green, or yellow grapes as constantly change to a yellow, and are never in the least tinged with purple, red, or scarlet. The breadth of the leaves varies from 5 to 7 or 10 inches, and the length of the footstalks from 4 to 8 inches. The flowers are produced on the shoots of the same year, which shoots generally proceed from those of the year preceding; they are in the form of a raceme, of a greenish-white colour, appearing in the open air in England in June; and the fruit, which is of the berry kind, attains such maturity as the season and situation admit by the middle or end of September. The berry or grape is generally globular, but often ovate, oval, oblong, or finger-shaped; the colours are green, white, red, yellow, amber, or black, or a variegation of two or more of these colours. The skin is smooth; the pulp and juice of a dulcet, poignant, elevated, generous flavour. Every berry ought to enclose five small heart-shaped stones; but as they are partially abortive, they have seldom more than three; and some varieties, as they attain a certain age, as the Ascalon or Sultana raisin, have none. The weight of a berry depends not only on its size, but on the thickness of its skin, and texture of the flesh, the lightest being the thin-skinned and juicy sorts, as the sweet-water or Muscadine."

Although we presume the excellent treatise of Mr. Clement Hoare on the Culture of the Vine is in the hands of most of our readers, yet, as there is no other standard work of reference on this subject, we must necessarily draw upon this for our extracts.

Of all the productions of the vegetable world (observes this experienced cultivator) which the skill and ingenuity of man have rendered conducive to his comfort and to the enlargement of the sphere of his enjoyments, and the increase of his pleasurable gratifications, the vine stands forward as the most pre-eminent conspicuously. Its quietness of growth, its great age to which it will live,—so great, indeed, as to be unknown; its almost total exemption from all those adverse contingencies which blight and diminish the produce of other fruit-bearing trees; its astonishing vegetative power; its wonderful fertility, and its delicious fruit, applicable to so many purposes, and agreeable to all palates, in all its varied shapes,—combine to mark it out as one of the greatest blessings bestowed by Providence to promote the comfort and enjoyments of the human race.

From the remotest records of antiquity, the vine has been celebrated in all ages as the type of plenty and the symbol of happiness. The pages of Scripture abound with allusions to the fertility of the vine as emblematic of prosperity; and it is emphatically declared, in describing the peaceful and flourishing state of the kingdom of Israel during the reign of Solomon, that "Judah and Israel dwelt safely, every man under his vine and under his fig tree, from Dan even to Beersheba." The source of enjoyment thus mentioned to record the happy state of the Jewish nation may be, with reference to the vine, literally possessed by the greater portion of the inhabitants of Great Britain.

The native country of the vine is generally considered to be Persia. The finest grapes in the world are those of Shiraz and of Casvin. The latter city, says M. Morier, is environed by vineyards and orchards, and the former yield a grape which is celebrated throughout Persia. It is along the line of mountains that stretch from the Persian Gulf to the Caspian Sea, that the best vine districts are situated; but the grape vine has been found wild in America, and has now become naturalized in all the temperate regions of the world. In the northern hemisphere it forms an important branch of rural economy, from the 21st to the 51st parallel of latitude; and by an improved method of culture very fine grapes may be annually grown on the surface of walls, in the open air, as far north as the 54th parallel, and even beyond that in favourable seasons. The vine is supposed to have been introduced into Britain at the commencement of the Christian era. It certainly did not exist before the Ro-
man invasion, as neither Cesar, Pliny, nor Tacitus notice it in the description of Great Britain. Bede informs us, that in the commencement of the eighth century the cultivation of the vine had made some progress in Great Britain: vines are mentioned in the laws of Alfred. History, indeed, amply proves, that for a long series of ages vineyards were common in the southern parts of England, and that the quantity of wine produced from them was so great as to be considered one of the staple products of the land. Lombard (Topographical Dictionary of England) informs us, that Halling, near Rochester, the bishop's vineyard yielded such excellent wine, that a present of it was sent to Edward II. when he was at Bakingfield. There was a royal vineyard at Rockingham, in the fifth year of King Stephen; and William of Malmsbury, speaking of the vale of Gloucester, says, "this district, too, exhibits a greater number of vineyards than any other county in England, yielding abundant crops, and of superior quality." The same author also says, that in the isle of Ely the soil is "covered with vines, which either trail along the ground, or are supported on poles." In the time of Richard II. also, the vine grew so plentifully in Windsor Little Park, that part of the wine made there was sold for the king's profit. From some cause or other, however, the cultivation of the vine has fallen into general neglect, although good grapes might be grown on vines trained as espaliers, or in the same manner as in the vineyards abroad, from which excellent wine could be made, at a cost that would not exceed that of moderately strong beer. Why vineyards should have so completely disappeared, it is difficult to say, since there are many thousands of acres of poor land that are of little value in an agricultural point of view, but on which vines would flourish, and produce abundant crops of grapes, and yield thereby a most profitable return.

Fruit-bearing Powers of the Vine.—From a long course of experiments, Mr. Hoare has computed the following scale of the greatest quantity of grapes which any vine can perfectly mature, in proportion to the circumference of its stem measured just above the ground.

<table>
<thead>
<tr>
<th>Circum.</th>
<th>3 inches</th>
<th>4 inches</th>
<th>5 inches</th>
<th>6 inches</th>
<th>7 inches</th>
<th>8 inches</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pounds</td>
<td>3</td>
<td>4</td>
<td>5</td>
<td>6</td>
<td>7</td>
<td>8</td>
</tr>
</tbody>
</table>

No vine should be suffered to ripen fruit until its stem measures 3 inches in girth. In general, vines are allowed to bear a much greater quantity of grapes than the above scale represents, but in all such cases it will be found that they are not perfectly ripened; and moreover, by producing a superabundance of fruit on the ground or on poles, the vine is exhausted and is unable to produce a sufficient quality of grapes.

Aspect.—The warmer the aspect, the greater perfection does the grape attain in the climate of England, provided all other circumstances are alike; and if the greatest quantity of the sun's rays shining on the surface of a wall were alone to be considered as constituting the best aspect, there would, of course, be no difficulty in naming a due southern one as better than any other. But warmth alone is not sufficient; shelter from the withering influence of the wind is equally necessary. The best aspects are those that range from the eastern to the southeastern, both inclusive. The next best are those from southeast to south.

Soil.—The natural soil which is most congenial to the growth of the vine, and to the perfection of its fruit in this country, is a light, porous, rich, sandy loam, not more than 18 inches in depth, on a dry bottom of gravel, stones, or rocks. A strong argillaceous soil is injurious to the vine: it checks the expansion of the roots, and retains too much moisture. In calcareous soils the vine always flourishes, especially if the bottom be stony or gravelly. No subsoil can possess too great a quantity of these materials for the roots of the vine, which run with eagerness into all the clefts, crevices, and openings in which such subsoils abound. In these dry and warm situations, the fibrous extremities, pushing themselves with the greatest avidity, form a fibrous root, which, in every possible direction, secure from that excess of moisture which frequently accumulates in more compact soils; and, clinging like ivy round the porous surfaces of their retreats, extract therefrom a species of food, more nourishing than that obtained by them under any other circumstances whatever. All borders, therefore, made expressly for the reception of vines, ought to be composed of a sufficient quantity of dry materials, such as stones and brickbats, broken moderately small, lumps of old mortar, broken pottery, oyster shells, &c., to enable the roots to extend themselves freely in their search after food and nourishment; to keep them dry and warm by the free admission of air and solar heat, and to admit of heavy rains passing quickly through, without being retained sufficiently long to saturate the roots, and thereby injure their tender extremities. The sweepings obtained from a turnpike road, or from any other high road kept in a good state of repair by the frequent addition of stones, and on which there is a considerable traffic of horses or other cattle, is the very best compost that can be added to any border intended for the reception of vines. Its component parts, consisting chiefly of sand, gravel, pulverized stones, and the residuum of dung and urine, afford a greater quantity of food, and of a richer and more lasting nature, than can be found in any other description of compost that I have ever seen or heard of being used for that purpose. Borders in which vines are planted should never be cropped nor digged.

Manure.—The best species of manure for the vine are those which afford a considerable degree of nourishment, but at the same time slowly decompose in the soil. Such are bones, whole or crushed, the horns and hoofs of cattle, the entrails and continually branching out of leather, woolen rags, feathers, and hair, and the leaves of the vines themselves. Liquid manures are also valuable, and forcing in their effect; of this class the most powerful are urine, sot-water, blood, the drainings of dung.
heaps, and soap-suds. It should, however, always be recollected, that the more manure is used, the poorer the wine procured from the grapes. As a top-dressing, and to be forked into the border, night-soil, refuse fish, stable manure, and the excrements of all birds and animals, will be found highly enriching substances as fertilizers, and their nutritive and stimulating properties have been frequently alluded to in the progress of this work; but if rich manures are used, they should be mixed with turf and sand. In the Alto Douro is a law which prohibits the vine being “littered;” as this operation, though it considerably augments the produce, tends to deteriorate the quality of the wine.

On the Construction of Walls.—No general rule can be laid down as to the height of the wall, which must necessarily vary under different situations and circumstances. Mr. Hoare states, that in unsheltered situations and exposed aspects he has never seen fine grapes produced more than 8 feet from the ground.

But, in favourable situations, height is no consequence. If built for the express purpose of rearing grapes, low walls of not more than 6 feet are to be preferred, as more convenient for pruning and training the vines. Brick walls are undoubtedly the best, the surface being smooth and even. A considerable heat is obtained by blackening the wall.

Propagation.—Vines are propagated in the open ground by layers and by cuttings. The former is the most expeditious mode, provided the shoots be laid down in pots, and planted out the same summer. The latter mode is much the best. To provide cuttings to be planted at the proper season, select at the autumnal pruning a sufficient number of shoots of the preceding summer’s growth. Choose such as are well ripened, of a medium size, and moderately short-jointed. Cut them into convenient lengths of 8 or 8 inches each, leaving at the ends not less than a couple of inches of the blank wood for the protection of the terminal buds. Stick these temporary cuttings about 9 inches in the ground, in a warm and sheltered situation, where they will be effectually protected from the severity of the winter. The best time to plant them out is about the middle of March, but any time from the 1st of that month to the 10th of April will do very well.

Pruning and training are so closely connected together, and so mutually dependent on each other, that they almost constitute one operation. The judicious pruning of a vine is one of the most important points of culture throughout the whole routine of its management. The object is to get rid of all the useless and superabundant wood, for those shoots of a vine which bear fruit one year never bear any afterwards.

There are three methods of pruning vines in practice amongst gardeners; namely, the long-pruning, spur-pruning, and the fan or fruit tree method. The first is considered to be the most eligible method, and is that which is practised and recommended by Mr. Hoare. As the sole object in view in pruning a vine is to increase its fertility, the best method to accomplish this is to leave a sufficient supply of bearing shoots on the least possible proportionate quantity of old wood.

Long-pruning appears to recommend itself by its simplicity; by the old wood of the vine being annually got rid of; by the small number of wounds inflicted in the pruning; by the clean and handsome appearance of the vine; and by the great ease with which it is managed, in consequence of its occupying but a small portion of the surface of the wall.

Mr. Hoare lays down the following practical general rules for the guidance of the pruner:—

1st. In pruning, always cut upwards, and in a sloping direction.

2d. Always leave an inch of blank wood beyond the terminal bud, and let the cut be on the opposite side of the bud.

3d. Prune so as to leave as few wounds as possible, and let the surface of every cut be perfectly smooth.

4th. In cutting out an old branch, prune it even with the parent limb, that the wound may quickly heal.

5th. Prune so as to obtain the quantity of fruit desired on the smallest number of shoots possible.

6th. Never prune in frosty weather, nor when a frost is expected.

7th. Never prune in the months of March, April, or May. Pruning in either of these months causes bleeding, and occasions thereby a wasteful and an injurious expenditure of sap.

8th. Let the general annual pruning take place as soon after the 1st of October as the gathering of the fruit will permit.

Lastly, use a pruning-knife of the best description, and let it be, if possible, as sharp as a razor.

Training.—To train a vine (Mr. Hoare goes on to observe) on the surface of a wall is to regulate the position of its branches, the principal objects of which are, to protect them from the influence of the wind; to bring them into close contact with the wall; for the purpose of receiving the benefit of its warmth; to spread them at proper distances from each other, that the foliage and fruit may receive the full effect of the sun’s rays, and to retard the motion of the sap, for the purpose of inducing the formation of fruit-buds. The flow of sap, it must be remembered, is always strongest in a vertical direction, and weakest in a downward one. For this reason, the method of serpentine training may be considered preferable to every other, being calculated in a greater degree to check the too rapid ascent of the sap, and to make it flow more equally into the fruiting shoots, and those intended for future bearers.

On walls that are much less than 5 feet high, a portion of the shoots must be trained horizontally.

Varieties of Grapes.—The following 12 sorts of grapes are those best adapted for culture on open walls in England:—

1. Black Hamburgh. As a splendid table fruit, this is, in every respect, one of the most valuable grapes that can be grown on open walls. It is a prolific bearer, hardy in its nature, and under judicious culture will ripen with as small a portion of direct solar heat as any grape we have.
2. Black Prince. This is a very fine grape, and nearly if not quite equal to the black Hamburgh; both of these sorts ripen in a southeastern aspect, about the middle of October.

3. Esperion. The Esperion grape is very hardy, extremely prolific, and ripens its fruit perfectly in any season, however unfavourable.

4. Black Muscadine. This is also a prolific bearer, but it requires a good aspect to ripen it perfectly.

5. Miller's Burgundy. This is a very hardy and prolific grape, and ripens perfectly in any season. Its leaves, which are very thick, distinguish it from every other sort, being covered on both sides with a hoary down, which, when they are young, is nearly white; hence it is called the "Miller's" grape.

6. Claret grape. This is a very fine wine grape. It requires a good aspect. Early in the summer its leaves change to a russet red, and die in the autumn of a deep purple blood colour.

7. S. 9. Black, grizzly, and white Frontignan. The flavour of these three sorts is so extremely delicious, that no good wine wall be without them. They ripen well in favourable aspects, and where the soil is very dry; but, being thin-skinned, and constitutionally disposed to decay after they become fully ripe, they cannot be kept long on the vine, particularly if the wall against which they are growing be destitute of a projecting coping.

10. White Muscadine. This is an exceedingly fine grape, and a prolific bearer; and from its hardy nature, and the certainty with which it ripens in any season, it may be considered as the best white grape that can be grown on open walls.

11. Malmsey Muscadine. This resembles the preceding, except that the berries are smaller, and the branches not so regularly formed; but the juice is sweeter, and possesses a higher flavour.

12. White sweetwater. This is a delicious grape; but, owing to its tenderness when in blossom, the berries sit very unevenly on the branches.

13. If it be desired to have a very early sort, to the preceding may be added the early black Juby; which, though the branches and berries are smaller, and the latter in general unevenly set, is a very sweet and also a well-flavoured grape. (Hoare on the Cultivation of the Grape-Vine on open Walls, 3d edition; Phillips's Hist. of Fruits, p. 177.)

The work of Mr. Hoare is so full of details that it is scarcely necessary to add anything to the directions contained in his work; and we shall therefore confine ourselves to a statement of a few general truths in regard to the cultivation of the vine in the United States, the results of much observation and some experience.

1. The vine is a native of America, as it is of Asia, while it was an exotic in Europe. There is nothing, therefore, in the soil or climate of America congenial to the vine, and, in fact, there are few parts of the United States where the forests are not filled with grape-vines growing with the greatest exuberance. If, therefore, the cultivation of the vine has made comparatively little progress, it is mainly because other fruits and other crops have offered greater attractions. But as the country has advanced, and the population is concentrated in large towns, the grape has become an object of more interest, and we think it would now reward the industry of our farmers.

2. This cultivation would have two objects, the making of wine, and the supply of grapes for the table. As to the first, we have no doubt that wine can be made of an excellent quality and at not unreasonable prices in the United States. In fact, we know that cultivators on a large scale, such as Mr. Rapp, at Harmony, Mr. Longworth, in Ohio, Mr. Geo. Sheaff, and Mr. N. Biddle, both of Pennsylvania, have succeeded in making wine—good, sound, palatable wine, which would require only the wine-dealers' arts to place it on a footing of equality with some of the best wines of Europe. But so long as the wines of France and of the old-established wine countries of Europe can be produced more cheaply, and imported with scarcely any duty, the competition of the foreign wine-makers is difficult to withstand, and it is mainly, therefore, when raised for the table that grapes will repay the labour of the farmer; and this, we think, they certainly would do. The importation of grapes and raisins into the United States will afford the best evidence of the consumption of those articles, and their cost to us.

We happen to have before us two returns of importations for different years, from which we make the following extracts.

In the year 1834 the importation stood thus—

<table>
<thead>
<tr>
<th>Description</th>
<th>Quantity</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Raisins in jars</td>
<td>6,697,517 lbs.</td>
<td>$177,316</td>

</tbody>
</table>

We have not at hand any more recent statements, and therefore do not know if these importations have been sustained. But the tables show an efficient demand for grapes, fresh and dried, of no less than 1,320,000 dollars in a single year. Such an object is worth contending for. These imported grapes are generally not of the best kind, even in their own country, being selected mainly on account of their hard skins and their ability to bear the long voyage. They are gathered before they are fully ripe, and, being packed in sawdust, they retain too much of the flavour of that material. Now, if these grapes were met on their arrival by grapes grown here, and plucked from the vines within a few hours instead of a few months before they are brought on the table, the preference could not fail to be given to the native fruits.

Such fruits might be furnished from vineyards covered with glass, or raised in the open fields.

For raising grapes under glass, we do not think it necessary to give any directions, since whoever proposes it will find ample instruc-
VINE.

Of the kinds of grapes best adapted for culture under glass we may speak with some confidence. These kinds are very numerous—great varieties of Chasselas—great varieties of Muscats—many of Frontignac. But we think that the labour and time are best rewarded by the black Hamburg, which, for its excellence and its abundant bearing, may perhaps be placed at the head of all the grape family; by the Muscat of Alexandria, the flavour of which is of surpassing richness, though an uncertain and scanty bearer; and by one or two varieties of the Frontignac. These are at the present time not cultivated, and none of the imported grapes can be placed in any sort of comparison with them.

The cultivation of grapes in the open air is of course cheaper and easier to farmers. The best kind of foreign grapes, such as are above enumerated, may be successfully grown in city gardens with much shelter and care, and there are few gardens in which they would not prosper. But as yet the foreign grape has not succeeded in field cultivation, and accordingly for this purpose we must employ other varieties, which, though of inferior quality, are not others cultivated. The cultivation, or foreigners gradually acclimated. The sorts which are most considered are the Scuppernong, a vine of doubtful origin, which thrives well and bears abundantly in North Carolina, but as yet has made little progress to the north, though worthy, we believe, of more extensive experiments. Those most known to field cultivation in the Middle States are the Alexander, the Isabella, and the Catawba; and on these our markets will probably rely for some time. They may be cultivated in rows exactly like Indian corn, with a hoe and the hoe-harrow; they do not require even as much trouble as a field of Indian corn, and, instead of being renewed and replanted every year, the plants will last for many generations of men. They require no covering in winter, but will stand unharmed the severest frosts and snows.

On the whole, what we think should come next in the progress of American farming is, that every farm-house should have its patch of grapes as well as of peas or beans, of the improved native grapes, and that by degrees the highest kinds of foreign grapes should be acclimated, so as to form a part of field cultivation. This we believe entirely practicable, and to this we invite the attention of farmers.

Of foreign grapes two kinds are well known in Virginia and other Southern as well as Middle States, namely, the Summer sweetwater and the White sweetwater. Highly interesting communications upon the subject of the vine culture in the United States will be found in the American Farmer, Farmer’s Register, and many other valuable periodicals.

Among the various species of grape-vines found wild in the forests of the United States, the following have been described by botanists.

1. Fox-grape (Vitia labrusca or Vitia vulpina). The berries of this luxuriant vine grow in short clusters, and are about half an inch and often more in diameter, varying at maturity from nearly black to dark amber or copper colour and greenish white. The flavour is musky and strong. “All kinds of this grape,” says Bartram, “possess a strong, rancid smell and taste, have a thick corrosive skin, and a tough, jelly-like pulp or tegument which encloses the seeds. Between this nucleus and the skin is a sweet, juicy, but a little acerb or stinging to the mouth if pressed hard in eating them. There is another property of this grape which alone is sufficient to prove it to be the V. vulpina, that is, the strong, rancid smell of its ripe fruit, very like the effluvia arising from the body of the fox, which gave rise to the specific name of this vine, and not, as many have imagined from its being the favourite food of the animal; for the fox (at least the American species) seldom eats grapes or other fruit if he can get animal food.” “In the wild state,” says Dr. Darlington, “we find varieties in the fruit, and in our gardens and vineyards we have grapes under several names, which appear to be nothing more than varieties of this,—(or possibly some of them may be hybrids)—such as the Isabella grape, the Schuykill (called also Alexander’s and Tusker’s grape), the Catawba grape, and Bland’s grape. The two former of these are nearly black, the latter copper or amber coloured—with less of the musky flavour than the others. The Schuykill and Catawba varieties have been cultivated with the most success in Chester county.” (Flora Cestrica.)

2. Little summer grape (V. aestivalis), called also the Common blue grape and Bunch grape. In this most common of all American wild grapes the berries are round and small, generally about one-fourth of an inch in diameter, of a deep blue or nearly black colour, covered when ripe with a thick bloom or powder. Their flavour when mature, which is generally after the first frost, is of an agreeable spicily acid. “This species,” says Dr. Darlington, “presents several varieties; some of them with a larger fruit, which is much esteemed, and well worthy of culture. It sometimes attains to a great height in rich woodlands; the upper branches sustaining it by clinging to the limbs of tall trees, and gradually ascending, whilst the older branches below die and drop off, leaving the stem naked and suspended, somewhat resembling a topgallant halyard, belayed at the root.”

3. Chicken grape (V. cordifolia and V. labrusca of Marsh, and V. amurensis of Bartram), also called Winter grape and Bermudian grape. This kind has very small berries, not so large as currants. They are very late in ripening, and, when mature, are nearly black, and possessed of so much acerbity, that even birds will not eat them until they have undergone mellioration from autumn frosts. This vine is remarkable for its sweet flowers. It mounts to the top of trees, and its stems and twigs are more hard and sturdy than those of the preceding variety, or Summer grape.

4. Bull or Bottle grape (V. taurina of Bartram, and V. vulpina of Linnceus and Walter). This excellent grape is a native of the Southern States, and in the Carolinas, Georgia, and the Floridas is called the Bull grape. It is pronounced by Bartram and others a distinct variety from that which it resembles in external
VINEGAR.

appearance, called Fox grapes from Pennsylvania to Florida. The Bullet or Bull grape is described by Bartram as having "a stiff, lig- neous, smooth stem, of pale ash colour, and mounts to a great height by climbing up trees. The leaves are cordate and serrated, thin, and both surfaces naked or smooth. The racemes or fruit bunches short, containing 15 or 20 grapes at a medium. The berries or acti are large, near the size of a ride-ball; of a black colour when ripe; having a blusth nebule over them, which being rubbed off, they appear of a deep blood colour. In figure they approach to an ellipsis or prolate spheroid; however, at a little distance they appear black and round. This species is deservedly esteemed the best native grape in America, and would make a rich and delicious wine. The juice is sweet, rich, and lively, and there is but little of the tough, jelly-like substance enclosing the seed. The skin of the grape is rather thick, yet there is a sweet, melting pulp within, which mixes with the saecarine juice when eaten. This undoubtedly is the first American grape which merits attention and cultivation for wine. It thrives in every soil and situation, from the sea-coast to the mountains; it even thrives and is fruitful when growing in the barren sandhills of Carolina and Florida."

After describing these distinct varieties of grapes found in the United States, Mr. Bartram mentions several others which he considers derived from a commixture of those described, as Alexander's or Bulker's grape; Blood's grape; Racoon grape. Other varieties, possessing still superior properties, have since been added, such as the Isabella, Powell, Catawba, Scuppernon, &c., already mentioned.

VINEGAR is the acetic and acetic acids of the chemist, containing a variety of foreign admixtures, some colouring matter, and an ethereal substance or spirit, which gives it a grateful aroma. Vinegar has been known from a very early age. It was by far the earliest known acid of commerce. That it was drunk in remote periods, diluted with water, by the labourers and soldiers, is very certain. It is repeatedly mentioned in the Old Testament. But then there are a good deal of contradictions, one of which, a kind of small wine, which they called posco or sera, is supposed to be that offered to Ruth (Ruth, ii, 14), and to our Saviour by the Roman soldiers (Matt. xxvii. 48). The stronger variety of vinegar is alluded to in another place (Prov. x. 26). They mixed it also with nitre, or, properly speaking, natron, which was an alkali that, by neutralizing, destroyed its sharpness. "As vinegar upon nitre, so is he that singeth songs to a heavy heart." (Prov. xxvi. 20.) They made it in those days from wine. (Num. vi. 3.) It is known to every one, that when wine or beer is exposed to the influence of the atmosphere, it becomes sour or acid; now this acid is the acetic. In the wine countries it is chiefly made from the produce of the vine, weak or low wines; the shoots of the vine, &c., being also employed for that purpose. It may be readily made from merely sugar and water. That of commerce in England is usually made from wort from malt liquor or cider. Vinegar is of a yellowish or reddish colour, an acid taste, and pleasant odour. Its specific gravity is commonly between 1035 and 1025. It usually holds in solution various foreign substances, such as colouring matters, sulphate of lime, mucilage, sulphuric acid, and the ethereal spirit already mentioned. Vinegars differ greatly in strength and in purity. The best known in England for domestic purposes is the French white wine vinegar; but the Vinaigre d'Orleans, made from the red wine of the Orleans, is that most esteemed in France; and that imported from Bourdeaux, although named Champagne vinegar, is often made from red wine. The density of French vinegars varies from 10-14 to 10-22. The free sulphuric acid in British vinegar is permitted by the English excise laws to the amount of one part in one thousand, but it is often added to four times that amount. Vinegar is readily purified from its impurities by distillation, and in this form is the transparent distilled vinegar of commerce. But even then it is united with a considerable portion of water.

The specific gravity determines this point. Thus, at 10-14 it contains 10 per cent. of real acetic acid, at 10-22 15 per cent., at 10-25 18 per cent., at 10-35 26 per cent., at 10-60 50 per cent., and so on, until it reaches 10-635, which is the strongest liquid acetic acid. When deprived of all impurities and water, by chemical means, pure acetic acid is composed, according to the analysis of M. Berzelius, of—

Some plants contain acetic acid naturally. M. Vaucoulin found it in the sap of various trees, and in the chick-pee. Scheele detected it in the elderberry. It has been found also in the date palm tree, and in several others; and few plants exist in which acetic acid in the form of salts, such as the acetates of lime or potassa, is not found.

In England, for domestic purposes, it is prepared in several very considerable manufactories from a mixture of barley or malt with water, by keeping the wash exposed in open vessels to the influence of the atmosphere, in rooms heated to a particular temperature. The formation of the acetic acid in this manner is in these works promoted by the addition of a certain small proportion of acetic acid.

An excellent vinegar for domestic purposes may be readily made by exposing a mixture of one part of brown sugar by weight with seven parts of water and some yeast, in a case whose bung-hole is only slightly covered over (as by a piece of gauze pasted down to keep out insects), for some weeks to the action of the atmosphere and the sun. The acetic fermentation and the goodness of the vinegar are promoted by the addition of vine leaves.

Although vinegar is familiarly used in small quantity as an agreeable and useful addition to food, yet in large quantities it interrupts digestion, and induces emaciation. In combination
WALNUT TREE.

with water, it is an excellent cooling and invigorating substance when employed for sponging the body, especially in febrile conditions of it: its vapour inhaled with the vapour of hot water relieves hoarseness; and, when moderately diluted, it forms an excellent gargle in inflamed or sore throats. See Acids and Pyroxylic Acid.

VIOLET. (Viola). All the species of this genus deserve to be cultivated, either for the beauty or the scent of their flowers. The species natives of America thrive best in vegetable mould or peat, and are readily increased by parting the roots or by seeds. There are 8 native species of violet in England, and, according to Schweinitz, 29 in the United States.

VIOLET, AMERICAN (Erythronium americanum). Sometimes called Dog's-tooth violet. This very pretty plant is found throughout the Atlantic States on the lower alluvial banks of streams, and in most moist places, where it puts forth its beautiful violet flowers in April and May. It has a perennial bulbous root, rather deep in the ground. Among other American species of the violet enumerated by botanists, is the white violet (E. albidum), found throughout the Western States and Territories, in Upper Louisiana, and on the banks of the Missouri, where no other species appears to exist. There appears to be a yellow-flowered species confounded with this white species, and nearly allied to it.

Viper's Bugloss. See Honeysuckle.

W.

WAGES. The price or hire paid to labourers or servants for performing different sorts of farm work.

These differ greatly in different districts and situations, and according to the character and employment of the workmen, but in all they are considerably increased within the last 15 or 20 years. They may perhaps be stated as varying, in England, under different circumstances, from 9s. to 18s. by the week, and from £l. to £15. or £18. by the year.

WAGON. A wheel-carriage, of which there are several varieties, accommodated to the different uses which they are intended to serve.

In the business of husbandry, wagons constructed in different forms, and of various dimensions, are made use of in different districts or parts of the kingdom; and mostly without much attention to the nature of the roads, or the articles which are to be conveyed by them; being in general heavy, clumsy, and inconvenient. There is, however, a wagon much employed in Berkshire, England, which is constructed on a more simple and convenient principle than those mostly met with in the other southern parts of the island, not having the height or weight of them, while it possesses sufficient strength, and is easy in the draught.

Wagons require more power in the draught than carts, which is certainly an objection, though they carry a much greater load, and are far from being so handy and convenient; and Mr. Parkinson is of opinion, that more work may be done in any particular time, with the same number of horses, by carts than by wagons, in the general run of husbandry business, especially where the distance is small between loading and unloading; a fact which has long been known and attended to in Scotland.

Where wagons are used for husbandry, they should be made wide and low. Manures may be carried in this sort of wagon almost as well as in carts. Broad wheels are improper for passing and repassing upon tillage lands; for, if in fallow, they press the land too much, and make it so hard as to prevent its being ploughed till wet comes; but on grass land broad wheels are proper for all uses, as there they operate as rollers.

Wagons are probably the best conveyances for different sorts of heavy loads to a distance; but for home business, especially harvest and other work, which requires to be speedily performed in the field, carts with proper shelving will be found preferable. See Cart and Highway.

WAIR (pl. Wains). A name applied to an ox cart, without side rails or ladders, in some districts in England; but in others shielings are added, and the body is large and open. They are rarely met with at present. In Gloucestershire they adapt them to harvest work by fixing ladders and rafters on them. In the lower part of the vale they are called dragspots; but in the forest districts, where drawn by oxen, wains.

WALNUT TREE (Juglans, from Iovi glans; literally the nut of Jove). All the species of the ornamental genus to which the well-known walnut tree belongs are tall, stately-growing trees, well adapted for parks and lawns. They grow freely in any rich loamy soil, and are raised from seeds. This deciduous tree was formerly held in great esteem in England for its wood, which is often very finely veneered; but, on account of its aptness to be worm-eaten, it has long since given place to the mahogany. As a fruit tree, independent of its timber, which is still of much value, it merits attention, and it is also useful as an ornamental tree. There are several species capable of being cultivated with advantage both for their wood and fruit; as the common walnut, the white walnut, and the black walnut tree.

The common walnut (J. regia) is a very large and lofty tree, which has spreading boughs. The leaves are pinnate, with a very strong but not unpleasant smell; the leaflets 3 pairs (sometimes 2 or 4), nearly equal, except that the odd one is largest; they are entire, smooth, and shining. The male flowers are in close, pendulous, subterminating filaments; the females scattered, frequently 2 or 3 together. Fruit an ovate, coriaceous, smooth drupe, inclosing an irregularly grooved nut, which contains a four-lobed, oily, edible kernel, with an irregular knobbed surface, and covered with a yellow skin. This tree is a native of Persia.

It has been noticed by Martyn, "that as they all vary again when raised from the seed, and that as nuts from the same tree will produce different fruit, those who plant the walnut for its fruit should make choice of the trees in the
nurseries, when they have their fruit upon them.

The common walnut has several varieties, as the oval walnut, the round walnut, the large walnut, the small-fruited walnut, the double walnut, the early walnut, the late walnut, the tender thin-shelled walnut, and the hard thick-shelled walnut.

There are also other species, the hickory-nut, or white walnut (J. albata), and the black walnut (J. nigra). Both these are natives of Virginia; but they are seldom cultivated in Britain, except as timber trees.

The best manner for the walnut is ashes, spread in the beginning of winter, the land having been first ploughed or trenched over in an effectual manner.

The length of time in which the English walnut bears well from the nut is about 20 years.

Mr. Knight has suggested that this tree will bear much sooner when raised by grafting, with bearing branches, by approach. But where the trees are intended for timber, it is a good practice to plant them out at once where they are to grow, as they thrive faster, and form better trees, by that method of raising them.

These trees should not be planted nearer together than 40 feet, and even more distant, if they are designed for fruit. They delight in a firm, rich, loamy soil, or such as is inclined to chalk or marl; and will thrive very well in stony ground, or on chalk hills, as is evident from those large plantations near Leatherhead, Godalming, and Carshalton in Surrey, where great numbers of these trees planted upon the downs produce annually large quantities of fruit, to the no small advantage of their owners.

In order to preserve this fruit, it should be left upon the tree till it is thoroughly ripe, and then, as it would be exceedingly troublesome to gather it by hand, it may be beaten off, but not with such violence as is commonly used, from a mistaken notion that the tree is improved thereby; for most certainly it cannot be benefited by that rough way of forcing off the young wood upon which this fruit grows.

The fruit is used in two different stages of its growth: as when green, to pickle; and when ripe, to eat the kernel. For the first purpose, the young green walnut, when about half or near three parts grown, before the outer coat and internal shell shall become hard, is most excellent, for which they are generally ready in July or the following month, and should be gathered by the hand, choosing such as are as free from specks as possible. But the fruit is discovered to be fully ripe by the outer husk easily separating from the nut, or by the husks sometimes opening at the valve, and the nuts dropping out, which occurs usually about the latter end of September. In trees of considerable growth, it is commonly beaten down with long poles; for, as the walnuts grow mostly at the extremity of the branches, it would, in very large spreading trees, be troublesome and tedious work to gather them by hand. As soon as gathered, they should be laid in heaps a few days to heat and sweat, to cause their outer husks, which closely adhere, to separate from the shell of the nuts; after which they should be cleaned from the rubbish, and deposited in a dry room for use, covering them over close with dry straw, a foot thick, where they will keep 3 or 4 months. They always command a ready sale at market in large towns, where, at their first coming in, they are bought with their husks on, and sold by the sack, or bushel, afterwards cleaned, and sold both by measure and by the thousand.

Plantations of these trees in England are therefore profitable, in their annual crops of fruit, while growing, and in their timber when felled or cut down.

It is stated in the Gloucestershire Report, that "it will grow almost in any soil, wants no pruning nor care, and in less time than the oak it will make a large tree. The wood is too valuable to apply to the usual purposes of timber trees, but is always used either in cabinet work or for gun-stocks; for the latter, indeed, so great has been the demand for a few years past, from the Birmingham gun-makers, that the county has been ransacked for this wood, and high prices have been held out to tempt the sale of it. In consequence of this, the stock has been much diminished, and, with very few exceptions, only here and there is a solitary walnut tree seen growing. In the parish of Arlingham there are more, perhaps, than in many other parishes combined."

Were it only for the oil that these nuts afford, the trees which produce them would be worth some care. It has been observed by Evelyn, that one bushel of them will yield 15 lbs. of peeled kernels, and that these will produce that weight of oil, which, the sooner it is drawn, is the more in quantity, though the drier the nut, the better is its quality. He adds, that the lee, or marc of the pressing, is excellent for fattening hogs. Certainly it would be good manure for land; as are the cakes of linseed, rape, &c., after the oil has been squeezed out of them. The green husks boiled, without any mixture, make a good colour to dye a dark yellow-brown. The kernel being rubbed upon any crack or chink of a leaking vessel, stops it better than either clay, pitch, or wax. (Philips's Fruits, p. 137.)

In the variety of trees which compose the vast forests of North America east of the Mississippi, the walnut, says Michaux the younger, ranks after the oak, among the genera whose species are most multiplied. In this particular, the soil of the United States is more favoured than that of Europe, to no part of which is any species of this tree indigenous. This ardent student of nature has designated 10 species of walnut in the United States, including the hickories, and thinks others may yet be discovered in Louisiana. There is, he adds, room to think that species may be discovered, such hickories, like the pecan and the chestnut, of speedy melioration, by the aid of grafting and attentive cultivation. Some weight is given this consideration, by an observation of Michaux the father, that the fruit of the common European walnut, in its natural state, is harder than that of the American species just mentioned, and inferior to it in size and quality. To the members of agricultural societies in
the United States it belongs to extend their observations and experiments on this subject, after the example of our ancestors, to whom we are indebted for a rich variety of fruits, equally salutary and beautiful.

The walnuts of North America appear to present characters so distinct as to require their division into two sections. These characters consist principally in the form of the barren aments or catkins, and in the greater or less rapidity of vegetation in the trees. The first section is composed of walnuts with single aments, and includes two species, the black walnut and the butternut; to which section is added the European walnut. The second section consists of such as have compound aments, and comprises the 8 species already described under the name of Hickory.

The black walnut (Juglans nigra), is known by no other name in all parts of the United States where it grows. East of the Alleghany mountains, the most northern point at which it appears, is, says Michaux, about Goshen in the state of New Jersey, in the latitude of 40° 50'. West of the mountains, it exists abundantly 2° farther north, in that portion of Genesee which is comprised between the 77th and 79th degrees of longitude. This observation, as I shall have occasion to remark, is applicable to several other vegetables, the northern limit of whose appearance varies with the climate, and this becomes milder in advancing towards the west.

This last observation of Michaux in respect to the amelioration of climate in going west, has been ascertained, from exact thermometrical observations, to be applicable only to those sections of country situated sufficiently near the Lakes, and to the eastward of them to be influenced by the greater equality of temperature maintained by bodies of water than by land. The proximity of those great internal seas have a similar effect in modifying climate in that manner on the Atlantic border, where many trees and plants creep up several degrees higher than they can be found further in the interior.

(See Climate of the United States.)

The black walnut is multiplied in the forests about Philadelphia, and, with the exception of the lower parts of the Southern States, where the soil is sandy, or too wet, it is met with to the banks of the Mississippi, throughout an extent of 2000 miles. East of the Alleghany mountains in Virginia, and in the upper part of the Carolinas and of Georgia, it is chiefly found on bare land, and, where it occurs, is peculiar, and which are watered by creeks and rivers; in the western country, in Genesee, and in the states of Ohio and Kentucky, where the soil in general is very rich, it grows in the forests, with the coffee tree, honey-locust, red mulberry, locust, shellbark-hickory, black sugar maple, hackberry, and red elm; all which trees prove the goodness of the soil in which they are found.

It is in these countries, says Michaux, that the black walnut displays its full proportions. On the banks of the Ohio, and on the islands of that beautiful river, I have often seen trees of 3 or 4 feet in diameter and 60 or 70 feet in height. It is not rare to find them of the thickness of 6 or 7 feet. Its powerful vegetation clearly points out this as one of the largest trees of America. When it stands insulated, its branches, extending themselves horizontally to a great distance, spread into a spacious head, which gives it a very majestic appearance.

The leaves of the black walnut when bruised emit a strong aromatic odor. They are about 18 inches in length, pinnate, and composed in general of 6, 7, or 8 pair of leaflets, surmounted by an odd one. The leaflets are opposite and fixed on short petioles; they are acuminate, serrate, and somewhat downy. The barren flowers are disposed in pendulous and cylindrical aments, of which the peduncles are simple, unlike those of the hickories. The fruit is round, odoriferous, of rather an uneven surface, and always appears at the extremity of the branches: on young and vigorous trees, it is sometimes 7 or 8 inches in circumference. The husk is thick, and is not, as in the hickories, divided into sections; but when ripe it softens and gradually decays. The nut is hard, somewhat compressed at the sides, and salted. The kernel, which is divided by firm ligneous partitions, is of a sweet and agreeable taste, though inferior to that of the European walnut. These nuts are sold in the markets of New York, Philadelphia, Baltimore, and by the Marylanders, who are indebted mostly to them for wafers, and the table. The size of the fruit varies considerably, and depends upon the vigour of the tree, and upon the nature of the soil and of the climate. On the banks of the Ohio, and in Kentucky, the fruit with the husk is 7 or 8 inches in compass, with the nut proportionally large: in Genesee, on the contrary, where the cold is intense, and in fields exhausted by cultivation, where these trees have been preserved since the first clearing of the land, it is not of more than half this bigness. Some variations are observed in the form of the fruit, and in the moulding of the shell; but these I consider as merely accidental differences. Indeed, there is no genus of trees in America, in which the fruit of a given species exhibits such various forms as in the walnut; and doubtless this circumstance has misled observers, who, being acquainted only with the small number of trees existing in European gardens, have described them as distinct species.

The bark of the black walnut is thick, blackish, and on old trees deeply furrowed. When the timber is freshly cut, the sap is white and the heart wood red; but in the husk, which after a short exposure to the air assumes an intense shade, and becomes nearly black: hence probably is derived the name of black walnut. There are several qualities for which its wood is principally esteemed: it remains sound during a long time, even when exposed to the influences of heat and moisture; but this observation is applicable only to the heart; the sap speedily decays. It is very strong and very tenacious: when thoroughly seasoned it is not liable to warp and split; and its grain is sufficiently fine and compact to admit of a beautiful polish. It possesses, in addition to these advantages, that of being secure from worms. On account of these excellencies, it is preferred and suc-
WARBLE. See Back-sore, Gall, and SIFTFAST.

WARP. A slimy deposit or ooze left upon land by the receding sea tides in particular situations. See ALLEVIUM and WARPING.

WARPING OF LAND. A mode of fertilizing and improving tillage lands practised in particular situations on the borders of large rivers and waters into which the sea tides flow, and where the level of the ground is such as to admit of their being flooded with great facility. The practice is, for the most part, confined to the strictest situation on the coasts of Lincolnshire and Yorkshire. The water of the tides that come up the Trent, Ouse, Don, and other rivers which empty themselves into the great estuary of the Humber, is muddy to an excess; insomuch that in summer, if a cylindrical glass, 12 or 15 inches long, be filled with it, it will presently deposit an inch, and sometimes more, of what is called warp: a circumstance which renders them so fertile.

The fertility of Egypt, of the land bordering on the shores of the Ganges, and some of the large American rivers, I have already shown to be attributable to the periodical overfowling of the waters, which are surcharged with a large quantity of earthy substances which they hold in solution.

"The effect of warping is very different from that of irrigation; for it is not the water that works the effect, but the deposition of the mud, so that in floods the business ceases, as also in winter; and the object of this practice is not to manure the soil, but to create it. The quality of the land intended to be warped is not of the smallest consequence; a bog, clay, sand, peat, or a barn floor, are all one; as the warp raises it in one summer from 6 to 16 inches thick, and in the hollows, or low places, 2, 3, or 4 feet, so as to leave the whole piece level. Thus a bank of any depth you please may be formed, which consists of mud of a vast fertility, though containing not much besides sand."

This is a practice which is begun in the month of July, and is proceeded with during the summer season; and as it can only be performed at that period, every occasion of having it executed should be embraced, by having the work in perfect repair, that every tide may be made to produce its full effect. With regard to the advantage of doing this work in the summer months, it may be remarked that at these times the lands not only become the softer, dryer, and more compact, but must always fully take place before the process of cultivation can be carried on, but the tides are less mixed with fresh water, in which situation they are constantly found the most effectual.

The method of executing the work is thus described, in the Agricultural Survey of the West Riding of Yorkshire, by Lord Hawke:—

"The land to be warped must be banked round against the river. The banks are made of the earth taken on the spot from the land: they must slope 6 feet, that is, 3 feet on each side of the top or crown of the bank, for every foot perpendicular of rise: their top or crown is broader or narrower, according to the impetuosity of the tide and the weight and quantity of water; and it extends from 2 to 12 feet: their height is regulated by the height to which the spring tides flow, so as to exclude or let them in at pleasure. In these banks there are more or fewer openings, according to the size of the ground to be warped, and to the choice of the occupier; but in general they have only two sluices, one called the flood-gate, to admit, the other called the clough, to let off the water gently; these are enough for 10 or 15 acres. When the tide begins to ebb, the flood-gate is opened to admit the tide, the clough having been previously shut by the weight of the water brought up the river by the flow of the tide. As the tide ebbs down the river, the weight or pressure of water being taken from the outside of the clough next the river, the tide water that has been previously admitted by the flood-gate opens the clough again, and discharges itself slowly but completely through it. The cloughs are walled on each side, and so constructed as to let the water run off between the ebb of the tide admitted and the flow of the next; and this point of particular attention is paid. The flood-gates are placed so high as only to let in the spring tides when

1091
WARRANTY.

opened. They are placed above the level of the common tides.

"Willows are also occasionally planted on the front of the banks, to break the force of the tides, and defend the banks by raising the front of them with warp thus collected and accumulated; but these willows must never be planted on the banks, as they would destroy them by giving the winds power to shake them."

It is stated that in England the first cost of a sluice for warping, that is, 5 feet in height and 7 feet in width, may be estimated at from 400l. to 500l.; and that such a sluice will in general be adequate to the warping of 50 acres annually, and, where the soil is contiguous to the river, for 70 or more.

The following is given as the substance of a note by a commissioner employed in warping:

"Warp leaves one-eighth of an inch every tide on an average; and these layers do not mix in a uniform mass, but remain in distinct layers.

"If only one sluice, then only every other tide can be used, as the water must run perfectly off, that the surface may incrust; and if the canal be not empty, the tide has not the effect.

"As a new soil is created by this practice, it is of little consequence what the original nature of the land may be, almost all kinds being improved by it. But at the same time it may be the most beneficial in such light soils as are very open and porous, and such stiff ones as are defective in calcareous matter, and which require substances of this kind to render them less tenacious. Land, when once well warped, will continue for a vast length of time in a good state of fertility, but still it is suggested by some experienced warpers as a better practice to apply a small portion of warp whenever the land is in the state of fallow, which will be about every 5 or 6 years, as by this means the farmer will be more secure of having good crops. The depth to which the lands are covered by the tides must be regulated according to their levels, and the height of the tide in the rivers from which they proceed. It may be admitted to the height of 3, or 4, or more feet; but the deposit of sediment is in some measure proportionate to the height of the water, though the same effects may be obtained from much smaller quantities of water by continuing the process a great number of tides."

The expense of this mode of improving lands must necessarily differ much in different cases, according as the circumstances of situation and distance vary; but, according to Mr. Young, it can seldom exceed 12l. or 15l. the acre, and in most instances it must be greatly below such estimates.

Warped lands are found capable of growing most kinds of crops in great plenty, but particularly oats, beans, wheat, flax, potatoes, and grass-seeds.

WARRANTY. In horsemanship, &c., a term applied to the assurance of the animal's being sound when purchased. See BUYING and SELLING.

WARREN. A franchise, or place privileged, either by prescription or grant from the king, to keep beasts and fowls of warren in; as rabbits, hares, partridges, pheasants, &c.

By statute 21 Edw. 3, a warren may lie open, and there is no need of closing it in, as there is a park.

In the forming a warren, great caution is to be used for the fixing upon a proper place and a right situation. It should always be upon a small ascent, if possible, and exposed to the east or the south. The soil that is most suitable is that which is sandy; for when the soil is clayey or tough, the rabbits find great difficulty in making their burrows, and never do it so well; and if the soil be boggy or moorish, there would be very little advantage from the warren; for wet is very destructive to these animals. See RABBIT.

WASP (Fiepsa). An extensive genus of insects, of which three species are common to Britain. The hornet, or V. crabro, already mentioned; common wasp, or V. vulgaris, which makes its nest in the ground; the small wasp, or V. coareata, the nest of which is a kind of paper made of woody fibre and suspended to the boughs of trees.

Of the wasps most commonly known in the United States there are two species, namely, the large, fierce, stinging insect which builds its flat paper nest in bushes, &c., and the more harmless blue-winged mud-wasp, commonly called the mason, from its plastering its nest with mud against the walls of houses, &c. These nests are composed of cells, each one of which contains a single egg, together with a considerable number of living spiders, caught and imprisoned therein solely for the purpose of affording the little mason's young a ready supply of food in revisions. In noticing this characteristic of the mud-wasp, Dr. Harris also refers to the habits and nests of some other tribes of the same family, such as the holes of the stump-wasp, stored with hundreds of horseflies for the same purpose; the skill of the leaf-cutter bee in cutting out the semicircular pieces of leaves for her patchwork nest; the thimble-shaped cells of the ground-bee, hidden in clusters under some loose stone in the fields, made of little fragments of tempered clay, and stored with bee-bread, the work of many weeks for the industrious labourer; the waxen cells made by the honey-bee, without any teaching, upon purely mathematical principles, measured only with her antenna, and wrought with her jaws and tongue; the water-tight nests of the hornet and wasp, natural paper-makers from the beginning of time, who are not obliged to use rags or ropes in the formation of their durable paper combs, but have applied to this purpose fibres of wood, a material that the art of man has not yet been able to manufacture into paper. These are only a few of the objects deserving of notice among the insects of this order; many others might be mentioned, that would lead us to observe with what consummate skill these little creatures have been fashioned, and how richly they have been endowed with instincts, that never fail them in providing for their own welfare, and that of their future progeny. (Treatise on Des. Insecta.)

Wasps are not only destructive to grapes, peaches, and the more delicate kinds of fruit, but also to bees, the hives of which they attack and plunder, frequently compelling these in-
dustrious insects to change their habitation. The nests of these wasps which build in the earth may be destroyed with hot water or oil; those on trees are best suffocated by lighted brimstone. (Kollar on Insects, p. 79.) Wasps are much affected by cold; so that when winter begins to set in they become less bold and savage, and they all perish, except a few females, as soon as the frost begins. This is a wise provision of nature; for, did they survive the winter, they would soon rival the locust in their destructive depredations.

WASTE LAND. The following is an account of the quantity of land uncultivated and waste in the British dominions, including Scotland, Ireland, and the British islands, according to the evidence of Mr. Cowling before the Emigration Committee in 1827:—

WATER. A well-known, universally diffused substance, which in ordinary temperatures is fluid but is solid when cooled down to 32° of Fahrenheit's thermometer. It rises into vapour at all temperatures, even below the freezing point, and at 212° expands suddenly into steam. It is composed, by weight, of oxygen 8 parts, and hydrogen 1 part.

Water is one of the most useful elements in the arts and manufactures, as well as in rural and domestic economy. The extensive utility of water for imparting motion to machinery, and for domestic purposes, is too well known to require explanation; and as we have already treated of its beneficial properties for irrigating land, under this head we shall have principally to confine ourselves to its uses to plants.

Its Uses to Vegetation.—The value of water to vegetation very early attracted the attention of mankind. In the most ancient of all books, Genesis ii. 10, we are told that “a river went out of Eden to water the garden.” And the earliest of the Greek and Egyptian philosophers, astonished and confused by the magic effects which water produced upon the rank and luxuriant lands of the warm eastern climates, were loud in their praises of the unaided powers of water to support vegetation. They not only regarded it as one of the four elements upon which the world was composed, but Hippocrates considered it to be the substance which nourishes and supports plants and animals. Theophrastus even considered that all metals were produced from water. The opinion that pure water, and water only, was able to support vegetation, was in succeeding ages long the opinion of many philosophers distinguished for their laborious investigations and their ardent love of truth. Amongst these may be named Van Helmont, Bonnet, Duhamel, Tillet, and the illustrious Boyle. These great men deceived themselves, however, by not sufficiently attending to the purity of the water with which they experimented, or guarding with rigid accuracy against other sources of error. Of the many researches which they instituted to determine this point, none was more apparently conclusive than that of the well-known willow tree experiment of Van Helmont, which long deceived, from its apparent accuracy, the philosophers of that age. This celebrated experimentalist planted a willow which weighed 5 lbs. in a common earthen vessel filled with 200 lbs. of soil, which had been previously thoroughly dried in an oven, and then moistened with only rain-water. This earthen vessel he placed in the earth in a garden, covering it over in such a manner that all access of dust, &c., was prevented. For five years this willow continued to grow, although moistened only with either rain or distilled water. At the end of that period, it was found to weigh 169½ lbs., although the earth in which it was planted, when again dried and weighed, was found to have lost only two ounces of its original weight. Here, then, said the contemporaries of Van Helmont, is an increase of 164 lbs., and yet the only food the willow had was water; it is evident, therefore, that pure water, and water only, is quite sufficient to support vegetation.

Various sources of error were, however, speedily discerned to prove that this experiment was totally insufficient to decide this question. Almost every species of plant suffered, and showed that the rain-water employed by Van Helmont, so far from being chemically pure, contained sufficient earthy matters to supply the whole of that found in the willow tree. And, in addition to this, it was afterwards shown that unglazed earthen vessels readily imbibe and transmit the moisture of the soil in which they are placed: now this moisture abounds with a variety of solid matters, both organic, earthy, and saline. (Thomson, vol. iv. p. 313.)

Still more accurate experiments have been since instituted with water chemically pure, with very different results. In this respect to raise plants have in every instance totally failed, although, as I have in another place had occasion to remark, I have fruitlessly varied the attempt in several ways. See LIQUID MANURE.

Although, however, it is, from the result of these laborious researches, pretty clearly proved that water is not the sole food of plants, yet it must be evident to the most casual observer what an indispensable food this universal fluid is to vegetation. To all vegetation, in fact, it is an indispensable necessary of life, although every species of plant requires to be supplied with it in varying proportions: some, such as the aerial epipodium, and other Oriental plants, being able to supply themselves from merely the aqueous portion of it which always exists in the atmosphere; while some, such as the rice plant, and the aquatics, cannot prosper without being supplied with it in such copious quantities as would be destructive to the ordinary crops of the farmer. In some proportion or other, however, they all require it, and all attempts have been in vain made to cause plants to grow in situations where moisture was absolutely
removed both from the earth and their surrounding atmosphere.

M. Berthollet was of opinion that the leaves of plants have the power of decomposing water when exposed to the light of the sun. The oxygen gas, according to this distinguished philosopher, which is always excited under these circumstances, is derived partly from the decomposition of the water. "Indeed," adds Dr. Thomson, "if we consider the great quantity of hydrogen contained in plants, it is difficult to conceive how they should obtain it, provided the water they absorb does not contribute to furnish it." (System of Chem. vol. iv. p. 349.) These views open a field for future and highly interesting researches, which will probably lead to the establishing of new facts highly important to the cultivator. And as Davy, the chief of chemists, well said, "We can only reason from facts. We cannot imitate the powers of composition belonging to vegetable structures, but at least we can understand them; and as far as our researches have gone, it appears that in vegetation compound forms are uniformly produced from simpler ones; and the elements in the soil, the atmosphere, and the earth, absorbed and made parts of beautiful and diversified structures." (Lectures, p. 314.)

Pure water, therefore, is certainly not capable of entirely supporting vegetation. Yet, although it cannot produce effects so extensive as these, yet its uses are many and important; and it is more than probable that it is decomposed by plants, its oxygen partially evolved, and its hydrogen assimilated with carbon and oxygen into a variety of vegetable substances, most of which contain hydrogen in some form or other: thus

It would be difficult indeed to account for the large proportion of hydrogen present in vegetable substances, without we allow that in some instances water is decomposed by the plant. "All the hydrogen," says Professor Liebig, rather too sweepingly, "necessary for the formation of an organic compound is supplied to a plant by the decomposition of water. (Organ. Chem. p. 66.)

That plants have a strong attraction for water is evident from a variety of circumstances; thus by their leaves and roots they separate the aqueous vapour of the atmosphere from the gases in which it is contained, and that too in all ordinary temperatures. This unvarying presence of aqueous vapour in the atmosphere is not less remarkable by the immense importance it is to vegetation; for without the assistance which the farmer's crops derive from it in dry weather, the warmth of the sun would cause them in the summer months wither and destroy them. This beautiful arrangement of creative wisdom did not escape the attention of Davy, who noted too the variations in its quantity according to the changing demands of vegetation. The quantity of water, he remarked (Elements of Agr. Chem. p. 207), which exists in air as vapour, varies with the temperature. In proportion as the weather is hotter the quantity is greater. At 50° of Fahrenheit's thermometer, air contains about one-fifteenth of its volume of vapour; and as the specific gravity of vapour is to that of air nearly as 10 to 15, this is about one seventy-fifth of its weight. At 100°, supposing that it has a free communication with water, it contains about one-fourteenth part in volume, or one twenty-first in weight. It is the condensation of vapour by the diminution in the temperature of the atmosphere which is probably the principal cause of the formation of clouds, and of the deposition of dew, mist, snow, or hail. The leaves of living plants appear to act upon the vapour likewise in its elastic form, and to absorb it. Some vegetables increase in weight from this cause when suspended in the atmosphere, and unconnected with the soil; such are the house-leek, and different species of the aloe. In very intense heats, adds Davy, and when the soil is dry, the life of plants seems to be preserved by the absorbent power of their leaves; and it is a beautiful circumstance in the economy of nature, that aqueous vapour is most abundant in the atmosphere when it is most needed for the purposes of life, and that when other sources of its supply are cut off, this is most copious.

And, again, when water is combined with saline substances, the roots of plants separate it from them in a very remarkable manner. Some curious experiments of this kind were made by M. Saussure. See Salts, their Uses to Vegetation.

That plants have the power, when nourished only with pure water, of decomposing the carbonic acid gas of the atmosphere, has been shown by some very careful experiments of M. Saussure. He found that some sprigs of peppermint, when supplied with pure water only, and allowed to vegetate for some time in the light, nearly doubled the portion of carbon which they originally contained. The quantity of water which, under ordinary circumstances, plants absorb, is very considerable; thus, Dr. Hales ascertained that a cabbage transmits into the atmosphere, by insensible vapour, about half its weight of water daily; and that a sunflower, 3 feet in height, transpired in the same period nearly 2 lbs. weight. (Veget. Statits, vol. i. p. 5, 15.) Dr. Woodward found that a sprig of mint, weighing 27 grams, in 77 days emitted 2543 grams of water. A sprig of spearmint, weighing 27 grams, emitted in the same time 2553 grams. A sprig of common nightshade, weighing 49 grams, evolved
3708 grains, and a lathyris of 98 grains emitted 2501 grains.

In a previous page of this Encyclopaedia, I have endeavoured to show the various uses of the earths to vegetation. (See Earths.) The cultivator will observe how many of their chief fertile properties are connected with their attraction for the aqueous vapour of the atmosphere, their powers of absorption, their capability of retaining it. It is in rain, indeed, by any contrivance to attempt to make plants of any description vegetate in absolutely dry earth, or in air from which the aqueous vapour is entirely withdrawn. It is true that some of the flowering roots of the East, and some of the mosses of our own country, almost appear to do so; but such plants support themselves by absorbing a certain degree of moisture, even when suspended, as in oriental countries, by a silken cord from the ceiling of the room, or from apparently dry brick walls; for when by chemical means the moisture is entirely removed from them, even these hardy plants cease to vegetate.

Various foreign substances have been supposed to exist in minute proportions in rain-water, to which its fertilizing effects have been chiefly ascribed; thus ammonia is believed by Professor Liebig to exist in rain-water. Nothing, however, is more likely to lead to erroneous general conclusions than the detection of minute foreign substances in water. Such hasty generalizations have often deceived the most excellent philosophers: thus the great Boyle, by digesting pure water for a lengthened period in glass vessels hermetically sealed, found that it deposited a minute quantity of flint in powder; and hence he was led to conclude that water was in this way converted by long boiling into silica, an error which several other philosophers adopted, until the celebrated Lavoisier and Dr. Priestley proved that the flint deposited arose from the water having, by long boiling, partially dissolved the glass. In the same way even Davy, the most cautious of experimentalists, once thought that chlorine and soda might, by the influence of the voltaic pile, be obtained from water absolutely pure; but more careful and rigid experiments soon convinced him of the extreme difficulty of procuring entirely pure water, the vessels in which the water was procured communicating, with every apparent caution, sundry impurities; and this difficulty, I think it very likely, the skilful chemists of Germany have not successfully escaped.

Water exists in all cultivated land in some proportion or other. The quantity, however, necessary to be present in the farmer's soils to obtain the maximum advantage varies with their nature, the climate, and the crop. For instance, the rice-fields of India require a degree of moisture which would be utterly destructive to the grain crops of the English farmer. The most porous, sandy land in a rainy climate will be prolific, when the same soil in a dry, warm country will be absolutely barren. Even the drifting sands of Arabia, for instance, if placed under the incessant rains of the American Andes, would certainly be speedily covered with vegetation. Some of the richest water-meadows of the south of England and of Scotland are formed on subsoils of broken flints, gravels, and the roughest shingle. And, again, the meadow-lands often need such copious supplies of moisture as would be the means of destroying the grain crops. The surface water which tenants many uncultivated soils is generally surcharged with a variety of foreign substances, very common with vegetable matters. That in the gravelly soils is usually surcharged with oxide of iron; that resting on calcareous soils, with sulphate of lime (gypsum); whilst those from peat lands commonly abound with sulphate of iron, or the red oxide of the same metal.

In most of the soils which the farmer has to bring into cultivation, the removal of these waters is his first care; for such an abundance of moisture is not only pernicious, from the usual bad quality of the land water, but from the quantity being far too great for the habits of the plants which the farmer intends to cultivate; such waters, too, dissolve, and sometimes carry with them from the soil the most susceptible drainage, all the soluble richest portion of the soil. For many reasons, therefore, draining has been long very justly held to be the foundation of all agricultural improvements; since its good effects are not confined to the low marsh land, but its beneficial influence is extended to the most upland soils. It removes the land springs, and dries the surface of thousands of acres of even the most elevated of the English gravels.

Almost to an equally beneficial extent has the addition of water to plants for a lengthened period been carried on by the cultivator in a variety of modes; by the gardener in steam in his conservatories, or by the watering-pot in the open ground. Almost endless, indeed, are the varieties of artificial irrigation, from the minor applications of the gardener to the more gigantic efforts of the managers of the water-means. It is this branch of the investigation of the uses of water to vegetation which is the most interesting to the farmer, and to the head Irrigation I must refer the reader. In regarding the uses of water to vegetation in this manner, however, the cultivator must remember that it is not pure water that he is thus using for his crops, but, as I have before remarked, water surcharged with a variety of earthly, saline, and organic matters, to whose presence a chief portion of the fertilizing effect of such streams must be attributed; for it is found that the most foul and impure waters are much the best for the purposes of irrigation; thus the water of a river below a town is found to be much more fertilizing than the same water before it has been mixed with the contents of the sewers. These are facts well known, for instance, to the owners of the fine water meadows of the valleys of the Ichen, the Ken, and the Avon. That of the Thames above the influence of the tide is not nearly so valuable to the grazier as it is after it has had mixed with its waters the huge mass of impure matters from the London sewers. Then, again, by far the richest irrigating waters, because the very foulest of all, are those of the sewers of the city of Edinburgh, which produce such singu-
larily luxuriant crops of grass on the Craigin-

nny meadows. This observation is not con-

fined to the English graziers: those of the duchy of Milan long since made the same remark.

Half a century since, Mr. Songa, when describ-
ing the meads of the banks of the Brembo, says it is found that a ditch which passes through the fosses of the town of Tre-
viglio, and discharges itself from them by form-
ing a canal of 8 or 10 feet broad, and 1 foot or 1½ foot deep. The lands irrigated with this water seem to receive every time the ad-
vantage of a dunging, and on this account sell from a third to a half dearer than any other of an equal quality of soil." (Young's *Annals*, 1793, p. 182.) Watering the land to add to its fer-
tility is a very ancient practice.

Such, then, are a few of the well-ascertained facts with regard to the application of water to vegetation, uses which are so valuable when well understood by the farmer. In all his op-
erations this universal fluid will be found to in-
fluence his arrangements; and in a due and regular supply of it to his crops consists, in fact, the success of most of his efforts. If, for

instance, a farmer would judge of the value of a particular field from merely a specimen of its soil, the attraction of the previously dried earth for the moisture of the atmosphere will afford a very tolerable indication of its comparative value; those soils which attract the most wa-
ter being commonly those which obtain the highest yields.

All researches like these, in many obvious and indirect ways, are attended with consider-
able advantage to the cultivator. For,

the more he becomes acquainted with the uses and properties of water, the more readily will he be able to avail himself of every opportunity which may present itself for extending its sphere of usefulness. It is idle to conclude that every thing possible has been effected with regard to the agricultural uses of water; for,

saying nothing of the inferior extent of our water meads to those of even the banks of the Italian rivers, much still remains to be ac-

complished in this article, not only the liquid drainage of our large towns, but in the use of the steam-engine for the purposes of ir-

igation; an agent to which I have in this work already alluded, and for obtaining whose magic assistance the farmers of no other coun-

try are so well situated as those of our own island. To the cultivator, therefore, an exami-
nation of the powers and properties of water will in many ways be attended with benefit; for if the farmer once seriously contemplates the powerfully invigorating and enriching qual-

ties of the waters near to which he is very often placed, the abundance of organic matters which they contain, and the advantages to be derived from their judicious application, he will speedi-

ly devise some means or other by which he may avail himself of this too often neglected agent. The finely divided earthy and organic matters which now so copiously pollute the waters of our rivers are in fact the only great drawbacks upon the otherwise gradually in-

creasing productiveness of the land. (See Al-

lumina and Warming.) These, he it remem-

bered, are ever quickly yet incessantly acting as drains upon the fertility of the land; they never cease the work of impoverishment; and it is only by the efforts of the merchant, the fisherman, and the irrigator, that any portion of these finely divided matters ever return again to the cultivated soils of our country. See Irri-
gation, Irrigation, Irrigation.

WATER-ALOE, or WATER SOLDIER

(*Strawbrotia absides*; from *strato*, an army, in allu-

sion to its long sword-like leaves). In England, an ornamental native aquatic, which fills the ditches in summer with a close phalanx of sword-like leaves, and increases so fast in the ponds where it is planted as to become almost a troublesome weed. In its wild state it inhab-

bits deep ditches and pools, and is a stolonife-

rous, smooth, floating herb, with numerous ra-
dical leaves, and a solitary central flower-stalk, but no stem. The parent plant sinks to the bottom after flowering, and sends out long simple runners, each terminating in a leaf, bud, or young plant, which first takes root in the mud, by several long fibres, and in the following summer rises to the surface of the water, blos-

sons and then again subsides to ripen its seeds and throw out fresh runners, each tuft of leaves flowering but once. The leaves are a span long or more, acute, highly vascular, fringed with very sharp saw-like teeth. Flow-

ers white, large and handsome, the stalk firm, stout, two-edged, much shorter than the leaves.

ter.

WATER-LILY, WHITE. See Lily, Water.

WATER-MELON. The following direc-

tions for cultivating water-melons for an early market, are given by Mr. Phipps in his *Agricultural Jour-

nal*. See Water, p. 88. Take the choice, or

high, dry soil for this purpose. Plough it up well, and narrow it. Check off the

spot thus treated at distances of 10 feet each way. Dig out each check with a hoe or spade, and into the same place 5 or 6 quarts of cotton seed; or if this cannot be procured, fill the place with stable manure, partly decom-

posed. Haul over this the earth before dug from the hole, and mix it well with the manure. If you have used cotton seed, in the spring, it

will have sprouted a week or two after being put into the hole; and must now be killed by chopping up the same well, and mixing it with the soil. This being done, you may now hand up the manure and earth as before directed, into hills, on the top of which you must place about a peck of sand, taken from some street or well-travelled road. Your hills will be now ready for planting. I should, however, state that the hills must, instead of being made high, be made flat and broad.

Soak your seed over night in milk-warm water, and plant them out the next morning, placing from 5 to 6 seed to each hill. The
WATER-PEPPER.

seed must not be covered more than 1 or 2 inches under ground. Water the hills for a few days until the seed has sprouted, and then leave the plants to run.

As soon as the plant has got 6 leaves, take off the centre plant with a sharp penknife, and when the lateral shoots are 6 inches or a foot long, take off all but three. When the shoots, thus left, begin to run to the ground between the hills, take them down with a small crosstick.

As the vines begin to branch, at every 3 or 4 feet, where the vine branches, put a shovelful of rich earth over the same, and press it down firmly with the foot. Wet weather should be selected for this operation, and by so doing the vines will never fail to take where they have been set. The spaces between the hills should be kept free of grass—and by following the above directions, large melons will be produced.

From a quarter acre of land thus treated, more melons will be made than from four times the amount as usually cultivated. See MEALY WATER.

WATER-PEPPER (Polygonum punctatum). A plant found in the Middle and other States, having very hard qualities, causing obstinate ulcerative inflammation when applied to the skin.

WATER-PLANTAIN (Alisma, from the Celtic alis, water). A genus of pretty little, aquatic, perennial, smooth plants, with simple, entire leaves, and numerous, stalked, white, yellowish or purplish, panicked or umbellate inodorous flowers. In England, there are four native species; viz.:

1. The greater water-plantain, or thrumwort (A. plantago), which is very common in pools, ditches, and about the margins of rivers. The root is fibrous. Leaves all radical, on long stalks, erect, ovate, acute, ribbed, in deep or running water lengthened out more or less. It has been recommended in hydrophobia; but, like many other wonder-working remedies, it is worthless.

2. Star-headed water-plantain (A. damasonium), found in ditches and pools on a gravelly soil, but not common. The root consists of many long pale fibres. The leaves all radical, floating, bluish or oblong, heart-shaped at the base. Footstalks very broad, with many ribs, and a membranous border, tapering upwards. Flower-stalks scarcely a span high, bearing 1 or 2 whorls of white flowers, yellow in the middle. Capsules six, spreading in the form of a star, half-ovate.

3. Floating water-plantain (A. natans). This species frequents the lakes of North Wales and Cumberland.

4. Lesser water-plantain (A. ranunculoides). This grows in swamps and turfgy bogs, but is not a very common species.

5. Creeping water-plantain (A. repens). This has only been found on the margins of some of the lakes in North Wales.

WAX (Germ. weiche). A solid concrete abounding in the vegetable kingdom, whence it is erroneously supposed that it is collected by bees. Bees' wax is a secretion in the body of the bee, and is accumulated in what are called the wax-pockets. Bees confined to a hive, and fed merely on sugar, form wax. It constitutes the partitions of the cells in which they store their honey. It is obtained by melting the comb. Wax, when pure, is of a whitch colour; it is destitute of taste, and has scarcely any smell. Bees' wax, indeed, has a pretty strong aromatic odour; but this seems chiefly owing to some substance with which it is mixed; for it disappears almost completely by exposing the wax, drawn out into thin ribbands, for some time to the atmosphere to blench, frequently changing the surface thus exposed, by remelting it, and remeltting again to thin flakes. By this process, which is called bleaching, the yellow colour of the wax disappears. White wax is principally used in making candles, and in white ointments, for the sake of its colour. Wax is insoluble in water; nor are its properties altered though kept under that liquid. When heat is applied to wax, it becomes soft; and at the temperature of 142°, if unblemished, or of 155°, if bleached, it melts into a colourless transparent fluid, which concretes again, and resumes its former appearance, as the temperature diminishes. If the heat be still further increased, the wax boils and evacuates; and if a red heat be applied to the vapour, it takes fire and burns with a bright flame. It is this property which renders wax so useful for making candles. Wax combines readily with fixed oils when assisted by heat, and forms with them a substance of greater or less consistency, according to the quantity of oil. This composition, which is known by the name of cerate, is much employed by surgeons.

According to the experiments of Gay-Lussac and Thenard (Rec. Physio-Chim. vol. ii. p. 316), 100 parts of wax are composed of—

</table>

Wax is sometimes adulterated with the white oxide of lead to increase its weight, with white tallow, and with potato starch. The first is detected by melting the wax in hot water, when the oxide falls to the bottom undissolved; the presence of tallow is indicated by the wax being of a dull opaque white, and wanting the transparency which distinguishes pure wax; and starch may be detected by applying a strong sulphuric acid to the suspected wax, as the acid carbonizes the starch without acting on the wax.

Notwithstanding the large supply of wax produced in England, a considerable quantity is imported from abroad; but it is subject to the high duty of 1l. 10s. per cwt. The price varies, duty included, from 5l. to 10l. per cwt. (Thomson's Chem. vol. i. p. 103; Thomson's Dispensatory; McCulloch's Corn. Diet.)

WAX-BREAD. One of the common names of the Common or Great Plantain.

WAYPARING TREE. See GLANDER ROSE.

WAY-GOING CROP. That which is taken from the land the year the tenant leaves a farm.
WEATHER.

WAY, PRIVATE RIGHT OF.

WAY, PRIVATE RIGHT OF. This may arise either from grant or by prescription and usage from time immemorial, for this is in law supposed to arise from a grant. According to English common law, a right of way may be to a particular person to go over the grantor's land, or to convey, to market, or to any particular close. Such a special permission is, however, to be construed strictly: the grantee cannot, under such a grant, justify going beyond the place specified in the grant; nor can he take any other person with him; neither can he assign over this right,—it dies with him. And a grant for agricultural purposes does not authorize the grantee to use the road for commercial or general purposes; neither does a prescriptive right of way for all kind of carriages, prove a right of way for all manner of cattle. If a grantor convey a piece of ground in the middle of his own land, the law will presume that he also granted a way to it. "When," said Lord Kenyon, in this case, "they made the conveyance, it must be taken for granted that they intended to convey some beneficial interest; but he can derive no benefit whatever from the grant unless he has a right of way to the land." But if by purchasing other land, or new circumstances afterwards arise by which he can approach the public road, then the right of way ceases with the necessity. And if a private way is granted, that does not justify a person for going over the land; if the side of it, even if the road is overflowed with water from an adjoining river, Lord Ellenborough, C. J., said, in this case, "It is a thing founded in grant, and the grantor of a private way does not grant a liberty to break out of it at random over the whole surface of his close." By the 2 & 3 W. 4, c. 71, it is enacted, that in all claims for right of way by prescription, where it has been enjoyed for 20 years, such right shall only be defeated or destroyed by showing that such right was first expired at any time previous to such 20 years; and where it has been enjoyed for full 40 years, the right shall be absolute and indefeasible. If, however, it shall appear that the same was enjoyed by some consent or agreement by deed or writing.

WEANING. The means employed to reconcile a young animal to the loss of its mother's milk, and habituate it to take common food. Under the head Foal we have already given directions for their management during and after weaning. The process of weaning calves is variously managed by different farmers. When not let run with the cow, the most advisable mode, as it regards the calf, is to place it loose in a crib, and to suckle it by hand with the mother's new milk, of which it will consume for some time not more than about four quarters per day: the quantity, however, must then be gradually increased, as it will, in the course of a few weeks, require as much as three gallons. If the weather be fine, it should be, within a fortnight or three weeks, turned out daily in the orchard, or some well-sheltered enclosure of sweet herbage; and, as it will in the course of 10 or 12 weeks have acquired some relish for the pasture, it may be regularly weaned by gradually diminishing the quantity of milk, and then substituting the skimmed for the new. Calves may, however, be reared with skimmed milk and meal, without any portion of new milk, except the first few days' bietings, and many persons give them nothing but water-gruel and hay-tea with a fortnight after they have been removed from the cow. Sago and linseed jelly are also very nutritious, and calves may be weaned on them without any other food. (British Husb. vol. ii. p. 441.)

The time of weaning lambs differs materially, according to the locality of the farms and the quality of the pasture. Four months old is about the period usually selected. The lambs should be turned into somewhat better pasture than that to which they had been accustomed, in order to compensate for the loss of the mother's milk. Many farmers are very fanciful as to the provision for the weaned lambs. The clover or the saffron, or the aftermath, are selected by some; others put their smaller and more weakly lambs to weed the turnip crops; but there can be nothing more desirable than a fresh pasture, not too luxuriant, and yet sufficient to maintain and increase their condition. (Youatt on Sheep, p. 516.) For directions as to weaning pigs, see Swine.

WEASEL-SNOUT (Galeodobolon lutreni). The weasel-snout, yellow archangel, or dead nettle, is a pretty, indigenous, perennial plant, found abundantly in most parts of England, in marshy, shady places. The root is somewhat tuberous, moderately creeping. The stems are 18 inches high, simple, leafy, covered with close deflexed hairs. Leaves stalked, ovate, acute, serrated, slightly hairy, bright green, various in breadth. Whorls numerous, each composed of many large, handsome, inodorous yellow flowers, whose lower lip is spotted with red, the middle segment stained with orange-colour. The flowers afford to bees an abundant supply of honey.

WEATHER (Sax.). A term applied to denote the state or disposition of the atmosphere, with regard to heat and cold, drought and moisture, fog, fair or foul, wind, rain, hail, frost, snow, &c.,

A knowledge of this is of vast importance to the farmer, as the securing of his produce in a perfect manner greatly depends upon it; and as it is in and by means of the atmosphere that plants are nourished, and animals live and breathe, any alteration in its density, heat, purity, &c., must, of course, necessarily be attended with proportionable effects on organization.

The great but regular alterations a little change of weather makes in many parts of inanimate matter is fully shown in the common instances of barometers, thermometers, hygrometers, &c.; and it is owing partly to our inattention, and partly to other causes, that man, like other animals, does not feel as great and as regular, ones in the tubes, chords, and fibres of his own body.

In order fully to establish a proper theory of the weather, it would be necessary to have registers carefully kept in different parts of the globe for a long series of years, whence we
might be enabled to determine the directions, breadth, and bounds of the winds, and of the weather they bring with them; with the corresponding between the weather of divers places, and the difference between one sort and another at the same place; and thus, in time, learn to foretell many great emergencies; as extraordinary heats, rains, frosts, droughts, &c. But this is to very few, and only partial, registers or accounts of the weather have been kept. The Meteorological Society of Great Britain, and the British Association for the Advancement of Science, have latterly done much towards increasing our stock of meteoric knowledge, and have collected an immense body of facts and registers, from which many useful inferences have been drawn, and some important theories deduced. The general conclusions that have been drawn from the experiments that have been made on this subject are:—that barometers generally rise and fall together, even at very distant places, and a consequent conformity and similarity of weather; but this is the more uniformly so, as the places are nearer together, as might be expected; that the variations of the barometer are greater as the places are nearer to the pole: thus, for instance, the mercury at London has a greater range by 2 or 3 lines than at Paris; and at Paris, a greater than at Zurich; and at some places near the equator there is scarcely any variation at all;—that the rain in Switzerland and Italy is much greater in quantity for the whole year than in Essex; and yet the rains are more frequent, or there are more rainy days, in Essex than at either of these places;—that cold contributes greatly to rain, apparently by condensing the suspended vapours, and so leading to their precipitation; thus, very cold months or seasons are commonly followed immediately by very rainy ones, and cold summers are always wet ones. High ridges of mountains, and the snows with which they are covered, not only affect the neighbouring places, but even distant countries often partake of their effects.

The science of meteorology, or the study of the changing phenomena of the atmosphere, &c., has from the earliest periods occupied a greater or less share of attention from the tiler of the soil, the gardener, and those engaged in the pasturage of animals. To no individual (the mariner, perhaps, excepted) is a foreknowledge of the probable future state of the weather of more consequence and importance than the agriculturist; for on this must mainly depend the progress and success of his field operations, his seedtime and his harvest, and the greater or less return afforded by his crops. It may not comport with the dignity of the man of science, or the elevated learning of the erudite philosopher, to have his eyes and ears open to the plain and simple rules and guides which nature lays out before him. Perhaps he has little of leisure to note the Every-day phenomena which the atmosphere and all animate and inanimate nature hold up to observation, as in a glass, where all who use their eyes may read as they run. The companions of his study are the more costly and elaborately prepared philosophical instruments: how much, however, might their value be enhanced by a careful and comparative observation of the "skye influences," as the poet terms them! But to these closet companions, the husbandman, the shepherd, the traveller, the fisherman, and the mariner have rarely access, while engaged in the busy out-of-door occupations of their several avocations. Those who till the land, or who go down to the sea in ships, of all others, are they who become, by habits of observation and reflection, most conversant with the signs and changes of the heavens; the sun, the moon, and the stars are to them monitors and instructors, whose warning voices meet a prompt and ready response. The ripple of the wave, the curl of the smoke, the passing shadow of the cloud, the budding of the tree, the arrival and departure of the migratory birds, the frolicsome gambols of animals, every leaf that quivers in the sunbeam, every plant that drinks the dew of heaven, the myriads of insects, and creeping things innumerable, that inhabit earth and open sky, are all fraught with instruction and information to the experienced and watchful observer.

Around, above, beneath, all animate and inanimate creation, animals, vegetables, the elements, a thousand objects in a thousand directions, in every recurring season, furnish their quota of information towards our stock of meteoric knowledge, and foretell the approaching variations of atmospheric phenomena. The experienced fisherman and the watchful and wary mariner will predict the coming storm, by the tiny cloud and other unerring criteria which frequent and attentive observation of the sky has rendered familiar, long before its approach is visible to the ken of the ordinary and inattentive observer.

It has been very remarked, that "the shepherd, whose sole business it is to observe what has a reference to the flocks under his care, who spends all his days and many of his nights in the open air, under the wide-spread canopy of heaven, is obliged to take particular notice of the alterations of the weather; and when he cares to take a pleasure in making such observations, it is amazing how much progress he makes in them, and to how much a certain man arrives at last, by mere dint of comparing signs and events, and connecting one observation with another. Every thing in time comes to him a weather-gauge: the sun, the moon, the stars, the clouds, the winds, the mists, the trees, the flowers, the herbs, and almost every insect, animal, and reptile with which he is acquainted—all these become, to such a person, instruments of real knowledge."

To the farmer, a careful study of the weather, and of the inferences to be drawn from precedent, and from natural and artificial data, come fraught with numerous and important considerations. Like the angler, the husbandman must observe the wind, sun, and clouds by day; the moon, stars, and waives of the air by night. Few are so entirely dependent on the caprice of the weather, for the commonest routine operations of the farm, as the agricul-
WEATHER.

Tourist. And how soon may his fairest crops be blighted by adverse and unfavourable seasons, or by the baneful effects of scorching and arid winds, of severe frosts, of heavy rains. Some winds come fraught with disease and death; murrain, stones, and the bee, which changes, will mild characters or, or the mysterious atmospheric agency: other winds bring swarms of noxious insects and predatory birds to our shores; the lightning and the whirlwind level his plantations or fire his ricks; the hail-storm, and the frost, and excess of rain, damage and destroy his growing crop, or that to which he has looked for reward and profit for all his toil and outlay.

The various casualties and diseases to which his crops are liable are frequently attributable to, and certainly much aided by, the state of the weather and conditions of the atmosphere. Information relative to many of the important phenomena connected with the atmospheric states and changes, will be found dispersed through this work under various heads, such as Atmosphere, Altitude, Barometer, Climate, Dew, Fogs, Frost, Hoar Frost, Lightning, Rain, Snow, Moon, Influence of, &c.

As means of prognosticating the future states of the weather, data, either natural, artificial, or both combined, are usually referred to. In the natural data are included those of—

1. The vegetable kingdom; many plants shutting or opening their flowers, contracting or expanding their parts, &c., on approaching changes in the humidity or temperature of the atmosphere.

2. The animal kingdom; most of those familiar to us exhibiting signs on approaching changes, of which those by cattle and sheep are more especially remarkable.

3. The mineral kingdom; stones, earths, metals, salt, and water of particular kinds, often affording indications of approaching changes.

4. Appearances of the atmosphere, the moon, the general character of seasons, &c. The shrinking or clouds, the prevalence of particular winds, and other signs, are very commonly attended to.

The artificial data are the various meteorological instruments, as the barometer, hygrometer, pluviometer, and thermometer, &c., which are all extremely useful aids to the farmer.

It is a very common error to predict the future state of the season from some single appearance in the commencement of it, as an early bee; an early bud or blossom, the premature appearance of a swallow; but this is both unphilosophical and fallacious.

In England a moist autumn, succeeded by a mild winter, is generally followed by a dry and cold spring, in consequence of which vegetation is greatly retarded. Should the summer be uncommonly wet, the succeeding winter will be severe; because the heat or warmth of the earth will be carried off by such unusual evaporation. Farther, wet summers are mostly attended with an increased quantity of fruit on the white-thorn. (Sorbus aucuparia) and dog-rose (Rosa canina); nay, the uncommon fruitfulness of these shrubs is considered as the presage of an intensely cold winter.

A severe winter is supposed to be indicated by the appearance of birds of passage at an early period in autumn; because they never migrate southward till the cold season has commenced in northern regions. Great storms, rains, or other violent commotions of the clouds, produce a kind of crisis in the atmosphere; so that they are attended with a regular succession either of fine or of bad weather for some months. An unproductive year mostly succeeds a rainy winter, as a rough and cold autumn prognosticates a severe winter. Very cold mouths or seasons are commonly followed immediately by very rainy ones, and cold summers are always wet ones.

Plants.—The sensitive indications afforded us by many plants first claim attention, and will be found amply to repay the time that may be bestowed upon the singular properties inherent to them.

Very many of our most common plants are unerring guides for the foretelling rain and other atmospheric changes. The opening and shutting of some flowers depends not so much on the action of the stimulus of light as on the existing state of the atmosphere, and hence their expansion or contraction betokens change.

The common chickweed or stitchwort (Stellaria media) may be considered a natural barometer; for if the small, white, upright flowers are closed, it is a certain sign of rain; while during the sun they expand freely, and are regularly open from nine in the morning till noon. After rain they become pendent, but in the course of a few days they again rise.

The purple sandwort ( Arenaria rubra) is another example of a true prophet prior to a coming shower. The beautiful pink flowers expand only during sunshine, and close at the approach of evening or before rain.

The pimpinell ( Anagallis arvensis) has been very justly named “the poor man's weather-glass.” This little plant blooms in June in our stubble-fields and gardens, and continues in flower all the summer. When its tiny brilliant red flowers are widely expanded in the morning, we may generally expect a fine day; on the contrary, it is a certain sign of rain when its delicate petals are closed.

The goat's-beard ( Tragopogon pratensis) will not unclose its flowers in cloudy weather. From its habit of closing its flowers at noon, this plant has received the common name of “Go-to-bed-at-noon,” and in many districts the farmers' boys regulate their dinner-hour by the closing of the goat's-beard.

It is stated in Keith's Botany, that if the Siberian sow-thistle shunts at night, the ensuing day will be fine; and if it opens, it will be cloudy and rainy.

When the African marigold remains closed after 7 o'clock in the morning or evening, rain may be expected. If the trefoil and the convolvulus contract their leaves, thunder and heavy rain may be expected. Lord Bacon tells us that the stalks of the trefoil swell and grow more upright previous to rain.
WEATHER.

The dark and lovely gentianella opens its blue eyes to greet the midday sun, but closes its petals against the shower.

The germander speedwell (Veronica chamaedrys), so universal a favourite in every hedge-row, closes its blue corolla before rain comes on, opening again when it ceases. The red campion (Lychnis dioica) uncloses its flowers in the morning. The flowers of the white campion (Lychnus alpinus) open and expand themselves towards the approach of night.

The wood sorrel (Oxalis acetosella, "la Petite Oxalis" of the French), a deli-cate, elegant little inhabitant of the moist, shaded bank, as soon as night approaches, as it is of too delicate a structure to bear the storm, closes up its curious triple leaves, hanging its flowers towards the earth, thus preserving the more tender parts from injury; but as soon as the morning sun arises, these expand and regain their beauty. Most of the Hieraciums, or hawkweed tribe, also open their flowers with the morning light, going to sleep again in the afternoon. The clear, bright, and gay flowers of the saxony (Cytherion viola) foretell the coming of the French rain. Among the components of Flora's clock, which deserves a passing word, is the common daisy (Ficaria verna), opening at sunrise, and closing its flowers at sunset: hence Chaucer called the "Eie of Day." The great white oxeye (Chrysanthemum leucanthemum), foretelling the coming storm, closes its flowers. The flowers of the alpine whitlow grass (Draba alpina), the bastard feverfew, the winter green (Trientalis europaea), all hang down in the night, as if the plants were asleep, lest rain or the moist air should injure the fertilizing pollen. The common nipplewort (Lapsana communis), that lovely gem, the white water-lily (Nymphaea alba, "the naiad of the river"), and several of the diadephous tribe of plants, in serene, calm weather expand their leaves in the day-time, and contract them during night.

Animals.—Among quadrupeds the following are believed to indicate, by their restlessness and peculiar actions, a foreknowledge of approaching changes of weather. When horses stretch forth their necks, neigh much, sniff the air with distended nostrils, and assemble in the corner of a field with their heads to leeward, rain may be expected.

Sheep are seen running to and fro, jumping from the ground, and in their gambols apparently fighting, previously to a change of weather. Fine weather may be expected to continue when cattle lie in the open field or in the courts instead of the sheds; when sheep take up their lair for the night on the brow of a knoll; when pigs lie down for the night without covering themselves up in litter. Bad weather is said to be prognosticated when asses hang their ears forward, or rub themselves against walls or trees. Swine also become uneasy, restless, grunting and squealing loudly, and return to their sties. Before rain pigs are apt to grow very sleepy and dull, and to lie all day before the fire, showing a reluctance to food, except grass. When cats lose their vivacity, remaining within doors, wet or windy weather may be expected. Finally, when rats and mice are more than usually restless, forsaking the fields and ditches, approaching rain may be anticipated.

Fallow deer, and many other animals, becoming restless from the uneasiness they feel owing to the altered condition of the atmosphere, prognosticate the approach of rain. If frogs croak more than usual—if toads issue from their retreats in great numbers—if earthworms come forth from their holes—if moles throw up the soil more than usual—if pigs shake and spoil the stalks of the corn—if oxen flick their tails—all these signs are said to indicate rain.

It may be remarked that, in summer, when sheep rise early in the morning, it is a sure sign of either rain or a very hot day; and that in all seasons when they jump and play about it is a sign of rain or wind (but generally both) in the summer, and very stormy weather in the winter.

In winter, when the sheep lie under a hedge, and seem both to go off to pasture, and bleat, it is considered a sign of a storm.

When rabbits come out to feed early in the evening, it is a sign of rain in the night in summer, and of either rain or snow in winter; and when it is likely to be a bad night, they will be apt to return to their burrows before it is dark.

Next, with respect to birds: there is an old saying that "when swans fly it is a sign of rough weather," and the correctness of this saying would appear to be proved. A late writer states that he had invariably found that when the swan flies any distance against the wind, however fine the weather may be at the time, so sure will a wind, almost amounting to a hurricane, arise within 24 and generally 12 hours after the bird has taken flight. The early appearance of woodcocks, snipes, field-fares, and other birds of passage, &c., are prognostics of severe winters. When owls hoot and screech during bad weather, it is a sign of coming fine weather. The misselite thrush (Turdus viscivorus) frequently sings particularly long and loud before rain, and sometimes even during severe storms: hence it is termed the "storm-cock." The blue macaw is said to be a true indicator of the changes of the weather. Dr. Thornton is stated to have had one some years ago whose blue feathers assumed a greenish hue in rainy weather, or gray in clear weather, if likely to change for wet.

When owls fly exceedingly high, in silence, and ranged in order, it is said to indicate fine weather; but if their flight is in disorder, and they speedily return with cries, it foretells wind. If owls roll themselves in the sand more than usual, it denotes rain; also when the cocks crow in the evening, or at unusual hours. When peacocks cry at night, rain may shortly be expected. When peacocks roost on the tops of houses, when the raven sails round and round high up in the air, and when the song-birds carol late in the evening, the weather will continue fair.

The croaking of crows is said to indicate fine weather. When ducks and geese fly backwards and forwards, and frequently plunge into the water, or send forth cries; or when pigeons return slowly to their houses, the probability
WEATHER.

is that the succeeding day will be rainy. It is a sign of rain or wind when sparrows chirp a great deal; if the redbreast be seen near houses; or swallows fly near the ground, or brush the surface of the water. When sea-fowl and other aquatic birds retire to the sea-shore, or more inland, it generally indicates a change of weather. If larks or kites soar high and continue so for some time, it is generally a sign of fine weather. If the kingfisher disappear, expect fine weather. If swallows and martins fly lower than usual, foul weather may be expected.

Mr. Yarrell, in his History of British Birds, vol. iii. p. 117, records an instance of instinct, showing how useful an attention to the movements of animals, &c. might occasionally prove:—"I am indebted to the kindness of Lord Braybrooke for the following account of a female swan, on the small stream at Bishop's Stockford. This swan was 18 or 19 years old, had brought up many broods, and was highly valued by the neighbours. She exhibited, some 8 or 9 years past, one of the most remarkable instances of the power of instinct that was ever recorded. She was sitting on four or five eggs, and was observed to be very busy in collecting grass, weeds, &c., to raise her nest; a farming man was ordered to take down half a load of haulm straw, with which she most industriously raised her nest and the eggs 2½ feet; that very night there came down a tremendous fall of rain, which flooded all the malts, and did great damage; but she made no preparation; the bird did. Instinct prevailed over reason; her eggs were above, and only just above, the water."

The same author, in his account of the green woodpecker (Picus viridis), known in some localities as the "rain-bird," from being very vociferous when rain is impending, alludes to the probable means by which birds and some other animals become cognisant of approaching changes in the weather. The following is the rationale referred to:—

"It is highly probable that no change takes place in the weather without some previous alteration in the electrical condition of the atmosphere, and we can easily understand the birds, entirely covered as they are with feathers, which are known to be readily affected with electricity, should be susceptible of certain impressions, which are indicated by peculiar actions; thus, birds and other animals, covered only with the production of their highly sensible skin, become living barometers to good observers." (Yarrell's British Birds, vol. ii. p. 136.)

Insects, being very sensible of every change in the atmosphere, are good weather guides. When gnats collect themselves before the setting sun, and form a sort of vortex in the shape of a column, it announces fine weather. If they play up and down in the open air near sunset, they presage heat; if in the shade, mild and warm showers; but if they sting those passing them, cold weather and much rain may be expected.

If garden spiders break off and destroy their webs, and creep away, expect continued rain and showery weather.

If spider webs (gossamer) fly in the autumn, expect fine weather.

The following curious observations on the singular foreknowledge possessed by the spider are extracted from a little work entitled The Pocket Barometer. This despised insect oftentimes indicates a coming change in the weather 10, 12, or 14 days previous to its taking place. The following directions will be a guide to the curious in their observations of this insect:—

If the weather is likely to become rainy, or windy, spiders fix the terminating filaments on which the whole web is suspended unusually short. If the terminating filaments, on the contrary, are very long, the weather will be serene, and continue so for 14 days. If spiders be totally indolent, rain generally ensues; though their activity during rain is a certain proof of its short duration, and that it will be followed by fine and settled weather. Spiders usually make some alteration in their webs every 24 hours. If this take place between the hours of 6 and 7 p. m., it foretells a clear and serene night.

The weather is about to become cloudy and change for wet, when flies sting and are more troublesome than usual. Most insects become torpid when their temperature is much reduced. When it approaches the freezing point, they fall into a lethargic state, and require no food. Ants present a remarkable exception to this rule; for they are not benumbed till the thermometer is 27° of Fahr., or 5° below freezing point. When bees do not range abroad as usual, but keep in or about their hives, it is a sign of rain.

In the summer season much information relative to the change of the weather may be gained from watching the movements of ants. The finer the day, the more busily are they employed, as they never bring out their corn to dry but when the weather is clear and the sun very hot. A celebrated naturalist relates the following curious anecdote:—He one day observed these little creatures, after having brought out their corn at eleven in the forenoon, removing the same, contrary to their usual custom, before one in the afternoon. The sun being now warm, and the sky remarkably clear, he could perceive no reason for it; but half an hour after, his surprise ceased—the sky began to be overcast, and there fell a shower of rain, which caused all this bustle, no doubt, among these active little creatures: they evidently foresaw rain, and provided accordingly; and were we minutely to examine into the economy and management of these wonderful artificers, many other similar and equally curious facts might be gleaned relative to the weather.

The leech also possesses the peculiar property of indicating approaching changes of the weather in a most eminent degree. In fair and frosty weather it remains motionless and rolled up in a spiral form at the bottom of the vessel; previous, however, to rain or snow, it will creep to the top, where, should the rain be heavy, or of long continuance, it will remain for a considerable time,—if transient, it will descend. Should the rain or snow be accompanied with wind, it will dart about with great velocity, and seldom cease its evolutions until it blows hard. If a storm of thunder or lightning be approaching, it will be exceedingly
WEATHER.

agitated, and express its feelings in violent convulsive starts at the top of the glass. It is remarkable, that however fine and serene the weather may be, and to our senses no indication of a coming change, either from the sky, the barometer, or any other cause, yet, if the leech shifts its position, or moves about sluggishlIy, the coincident results will undoubtedly occur within 26 hours.

Signs of Rain.—Although we have incidentally glanced already at some of these indications, it may be well to sum them up in a body, as being more easy of reference.

A white mist in the evening over a meadow or a river dispersed by the sun next morning, indicates that the day will be bright. Five or six fogs, successively, portend rain. Where there are high hills, and the mist which hangs over the lower land draws toward the hills in the morning, and rolls up to the top, it will be fair; but if the mist hangs upon the hills, and drags along the woods, there will be rain soon. A general mist before the sun rises is a sign of fair weather.

If it rains, the clouds grow bigger and increase very fast, especially before thunder. When the clouds are formed like fleeces, but dense in the middle, bright towards the edge, with the sky bright, they are signs of a frost, with hail, snow, or rain. If clouds breed high in the air, in the white train like locks of wool, they portend wind, and probably rain. When a general cloudiness covers the sky, and small black fragments of clouds fly underneath, they are sure signs of rain, and probably it will be lasting. Two currents of clouds generally portend rain, and in summer thunder.

If the dew lies plentifully on the grass after a fair day, it is a sign of another fine day. If not, and there is no wind, rain will follow. A red evening portends fair weather; but if spread too far upward from the horizon in the evening, and especially morning, it foretells wind or rain, or both. When the sky in rainy weather is tinged with sea-green, the rain will increase; if deep blue, it will be showery.

If there be a haziness in the air, which fades the sun's light, and makes the orb appear whitish or ill-defined; or at night, if the moon and stars grow dim, and a ring encircles the former, rain must follow. If the sun appears white at setting, or goes down into a bank of clouds in the horizon, bad weather is expected. If the moon looks pale and dim, we expect rain; if red, wind; and if the natural colour, with a clear sky, fair weather. If the setting sun appears yellow or gold colour, and particularly if accompanied with purple streaks, the following day will be fine.

If the wind veers about much, rain is pretty sure. If, in changing, it follows the course of the sun, it brings fair weather; the contrary, foul. Whistling or howling of the wind is a sure sign of rain.

The aurora borealis, after warm days, is generally succeeded by cooler air. Shooting stars are supposed to indicate wind.

Before rain, swallows fly low; dogs grow sleepy and eat grass; waterfowls dive much; fish will not bite; flies are more troublesome; toads crawl about; moles, ants, bees, and many insects, are very busy; birds fly low for insects; wine, sheep, and cattle are uneasy, and even the human body.

"The air, when dry, I believe, refraets more red or heat-making rays; and as dry air is not perfectly transparent, they are again reflected in the horizon. I have generally observed a coppery or yellow sunset to foretell rain; but, as an indication of wet weather approaching, nothing is more certain than a halo round the moon, which is produced by the precipitated water; and the larger the circle, the nearer the clouds, and consequently the more ready to fall." (Sir H. Davy.)

To turn now to the atmosphere: the bulk of our most valuable meteorological observations are, of course, deducible from its electrical condition, and the precise kind of electricity present; from the power of evaporation exercised, from the state and direction of the wind, from a careful examination of the clouds; in fact, the phenomena of the atmosphere are wellnigh endless. But, though endless in the variety of forms and consequences, and for the most part uncertain in the time of their occurrence, yet they are successively the same in their nature to parts and properties, and are all the production of simple causes. The principal agents in producing these phenomena have already been noticed under the head Meteorology. I need not enlarge further upon the advantages to science in general derivable from the accurate and careful investigation of meteorological researches, aided by the excellent instruments that are now attainable, and at a moderate expense. From the accumulation of a multitude of such facts can we alone hope at some future time to derive that accurate knowledge and insight into the secret springs that would appear to be the movers of these phenomena. This may not be too much to effect from the analogies of the seasons and the results of experience; and this, we may venture to predict, will be the crowning reward of meteorological research. (Trans. of Met. Soc. vol. i. 1839.) See Moon, Influence of Clouds.—The following definition of the descriptive terms now employed by meteorologists to define various clouds, may prove useful to those in the habit of consulting meteorological registers, which are occasionally published in newspapers and scientific journals. It is taken from Ure's Chemical and Miner. Diet., article "Cloud," p. 338.

A cloud is a mass of vapour, more or less opaque, formed and sustained at considerable heights in the atmosphere, probably by the joint agencies of heat and electricity. The first successful attempt to arrange the diversified forms of clouds, under a few general modifications, was made by Luke Howard, Esq. We shall here give a brief account of his ingenious classification.

The simple modifications are thus named and defined—1. Cirrus: parallel, flexuous, or diverging fibres, extensible in any or in all directions. 2. Cumulus: convex or conical heaps, increasing upwards from a horizontal base. 3. Stratus: a widely extended, continuous horizontal sheet, increasing from below.
The intermediate modifications which require to be noticed are—4. Cirro-cumulus; small, well-defined, roundish masses, in close horizontal arrangement. 5. Cirro-stratus; horizontal or slightly inclined masses, attenuated towards a part or the whole of their circumference, bent downward, or undulated, separate or in groups, consisting of small clouds having these characters.

The compound modifications are—6. Cumulo-stratus; the cirro-stratus blended with the cumulus, and either appearing intermixed with the heaps of the latter, or superadding a wide sheet to its base. 7. Cumulonimbus-stratus, vel Nimbus; the rain cloud, a cloud or system of clouds from which rain is falling; it is a horizontal sheet, above which the cirrus spreads, while the cumulus enters it laterally and from beneath.

The cirrus appears to have the least density, the greater variety of extent and direction, and to appear earliest, in serene weather, being indicated by a few threads pencilled in the sky. Before storms they appear lower and denser, and usually in the quarter opposite to that from which the storm arises. Steady high winds are always preceded and attended by cirrus streaks running quite across the sky in the direction they blow in.

The cumulus has the densest structure, is formed in the lowest atmosphere, and moves along with the current next the earth; a small irregular spot first appears, and as it were the nucleus on which they increase. The lower surface continues irregularly plain, while the upper rises into conical or hemispherical heaps, which may afterwards continue long nearly of the same bulk, or rapidly rise into mountains; they will begin in fair weather to form some hours after sunrise, arrive at their maximum in the hottest part of the afternoon, then go on diminishing, and totally disperse about sunset. Previous to rain the cumulus increases rapidly, appears lower in the atmosphere, and with its surface full of loose fleeces or protuberances. The formation of large cumuli to leeward in a strong wind indicates the approach of a calm with rain; when they do not disappear or subside about sunset, but continue to rise, thunder is to be expected in the night. The stratus has a mean degree of density, and is the lowest of clouds, its inferior surface commonly resting on the earth or water. This is properly the cloud of nights and the morning after sunset. It comprehends all those creeping mists which in calm weather ascend in spreading sheets (like an inundation of water) from the bottom of valleys and the surfaces of lakes and rivers. On the return of the sun the level surface of this cloud begins to put on the appearance of cumulus, the whole at the same time separating from the ground. The continuity is next destroyed, and the cloud ascends and evaporates, or passes off with the appearance of nascent cumulus. This has long been experienced as a prognostic of fair weather. The cirrus having continued for some time increasing or stationary, usually passes either to the cirro-cumulus or the cirro-stratus, at the same time descending to a lower station in the atmosphere. This modification forms a very beautiful sky, and is frequent in summer, as an attendant on warm and dry weather. The cirro-stratus, when seen in the distance, frequently gives the idea of shoals of fish (a mackerel sky). It precedes wind and rain; is seen in the intervals of storms, and sometimes alternately with the cirro-cumulus in the same cloud, when the different evolutions form a curious spectacle. A judgment may be formed of the weather likely to ensue, by observing which modification prevails at last. The solar and lunar halos, as well as the parhelion and parasecline (mock sun and mock moon), prognostics of foul weather, are occasioned by this cloud. The cumulo-stratus precedes, and the nimbus accompanies rain.

When there are small round clouds, of a dapple-gray colour, with a north wind, it may be concluded that there will be fair weather for 2 or 3 days, but that large clouds like rocks are a sign of great showers. And when small clouds increase, it is a sign that there will be much rain, but if the large clouds are seen to lessen, there will be fair weather.

In summer or harvest, when the wind has been south 5 or 3 days, and it grows very hot, and clouds are seen to rise, they will appear tops like towers, as if one were on the top of another, and joined together with black on the lower side, it may be considered a sign that there will be thunder and rain suddenly. When two such clouds rise, one on each hand, it is time to make haste to shelter.

When a cloud is seen to rise against the wind or side wind, it is a sure sign that when the cloud comes up near you, the wind will blow the way that the cloud came. It is the same with the motion of a clear place, when all the sky is thick except one edge.

At all times, when the clouds look black in the west, it is sure to rain, or if raining, it is sure to continue, whatever quarter the wind may be in; and, on the contrary, if it breaks in the west, it is sure to be fair.

It is often observed, on those clear sunny mornings which occur in summer and autumn, that it is very likely, if not certain, to rain before evening; and there is frequently much truth in the remark. The reason is, that when moisture accumulates in the air, before it begins to be precipitated, it imparts to it a higher refractive power; and it becomes, in consequence, more bright and transparent. (British Almanac, 1830.)

The gradual diminution of clouds, till they are no longer observable, is a sign also of fine weather. So, likewise, is the continuance or abundance of dew upon the grass, after a serene day.

During winter, fleecy clouds being thick and close in the middle, and very white at the edges, the surrounding sky being remarkably blue, indicate hail or snow, or cold, chilling, showers of rain.

Where the clouds appear moving in two opposite currents, and the lowest is wafted rapidly before the wind, it is a certain sign of rain; and if this occurs during summer, or generally in hot weather, it announces a thunder-storm. It may be a useful piece of information for agriculturists, or those concerned in getting in
their crops, to describe the appearance of a small cloud, which, from its rapid formation and disappearance, is likely to escape the observation of most persons, but which, from my own experience, I have found a very faithful forerunner of foul weather. It appears mostly in the mild weather of spring, summer, and autumn, when its warning token becomes most acceptable. It is a small, delicately soft, thin, white, curved cloud, formed suddenly upon the summit of those bunched clouds (termed cumuli) which often prevail in warm weather, and appear to tower up to a prodigious height. It is necessary to keep a watchful eye upon the summit of the cumulus. When this little film, which I term "the storm cap," appears, it lies closely over the rounded summit, like a white silken web; in a very few seconds it will disappear, sinking, I suppose, into the cumulus; but in a little time, and when heavy foul weather threatens, the film again appears, disappearing as shortly as before. (Mag. Nat. Hist., vol. iv. 441.)

The following indications have been recorded, as shown by the predominance of certain of the prismatic colours of the rainbow, but they are perhaps too fanciful to be deserving of much credence.—1. Red; if this colour be very predominant, wind, or wind and rain, may be expected. 2. Orange; when the orange colour appears strong and very full, it generally indicates approaching rain. 3. Yellow; when yellow is more conspicuous than the other colours, it foretells dry weather. 4. Green; approaching rain may be expected when the green is very predominant. 5. Blue; fine weather is expected when the blue is particularly full. 6. Purple; if the purple be a very full colour, wind and rain may be expected. 7. Violet; the violet, when very clear, generally indicates approaching fine weather. See Rainbow.

The Wind.—The earth is surrounded to the extent of 60 miles with an atmosphere, on which all nature mutually depends for life. This aerial ocean revolves with our earth round the sun, is very susceptible of motion, and some parts of it is constantly in restless commotion. These commotions are called winds, and are principally caused by heat from the rays of the sun, which, rarefying the air, causes it to ascend; and the vacuum thus formed is filled up with a colder air from the north and south. Wind has been explained in the following manner:—Heated air has a tendency to rise, and cold air rushes into its place. Thus the heated air of the equatorial regions rises and gives place to a current sent from the polar regions, which is a process that serves to equalize the temperature of the world. But the polar countries lying near to the axis of the sphere, the air from those regions has not received so much motion as that about the equator, or greatest distance from the axis, wherefore it arrives at the equator, where the motion of the earth is greater. If it had no motion before, an east wind would be the consequence, and the force of that wind would be as the difference between the motion of the earth where the air came from, and that where it arrived: but then, in the northern hemisphere, it has a motion to the south; for it is rushing into a vacuum left by the air which rises; so that the wind will not be from the east, but northeast; and the number of degrees north of the east from which it will blow will depend upon the comparative force of the current of air from the north to the difference between the earth's motion at the equator and at the polar region, whence the air comes. As there must be a corresponding efflux from the equator higher up, according to this theory the wind should everywhere be northeast or southwest, but it blows in very different directions at different times and places, owing chiefly to circumstances connected with the distribution of land and water, and the variations in temperature at different times and places.

From observing the wind a fair idea of the coming weather may oftentimes be drawn; and yet, as Solomon observes, "he that considers the wind shall never sow;" that is, he that busies himself too much about the wind will become a weary philosopher. These canons be drawn from observing the direction and changes of the wind must vary in different countries, according to the relative positions of these in regard to the sea, lakes, plains, or mountains covered with snow. For an explanation of some of the phenomena of climate and weather, the reader is referred to preceding articles, under the heads of Barometer, Climate of the United States, &c.

In all countries, therefore, particular winds are noted for being accompanied with either wet or dry weather. Thus the south and southwest winds bring much moisture into Britain; while those from the north and northeast are cold, dry, and penetrating. Hence the old English proverb—

"When the wind's in the south, It's in the rain's mouth."

Not only does this arise from the immense surface of ocean over which these winds sweep south of the equator, the evaporation from which must be prodigious; but from these southerly winds being of a higher temperature, whereby they hold a greater quantity of vapour in suspension or solution, the condensation of which must be proportionally greater on arriving in this colder climate. Accordingly, it has been observed that the wind will turn from the north to the south quietly and without rain; but on returning from the south to the north, will blow hard and bring much rain. Again, if it begin to rain from the south, with a high wind for 2 or 3 hours, the wind falls; but if the rain continues, it is likely to rain for 12 hours or more, and does usually rain until a strong north wind clears the air. For the same reason, winds from the west and southwest are in England considered to bring with them wet weather. (Chambers' Information for the People, No. 58, New Series) be a corrupt "Clouds in the atmosphere.

A change in the warmth of the weather is often followed by a change in the wind. Thus, the northerly and southerly winds, though commonly accounted the causes of cold and warm weather, are really the effects of the cold or warmth of the atmosphere.
Mr. Towers (Quart. Jour. of Agr. vol. ix. p. 39) relates the case of a person in Somersetshire who had been haymaking nearly 40 years, and had hardly in one instance failed to carry in good condition. He had observed that in the month of June, earlier or later, there are three or more days wherein the wind blows from the northeast, and that this wind is very inveterately dry. When this wind first occurred, he seized the opportunity of cutting his grass and carrying the crop before the wind veered to the south. This theory holds good as respects the southwestern counties, where the wind from any quarter between north and east is the sure concomitant of dry weather.

The following predictions of the weather are met with in the Holy Scriptures; and, applying with equal correctness in the present day as at the time they were written, I subjoin them:—

A south wind, or great heat in summer, portends a whirlwind. (Job xxxxi. 9.) Cold or fair weather is indicated by the north wind, which drives away rain. (Job. xxxvii. 9, 22.) A red sky in the evening foretells fair weather; in the morning, foul. "When it is evening ye say, It will be fair weather, for the sky is red. And in the morning, It will be foul weather today, for the sky is red and lowering." (Matt. xvi. 2, 3.) "When ye see a cloud rise out of the west, straightway ye say, There cometh a shower; and so it is. And when ye see the south wind blow, ye say, There will be heat; and it cometh to pass." (Luke, xii. 54, 55.)

It results from observations made by Mr. Schow, that in the north of Europe the western winds are more frequent than the eastern. This rule is without exception; but the western winds diminish more and more as we approach the centre of the Continent, being more frequent in England, Holland, and France than in Denmark and the greater part of Germany; and more frequent in these latter countries than in Russia and Sweden. At London, the east wind is to the west as 1 to 1.7; at Amsterdam, as 1 to 1.6; at Copenhagen, as 1 to 1.5; at Stockholm, as 1 to 1.4; at Petersburg, as 1 to 1.3. The south winds seem to incline the more to the south according to the propinquity of the Atlantic sea; towards the interior of the Continent they incline more to the northwest. The north winds appear to increase towards the east. Amongst the winds which come from the west, that of the southwest predominates in England, Holland, and France; that of direct west in Denmark and the greater part of Germany; at Moscow the northwest predominates; at Petersburg and Stockholm the north wind is much more frequent than in the western parts of Europe. In the western and middle districts of northern Europe, such as England, France, Denmark, Germany, and Norway, the west winds are much more frequent during the summer than during the winter or spring. This does not appear to be the case in Sweden and Russia. During the winter the west winds are more southerly; during the summer more direct and more northerly. (Jahrb. der Phys. und Chem. 1828.)

With regard to the supposed influence of the moon upon the conditions of the weather, and the strong evidences to prove that this satellite exerts no influence in controlling the atmosphere, so far as wet and dry weather are concerned, see Moon, Influence of.

Under the head of Barometer it has been observed that changes of weather are indicated, not by the actual height of the mercury, but by its changes of height. One of the most general, though not absolutely variable, rules, is, that where the mercury is very low, and, therefore, the atmosphere very light, high winds and storms may be expected.

In winter the rising of the barometer presages frost; and in frosty weather, if it falls three or four divisions, there will follow a thaw; but if it rises in a continued frost, snow may be expected.

The mercury generally rises very fast after great storms of wind, when before it was very low. In England it has been observed to rise an inch and a half in six hours, after a long-continued storm of southwest wind.

The words on the plate of a barometer are not strictly to be adhered to, though they will in general agree; for a fluctuating and unsettled state of the mercurial column indicates uncertain or changeable weather. The height of the mercury does not so much indicate the weather as its motion up and down: to know, therefore, whether the mercury is actually rising or falling, observe—

1st. If the surface of the mercury is convex (or stands high in the middle), it is then rising.

2d. If the surface of the mercury is concave (standing low in the middle), it is then falling.

3d. If the surface is plain, or a little convex, it may be considered as stationary.

4th. A small tap on the barometer case, by shaking the tube will sometimes bring the mercury to its approaching height.

The greatest heights of the mercury are on easterly and northeasterly winds; and its lowest station on southerly winds.

If the weather is about to be cold, frosty, or foggy, it rises pretty high; but if going to be windy or tempestuous, it will then sink very low, and, as soon as the first storm is over, it will rise again, appeasing the storm. The barometer is in a vestibule. No corrections of any kind have been made in registering the barometer. (Johnson's and Shaw's Farmer's Almanac, vol. i. p. 157.)
Weeds and troublesome Plants
Tables calculated from Atmospheric Observations, made in the Parish of Coham, Surrey, England, during the Eight Years from 1833 to 1840.

Tables showing the mean temperature in most sections of the United States, and also at many noted places in Europe and Asia, will be found under the heads of Atmosphere and Climate.

**WEEDS.**

A weed has been aptly defined "a plant out of place." The clearing of all kinds of crops, and keeping them free from weeds, is an essential part of cultivation: if this be omitted, neglected, or but partially performed, a portion of the crop will be lost, in proportion to the prevalence of such weeds, from defective preparation or partial extirpation. The nourishment drawn from the ground by the roots of all vegetables being somewhat similar, where that has been obtained that bees have not thriven so well in England, since the extinction of weeds has been more attended to. In China and Japan, it is said, not a weed is to be seen, and that they only make use of night-soil as a manure, partly with a view of preventing any rise of weeds.

Weeds, like all other vegetables, may be distinguished into annuals, biennials, and perennials, according to their term of duration.

Annuals are those which continue only one year, the plants dying after perfecting their seeds: these are generally very prolific in seed. Biennials are those which continue two years, and die after perfecting their seed: these also produce an abundance of seed. Perennials are those which continue many years: some of these perfect their seeds every year, and others, being very tenacious of growth by their roots, and having the faculty of reproducing themselves in this way, are less prolific in seeds; but many of them increase both by seeds and roots.

The weeds of agriculture are very numerous, but by far the greater part are underlings, and...
are little noticed; these are comparatively innocent, and a very great portion of them have no local or common names. Mr. William Pitt, in his essay On the Extirpation of Weeds (Com. to Board of Agr., vol. v. p. 233), enumerates 55 weeds, and the list might have been greatly extended; but few farmers, whose knowledge is bounded by the soils they respectively cultivate, and whose hands are occupied with more than a dozen to twenty; that is, four or five which trouble them in their fallows; four or five, the seeds of which infest their samples of corn; and a few besides, which are locally prevailing and obtrusive, but (as seems to have been too generally considered) not very harmful.

The fact was, that, before the improved agriculture became so generally known, those weeds which did not hurt the samples the farmers cared little about; not considering how much they hurt the crops: and hence it has been, that on the different soils corn poppy, charlock, blue-bottles, corn marigold, Mayweed, and dandelion were suffered.

The weeds of agriculture may be divided into, 1. Those which infest samples of corn; 2. Rooted or fallow weeds, and such others as are hard to destroy; 3. Those which are principally objectionable as they encumber the soil; 4. Underling weeds, such as never rise with the crop or come into the sickle. Under their respective heads, in alphabetical order, we have already treated of the deteriorating qualities and mode of destruction of each weed; but, following the above arrangement, we shall classify them, and add such further remarks as may be required.

1. Weeds which infest Samples of Corn.—In England the weeds of this description do not exceed ten in number, and it very rarely happens that more than two sorts are found associated in one sample of wheat. They vary as to soil so much, that some of the worst weeds in fens and marshes are not known at all on clay, cold soils, and are but very little seen on any sort of dry turnip land. Light loams and deep, loose soils generally have most weeds by nature. The weeds which infest the sample are, darnel, cheat, or chess (Bromus secalinus and mollis), cockle (Agrostemma Githago), tares (Crepis trachyspermum and hispanum), mellow (Melhota officinalis), wild oats (Avena fatus), hariff (Galium aparine), crow-weeds, or shepherd's needle (Senecio pecten Veneris), black bindweed (Polygonum persiculums), annual snake-weed (Polygonum lapathifolium), and charlock seeds in barley sometimes.

Of these ten weeds, whose seeds infest samples of corn, five are principally injurious to wheat; the others are partial, and more common in barley and oats.

2. On Fallow Weeds.—The objects of a fallow are, and always were, first, to eradicate root weeds, and cleanse and open the soil to the fibres of future crops; second, to pulverize and break down the texture of clay soils, and mix them with manure, in order to bring the land periodically, into a mild and fertile condition. Seeding weeds are destroyed incidentally; and good fallows, with good seasons, kill a great many, though it be not the object of fallowing.

The English fallow weeds are principally the following: couch, including Triticum repens, Agrostis repens, Holcus mollis, and Poa pratensis, rest-harrow (Ononis arvensis), saw-wort, the common way-thistle, or pasture-thistle (Carduus arvensis), curled dock (Rumex crispus), tall oat-like softgrass (Holcus arvensis), colt's foot (Tussilago Farfara), corn bindweed (Convolvulus arvensis), cow-wheat (Melampyrum arvensis), surface-witch (Agrostis stolonifera angustifolia), black foxtail-grass (Alopecurus agrestis), common knot-grass (Polygonum aviculare), wild carrot (Daucus Carota), hedge parsley, or dill (Torilis infesta), common foot's parsley (Echium Plantagineum), spangled or fennel (Mnnia Funiculata).

3. Weeds which are principally objectionable as they encumber the Soil, or whose Roots are annual, and whose Seeds pass the Corn-sieve.—Of this class of weeds, the following deserve particular notice: charlock (several species), corn poppy (Papaver Rhoeas), blue-bottle (Centaurae Cyanus), tansy (Tanacetum vulgare), dandelion (Taraxacum officinale), corn marigold (Chrysanthemum segetum).

To extirpate these weeds, clean corn-seed must be used, not a single plant of these weeds must be suffered to perfect seed in the hedge-rows, and a judicious rotation of crops adopted, so as to admit of the unsparing use of the horse-hoe, as well as of the hand, in weeding; by which means these noxious and disgraceful pests of corn-fields will be overcome, and banished from the soil.

The corn-poppy particularly accumulates upon gravelly soils of low quality, also on dry sandy soils, and generally on all dry and shallow lands which are overcropped and neglected. But much better soils, as loamy gravel, &c., are infested with it; only here the crops are generally good enough to keep it under, and being less abundant, it is much easier subdued by weeding. But the corn poppy is never so triumphant as in a hot and dry season, in which case many fields, which should have been corn, are wholly covered with it. One of three things must be done by way of remedy: 1st, the soil must be plowed or harrowed; 2d, or it must be fed with much larger quantities of farm-yard dung or compost; 3d, if neither of these be easily practicable, the rotation must be changed.

4. Of the Weeds called Underlings, or such as never rise in the Crop, nor come into the Sickle.—These are groundsel or Sisson (Senecio vulgaris), annual meadow-grass (Poa annua), chickweed (Stellaria media), shepherd's purse (Thaspia Lusoria pastoris), spurry (Spergula arvensis), camomile feverfew (Matricaria Chamomilla), fat hen or wild spinach (Chenopodium album), corn salad, or lamb's lettuce (Folia olibaria), fiddixweed (Styospermum Sphoia), common humillory (Bumaria officinalis), and sand mustard (Sinapis sexualis).

Land may be rendered inert or unfertile from an excess of manure, as well as from the want of it; severe and avaricious cropping, long persevered in, being understood in both cases. Over-stimulus, as in the first instance, wears out, or renders inert, the principle of fertility in the land; and, in the latter instance, the want of stimulus produces the same effect.
The underling weeds, above mentioned, flourish and prosper under this state of the land, brought on by either cause. The remedy is therefore obvious, viz., rest, or a clear-out summer follow; and if in the first mentioned case (which is to be met with in deep and poor staple of the soil, then a full application of manure, or marl and manure, the latter consisting as much as possible of cow-dung, should be given, and the land sown down with the superior pasture-grasses and clovers, to remain for not less than five years. In the latter case, or when the fertility of the soil is worn out by injudicious cropping, and a greedily supply of manure, is given to the naturally thin and poor staple of the soil, then a substituted supply of manure, or marl and manure, the latter consisting as much as possible of cow-dung, should be given, and the land sown down with the superior pasture-grasses and clovers, to remain for not less than five years.

5. Pasture Weeds.—Some farmers seem to suppose that if they keep the weeds subdued in the growing crops, they have performed wonders (and too many have reason to congratulate themselves if they do this), while all kinds of nuisances in the shape of weeds will disappear from their pastures. But thistles, milkweed, everlasting, John’s-wort, sweet elder, &c., flourish undisturbed, and fill the earth with seeds or roots in readiness to spread and grow whenever the earth is moved for their reception. Any plant not wanted on a farm, or not required in course of cultivation, should never be allowed to perfect its seeds on any part of it; if they are, the farmer will find, to his sorrow, that he has suffered an enemy to steal a march upon him, one which it may require much time and labour to subdue. Allow, then, nothing to go to seed on your farm, for you do not mean to cultivate; dig them up root and branch, or, if this is not practicable, take your scythe and cut them at once.

The following weeds are more frequently found to infect dry, sandy pastures, and calcareous soils, than loamy or damp grass lands. Dwarf-thistle (Carduus arvensis), common camomile (Asthenium nobilis), ox-eye daisy (Chrysanthemum leucanthemum), great l Heinan (Ploughman’s spikenard (Coryza squarrosa), cheese refining, or yellow ladies’ bedstraw (Galium verum), long rooted hawk-weed, wild thyme (Thymus serpyllum), sheep’s sorrel (Rumex Acetosella), knot-grass, or snake-weed (Polygonum aviculare), yellow rattle (Rhinanthus cristagalli), common Cardine thistle (Corina vulgaris).

Where these are found to prevail to a great extent, there is no remedy like breaking up the land and taking a course of crops, for palliative remedies are of little avail. The thistles, sheep’s sorrel, and knot-grass, are the most formidable. Hand-weeding, when the weeds are confined to local spots, and are only just beginning to spread generally over the land, will be found effectual; but when once the pasture becomes generally infected with the seeds and roots of these plants, no time shall be lost in using the plough, harrow, and horse-hoe, and a judicious course of cleansing crops, before returning the land again to permanent pasture.

The pasture weeds which generally prevail in loamy soils, and such as are prevalent in clayey and damp soils, are principally as follows:—yellow goat’s beard (Tragopogon pratensis), marsh, or red thistle (Carduus palustris), melancholy plume-thistle (Carduus heterophyllum), meadow plume-thistle (Carduus pratensis), common butter-burr (Tussilago Patens), ragwort (Senecio Jacobeus), common daisy (Bellis perennis), black knapweed, or matfellow (Centaurea nigra), broad-leaved dock (Rumex obtusifolius); several species of orchis, common cow parsnip, or hog-weed (Heracleum Spikndifolium), and sedge (Cen.

The means to be adopted for the extirpation of these noxious weeds in pastures must be regulated by the nature of the soil and the comparative prevalence of the weeds. In good pasture land, where, from accident or neglect, these weeds, in part or wholly, have insinuated themselves, hand-weeding may most advantageously be had recourse to; and particularly for the larger weeds, such as thistles, rag-weed, docks, and knapweed, it will be found the best temporary remedy. Should the coarseness of the pasture have been occasioned by too frequent haying, or the land being closely sown, with a good top-dressing of dung compost applied in the early part of the spring, or late in the autumn, with strict attention to hand-weeding, will be found effectual to recover the pasture and extirpate the weeds. Frequent top-dressings are of the greatest use in effecting the above improvements on deteriorated thin pasture lands, as regards the destruction of weeds, as well as of improving the quality of the pasture. When the sedges, marsh-thistle, pestilent wort, &c., prevail in meadows, then recourse must be had to other means than that of hand-weeding, viz., draining, paring and burning, liming, and a judicious rotation of crops under the horse-hoe husbandry, until every vestige of the seeds and roots of these noxious weeds disappear. The ground may then be laid down to permanent pasture, with the seeds of the most valuable species adapted to the soil, and, where water can be commanded, converted to water meadow, by which the value of the land will be considerably increased. (Hollick’s Weeds; Pitt’s Essays on Weeds.) See Canada Thistle, Charlock, Couch, &c. &c.

WEEViLS. In the winged state, the insects thus called are hard-shelled beetles, which, says Dr. Harris, are distinguished from other insects by having the forepart of the head prolonged into a broad muzzle or a longer and more slender snout, in the end of which the opening of the mouth and the small horns jaws are placed. The flies and moths produced from certain young insects, called weevils by mistake, do not possess these characters, and their larvae or young differ essentially from those of the true weevils. The latter belong to a group called Rhynchophoridae, literally, snout-bearers.

Among insects of this class is the Pales weevil, Curculio (Hylobius) Pales. See Pl. 16, 6. This is a beetle of a deep chestnut-brown colour, having a line and a few dots of a yellowish-white colour on the thorax, and many small yellowish white spots sprinkled over the wing-covers. All the thighs are toothed beneath.
WEIGHTS AND MEASURES.

and the snout is slender, cylindrical, inclined, and nearly as long as the thorax. On account of the length of the snout this insect has been placed in the genus Rhyynchus by some naturalists; but the antennae are implanted before the middle of the snout, and not far from the sides of the mouth. This beetle mealies from two to three-eighths of an inch in length, exclusive of the snout. It may be found in great abundance, in May and June, on boardfences, the sides of new wooden buildings, and on the trunks of pine trees. I have discovered them, in considerable numbers, under the bark of the pitch pine. The larvae, which do not materially differ from those of other weevils, inhabit these and probably other kinds of pines, doing sometimes immense injury to them. Wilson, the ornithologist, describes the depredations of these insects, in his account of the ivory-billed woodpecker, in the following words. "Would it be believed that the larvae of an insect, or fly, no larger than a grain of rice, should silently, and in one season, destroy some thousand acres of pine trees, many of them containing thirty thousand feet in diameter and 150 feet high? Yet whoever passes along the high road from Georgetown to Charleston, in South Carolina, about 30 miles from the former place, can have striking and melancholy proofs of the fact. In some places the whole woods, as far as you can see around you, are dead, stripped of the bark, their wintry-looking arms and bare trunks bleaching in the sun, and tumbling in ruins before every blast, presenting a frightful picture of desolation. Until some effectual preventive or more complete remedy can be devised against these insects and their larvae, I would humbly suggest the propriety of protecting, and receiving with proper feelings of gratitude, the services of this and the whole tribe of woodpeckers, letting the odium of guilt fall to its proper owners." (American Ornithology, vol. iv. p. 21.) Some years ago Mr. Nuttall procured, near the place above mentioned, specimens of the destructive insects referred to by Wilson. They were of three kinds. Those in greatest abundance were the pales weevil. One of the others was a larger, darker-coloured weevil, without white spots on it, and named Homobius piscivora, by German and Schanber, or the pitch-eating weevil; it is seldom found in Massachusetts. The third was the white pine weevil. It is said that these beetles puncture the buds and the tender bark of the small branches, and feed upon the juice, and that the young shoots are often so much injured by them as to die and break off at the wounded part. But it is in the larva state that they are found to be most hurtful to the pines. The larvae live under the bark, devouring its soft inner surface, and the tender newly formed wood. When they abound, as they do in some of the pine forests of the United States, they separate large pieces of bark from the wood beneath, in consequence of which the part perishes, and the tree itself soon languishes and dies.

The white pine weevil, Rhyynchus (Pinnates) Srohi, of Professor Peck, unites with the two preceding insects in destroying the American pines, as above described. But it employs also another mode of attack on the white pine, of which an interesting account is given by the late Professor Peck, the first describer of the insect, in the 4th volume of the Massachusetts Agricultural Repository and Journal, accompanied by figures of the insect. The lofty stature of the white pine, and the straightness of its trunk depend, as Professor Peck has remarked, upon the constant health of its leading shoot, for a long succession of years; and if this should be destroyed, the tree becomes stunted and deformed in its subsequent growth. This accident is not uncommon, and is caused by the rAVAGES OF THE WHITE PINE WEEVIL. This beetle is oblong-oval, rather slender, of a brownish colour, thickly punctured, and variegated with small brown, rust-coloured, and whitish scales. There are two white dots on the thorax; the scutel is white; and on the outer wings, covers, which are punctured in rows, there is a whitish transverse band behind the middle. The snout is longer than the thorax, slender, and a very little inclined. The length of this insect, exclusive of its snout, varies from one and a half to three tenths of an inch. Its eggs are deposited on the leading shoot of the pine, probably immediately under the outer bark. The larve, hatched therefrom, bore into the shoot in various directions, and probably remain in the wood more than one year. When the feeding state is passed, but before the insect is changed to a pupa, it gnaws a passage from the inside quite to the bark, which, however, remaining untouched, serves to shelter the little borers from the weather. After they have changed to beetles, they have only to cut away the outer bark to make their escape. They begin to come out early in September, and continue to leave the wood through that month and a part of October. The shoot at this time will be found pierced with small round holes on all sides; sometimes 30 or 40 may be counted on one shoot. (Harris.) See Corn Weevil, Curculio, Grain Weevil, Pea Weevil, Plum Tree Weevil, &c.

WEIGHT. In England, a weight of cheese, wool, &c., containing 256 lbs. avoirdupois. Of corn, the weigh contains 40 bushels; of barley or malt, 6 quarters. A weight of cheese or butter in Suffolk is 256 lbs., and in Essex 360 lbs.

WEIGHTS AND MEASURES. The proportions or quantities by which various sorts of agricultural or other produce are disposed of. In Britain they vary greatly in different districts, and even in different places of the same district or county.

In a general sense the term measure is applied to that by which any thing is compared in respect of quantity. Thus we have measures of extension, of weight, time, force, resistance, temperature, &c.; in short, of everything of which greater or less can be predicated; and it frequently happens that the unit or measure is not taken in the thing or property, which is the immediate subject of consideration, but in something else which depends on it, or is proportional to it. Angular space, for example, is measured by an arc of a circle; time, by the rotation of the earth upon its axis, or its revolution around the sun; force, 1110.
by the quantity of motion it impresses on a body; degrees of heat, by the expansion of metals or other substances; muscular strength, by the resistance of a spring. See Dynamometer, Strength, Thermometer, &c.

By measure, in an absolute sense, is understood the unit, or standard, by which we measure extension. We have, therefore, measures of length, of superficies, and of volume or capacity; but, as the two latter may be deduced in all cases from the former, it is only necessary to establish a unit, or standard of length. The choice of such a standard, and the different multiples and parts of it taken for the uses of society, form a metrical system, or system of metrology.

As no precise notion can be formed of the magnitude of a line in any other way than by comparing it with another line of a known length, the necessity of having recourse, for the interchange of ideas, to measures not entirely arbitrary, but fixed by nature and intelligible alike to all mankind, seem to have been perceived in the earliest ages. Hence originated the foot, the cubit, or length of the arm from the elbow to the tip of the middle finger; the ulna, arm, or yard; the span; the digit, or finger; the palm; the fathom, or space from the extremity of one hand to that of the other; when they are both extended in opposite directions; the pace, the barley-corn, the hair's breadth, and other denominations of measure taken from parts of the human body, or from natural objects, which, though not of an absolute and invariable length, have a certain mean value sufficiently definite to answer all the purposes required in a rude state of society. But as civilization advanced, the necessity of adopting more precise standards would be felt, and the inadequacy of such measure as the foot, the cubit, &c. (referred only to the human body), to convey accurate notions, would be rendered most apparent in their application to various measures, or the estimation of great distances.

**English System of Linear Measures.**—The unit of linear measure in England is the yard, all other denominations being either multiples, or aliquot parts of the yard. The yard is divided into 3 feet, and the foot subdivided into 12 inches. The multiples of the yard are the pole or perch, the furlong, and the mile; 3½ yards being a pole, 40 poles a furlong, and 8 furlongs a mile. But the pole and furlong are now scarcely ever used, itinerary distances being reckoned in miles and yards.

The relations of these different denominations are exhibited in the following table:

See Foot, League, Mile, &c.

Land is usually measured by a chain of 4 poles or 22 yards, which is divided into 100 links. Three chains in length and one in breadth make an acre, which equals 160 square perches, or 4810 square yards.

**Measures of Superficies.**—In square measure the yard is subdivided, as in general measure, into feet and inches; 144 square inches being equal to a square foot, and 9 square feet to a square yard. For land measure the multiples of the yard are the pole, the rod, and the acre; 30| (the square of 5|) square yards being a pole, 40 poles a rod, and 4 rods an acre. (See Acre.) Very large surfaces, as of whole countries, are expressed in square miles.

The following are the relations of square measure:

**Square, or Superficial Measure.**

144 square inches = 1 square foot.
9 = feet.
30| = yards.
40 = rods.
640 = acres.

**Measures of Volume.**—Solids are measured by cubic yards, feet, and inches; 1728 cubic inches making a cubic foot, and 27 cubic feet a cubic yard. For all sorts of liquids, corn, and other dry goods, the standard measure is declared by the act of 1824 to be the imperial gallon, the capacity of which is determined immediately by weight, and remotely by the standard of length. See Gallon.

The parts of the gallon are quarts and pints, 2 pints being a quart, and 4 quarts a gallon. 1111
WEIGHTS AND MEASURES.

Its multiples are the peck, the bushel, and the quarter; the peck being 2 gallons, the bushel 4 pecks, and the quarter 8 bushels. The following are the rotations:

Cubic or Solid Measure.

1728 cubic inches make = 1 cubic foot.
27 cubic feet = 1 cubic yard.
40 feet of rough timber = 1 cord. 50 feet of hewn timber = 1 load.

This comprehends length, breadth, and thickness.

And 10S solid feet, that is, 12 feet in length, 3 feet in breadth, and 3 feet deep, or commonly 14 feet long, 3 feet 1 inch broad, and 3 feet 1 inch deep, are a stack of wood.

And 15S solid feet, that is, 8 feet long, 4 feet broad, and 4 feet deep, are a cord of wood.

See Bushel, Peck, Quarter.

The Winchester quarter is more than the Imperial quarter, being in the proportion of 1 to 0.96945. The English Imperial quarter, in estimating weight, means the $\frac{1}{2}$ of a ton of 2240 lbs. = 560 lbs. or 1 quarter.

English Measure of Wood and other Fuel.—Cord-wood, being the bigger sort of fire-wood, is measured by a cord or line, whereof there are two measures; that of 14 feet in length, 3 feet in breadth, and 3 feet in height. The other is 8 feet in length, 4 feet in height, and 4 feet in breadth. This last is generally adopted in the United States.

Weights.—Weights are used to ascertain the gravity of bodies, a quality depending partly on their magnitude and partly on their density. The determination of the gravity or weight of different bodies supposes the invention of the balance. Nothing is known of the steps which led to its introduction; but it was used in the remotest antiquity. Weights have frequently been derived from grains of corn. Hence in England, and in some other European countries, the lowest denomination of weight is a grain; and 32 of these grains are directed, by the ancient statute, called Composicio devarium, to compose a pennyweight, 1112

whereof 20 make an ounce, 12 ounces a pound, and so upwards.

In England the stone is generally 14 lbs.avoirdupois weight, but for butchers’ meat or fish it is 8 lbs. Hence the cwt. equals 8 stone of 14 lbs., or 11 stone of 8 lbs.

Hay and straw are sold by the load of 36 trusses. See Hay and Truss.

The custom of allowing more than 16 ounces to the pound of butter used to be very general in several parts of England.

Wool Weight.—Like all other bulky articles, wool is weighed by avoirdupois weight, but the divisions differ thus:

Miscellaneous Information relative to Weights and Measures.—Specific gravity is determined by weighing the substance first in air, and then in water at the temperature of 60° Fahrenheit. In the latter case the substance loses of its weight a quantity precisely equal to the weight of its own bulk of water. The total weight in air is then divided by the loss of weight in water, and the quotient is the specific gravity. This is either over or under that of pure water, which is the standard of comparison. The standard of weights is, the cubic inch of distilled water, weighing 253.458 Troy grains; the Troy pound, 5760 grains, or 22.8157 inches. The standard of 7000 Troy grains makes the pound avoirdupois, 27.7274 cubic inches; 10 of which, or 277.274, being the imperial gallon, or a quart 39.22; and a gill of 5 ounces of water, equal to 8.564.

The specific gravity of water being 1.000, that of alcohol, pure, is 0.829; beer, 1.034; cider, 1.018; milk, 1.032; linseed oil, 0.94; vinegar, 1.025; sea-water, 1.026; ox bone, 1.666; brass, 7.824; brick, 2; cork, 0.241; gold, 19.2587; granite, 2.728; bar iron, 7.68; lead, 11.352; lignum vitae, 1.33; mahogany, 1.46; marble, 2.716; mercury, 13.58; oak, 1.17; platinum, 26.722; silver, 10.474; clay-slate, 2.67; tin, 10.717; limestone, 1.396; elm, 0.671; honey, 1.43. (Treasury of Knowledge.)

A cubic foot of loose earth or sand weighs 95 lbs.

A cubic ft. of common soil weighs 124 lbs.
WEIGHTS AND MEASURES.

A cubic ft. of lead, weights 700-9 lbs.

'' platina, " 1,218-75 "

'' copper, " 48-75 "

'' cork, " 15 "

'' tallow, " 59 "

'' oak, " 73-15 "

'' brick, " 125 "

'' air, " 0-753 "

The American quintal is 100 lbs. The ton 2240 lbs.

The weight of a cubic inch of distilled water, in a vacuum, is 252-722 grains, and in air, is 252-458 grains.

The Turkish pound is 7578 grains; the Danish, 6941; the Irish, 7774; the Neapolitan, 4907; the French, 3247; the American, 3571.

The imperial gallon contains 10 lbs. avoirdupois of distilled water, weighed in air at 62°, with the barometer at 30 inches. Two gallons are equal to a peck, 8 gallons to a bushel, and 8 bushels to a quarter.

Heaped measure, per bushel, is 58154 cubic inches clear.

The Winchester bushel is 815 2/3 inches in diameter, and 8 inches deep, containing 2154-42 cubic inches.

1000 ounces of rain-water are equal to about 717 gallons wine measure, or to a cubic foot.

Seven lbs. avoirdupois is a gallon of flour. A firkin of coals is 33 1/3 cubic feet.

Twelve wine gallons of distilled water weigh 100 lbs. avoirdupois.

The imperial dry-bushel, when heaped, is 2218-192 cubic inches; the peck, 554-548; gallon, 277-374, and quart, 69-3185. The bushel is 8 inches deep, and 18-8 wide, with a heap 6 inches high.

A bushel of wheat is 60 lbs.; rye, 53 lbs.; barley, 47 lbs.; oats, 38; peas, 64; beans, 63; clover-seed, 68; rape, 48 lbs.

A Scotch pint is equal to 4 English pints.

A Scotch quart is 208-6 cubic inches.

There are 545,297,000 cubic yards in a cubic mile.

According to usage in Philadelphia and other parts of the United States, building-stone, when piled, or "perched," as it is usually termed, is measured by allowing 25 cubic feet to the perch. But when placed in the wall, only 22 feet are allowed to the perch. In measuring stone wall, 14 inches of thickness is usually allowed. When the thickness of the wall exceeds 14 inches, the extra thickness is estimated and made an additional charge. This is the common rule when the walls have only one face. In double-faced walls, there is commonly an allowance of about one-third more. Three pecks of good lime will generally suffice to lay one perch of stone wall. About 2 one-horse loads of sand are allowed to make mortar for 3 perches of stone wall.

To convert cubic feet into perches, divide by 25; or, what is still more easy, multiply by .04.

In brick-work, 14 bricks are usually allowed to the cubic foot: sometimes only 13 are allowed. To convert cubic feet into cubic yards, divide by 3, and the product by 9.

Lumber Measure.—In estimating the number of feet in a boards, the length in feet is to be multiplied by the width in inches, and the result, divided by 12, shows the contents in feet. When boards are more than 1 inch thick, all over is multiplied. A board 12 feet long and 1 inch thick, would of course be estimated to contain one-fourth more than a board only 1 inch thick.

A bill passed by the legislature of Pennsylvania, in 1833, for the regulation of weights and measures in the state, provides for procuring and preserving standards, which are to conform to those of the United States, when established; the linear standard to be the yard, with the customary multiples allowed.

Superficial Measure.—Acre defined to be 4840 sq. yards.

Weights.—Troy pound to be equal to that of the United States mint, and the avoirdupois pound to bear to it the ratio of 7000 to 5766 lbs. of wheat to pass for a bushel.

58 — rye.

58 — corn.

48 — buckwheat.

47 — barley.

32 — oats.

85 — coarse salt (foreign).

70 — ground salt.

62 — fine.

80 — anthracite coal, 112 lbs. to make 1 cwt., and 2240 lbs. = 1 ton.

If the square of the diameter of a circle be multiplied by .7854, the product is the area. If the diameter of a sphere be cubed and multiplied by .5236, the product is the solidity; and the square of the diameter, multiplied by 3.14159, is the surface of the sphere.

To find the contents of a cask, add double the square of the bung diameter to the square of the head diameter, and multiply this sum by the head of the cask; than divide the product by 1077 for ale gallons of 280 cubic inches each, or by 582 for wine gallons of 321 cubic inches each.

Method of ascertaining the Weight of Cattle while living.—This is of the utmost utility for all those who are not experienced judges by the eye, and, by the following directions, the weight can be ascertained within a mere trifle. Under the head CATTLE we have already given a useful table on this subject; but the annexed rules will be found of service. Suppose a string to put round the beast, standing square, just behind the shoulder-blade; measure on a foot-rule the feet and inches the animal is in circumference; this is called the girth; then with the string measure from the bone of the tail, which plumbs the line with the hinder part of the buttock; direct the line along the back to the fore-part of the shoulder-blade; take the dimensions of the foot-rule, as before, which is the length, and work the figures in the following manner; —Girth of the bullock, 6 feet 4 inches; length, 5 feet 3 inches; which, multiplied together, make 31 square superficial feet; that again, multiplied by 29 (the number of

140

1113
pounds allowed to each superficial foot of all cattle measuring less than 7 and more than 5 feet in girth), makes 713 lbs.; and allowing 14 lbs. to the stone, is 50 stone 13 lbs.; and where the animal measures less than 9 and more than 7 feet in girth, 51 is the number of pounds to each foot. Again, supposing a pig or any small beast should measure 2 feet in girth, and 2 feet along the back, which, multiplied together, make 4 square feet, that multiplied by 11, the number of pounds allowed for each square foot of cattle measuring less than 3 in girth, makes 44 lbs.; which, divided by 14, to bring it to stones, is 3 stones 2 lbs. Again, suppose a calf, sheep, &c., should measure 4 feet 6 inches in girth, and 3 feet 9 inches in length, which, multiplied together, makes 16 1/4 square feet; that multiplied by 16, the number of pounds allowed to all cattle measuring less than 5 feet and more than 3 in girth, makes 264 lbs.; which, divided by 14, to bring it to stones, is 18 stones 12 lbs. The dimensions of the girth and length of black cattle, sheep, calves, or hogs, may be as exactly taken this way as it is at all necessary for any computation or valuation of stock, and will answer exactly to the four quarters, sinking the offal, and which every man who can get even a bit of chalk may easily perform. A deduction must be made for a half-fatted beast of 1 stone in 20 from that of a fat one, and for: a cow that had had calves, 1 stone must be added, and another for not being properly fat.

The last act of Parliament on the subject of weights and measures is the 5 & 6 W. 4, c. 63, which contains some important provisions. It abolishes all local or customary measures under a penalty of 40s. for every sale made by them; it prohibits the mischievous practice of selling by heaped measure; it enacts that coals shall in all cases be sold by weight; that with the exception of the precious metals, jewels, and drugs, all other articles sold by weight shall be sold by avoirdupois weight only; and that a stone shall in all cases consist of 14 lbs. avoirdupois; a hundred weight of eight such stones, &c. Lead and pewter weights are not to be deemed. It enacts that the Winchester bushel, the Scottish ell, and all local and national measures shall be abolished; and every person who shall sell by any measure other than one of the imperial measures, or some multiple or aliquot part thereof, shall be liable to a penalty not exceeding 40s. for every such sale. That the use of heaped measure shall be abolished, and all bargains, sales, and contracts made after the passing of this act, by heaped measure, shall be null and void.

Articles sold by heaped Measure, how to be sold. — Whereas some articles heretofore sold by heaped measure are incapable of being stricken, and may not be conveniently sold by weight; it is enacted, that all such articles may henceforth be sold by a bushel measure, corresponding in shape with the bushel prescribed by the 5 G. 4, c. 74, for the sale of heaped measure, or by any multiple or aliquot part thereof, filled in all parts as nearly to the level of the brim as the size and shape of the articles will admit; but nothing herein shall prevent the sale by weight of any article heretofore sold by heaped measure.

All coals, slack, culm, and cancel of every description shall be sold by weight and not by measure.

All articles sold by weight shall be sold by avoirdupois weight, except gold, silver, platinum, diamonds, or other precious stones, which may be sold by Troy weight, and drugs, which, when sold by retail, may be sold by apothecaries' weight.

The stone, hundred weight, &c.—From and after the passing of this act, the weight denominated a stone shall, in all cases, consist of 14 standard pounds avoirdupois, the hundred weight of 8 such stones, and the ton of 20 such hundred weights; but nothing herein shall prevent any bargain, sale, or contract being made by any multiple or aliquot part of the pound weight.

Fair prices.—In Scotland, from and after the passing of this act, the fair prices of all grain in every county shall be struck by the imperial quarter, and all other returns of the prices of grain shall be set forth by the same, without any reference to any other measure whatsoever; and any sheriff-clerk, clerk of a market, or other person offending against this provision shall forfeit not exceeding 5l. See Flan.

Penalty on price lists, &c.—From and after the 1st of January, 1836, any person printing, or clerk of any market or other person making any return, price list, price current, or any journal or other paper containing price list or price current, in which the weights and measures quoted or referred to denote or imply a greater or less weight or measure than is denoted or implied by the same denomination of imperial weights and measures under the provisions of this act, shall forfeit and pay not exceeding 10s. for every copy of every such return, price list, price current, journal, or other paper which they publish. (Laudie's Dict. of Science; McCulloch's Com. Dict.)

The following observations relative to the weights and measures of the United States are derived from a correspondent of the Farmer's Cabinet:

The subject of establishing by the Congress of the United States a uniform standard of weights and measures for the whole confederacy, is a matter of great importance to the agricultural and commercial interests. Most of the states, perhaps all, have legislated on this very interesting, important, and difficult subject, and it is obvious, from the results of their disjointed labours, that there is still room for the exercise of the skill, judgment, and science of the most learned men in the nation, to reduce the chaos to order, and to prepare a uniform system, founded on scientific principles, for the use of the whole nation. Much confusion and loss must be sustained by the great discrepancies which exist in the weights and measures in use in the different states which are in habits of constant commercial intercourse.

On an examination of the learned and able report made by John Quincy Adams to the Senate of the United States in 1821, and that made by F. R. Hassler to the same body in

In the plant, the seed is sown in April or the beginning of May, generally broadcast. The quantity of seed is from two quarts to a gallon per acre, and it should either be fresh, or, if two or three years old, steeped a few days in water previously to being sown. Being a biennial, and no advantage obtained from it the first year, it is sometimes sown with corn crops in the manner of clover, which, when the soil is in a very rich state, may answer, provided also, that hoeing, weeding, and stirring take place as soon as the corn crop is of the best growth, but obviously the result of drilling and cultivating the crop alone. The drills may be a foot asunder, and the plants thinned to 6 inches in the row. In the broadcast mode it is usual to thin them to 6 or 8 inches distance every way; often, when weld succeeds corn crops, it is never either thinned, weeded, or hoed, but left to itself till the plants are in full blossom.

The crop is taken by pulling up the entire plant, and the proper period for this purpose is when the bloom has been produced the whole length of the stems, and the plants are just beginning to turn of a light or yellowish colour; as in the beginning or middle of July in the second year. The plants are usually from 1 to 2 feet in height. It is thought by some advantageous to pull it rather early, without waiting for the ripening of the seeds, as by this means there will not only be the greatest proportion of dye, but the land will be left at liberty for the reception of a crop of wheat or turnips; but in this case a small part must be left solely for the purpose of seed. In the execution of the work, the plants are drawn up by the roots in small handfuls, and set up to dry after each handful has been tied up by one of the stalks, in the number of 4 together in an erect position against each other. Sometimes they, however, become sufficiently dry by turning without being set up. After they have remained till fully dry, which is mostly effected in the course of a week or two, they are bound up into larger bundles, that contain each 60 handfuls, and which are of the weight of 56 lbs. each: 60 of these bundles constituting a load. These fast, in places where this kind of crop is much grown, are tied up by a string made for the purpose, and sold under the title of weld cord.

The produce of weld depends much on the nature of the season; but from half a load to a load and a half is the quantity generally afforded, which is usually sold to the dyers at from 5l. or 6l. to 10l. or 12l. the load, and sometimes considerably more. It is mostly bought by persons who afterwards dispose of it to the dyers occasionally as they find it convenient. The demand for it is sometimes very little, while at others it is so great as to raise the price to a high degree. It is sometimes gathered green, and treated like woad or indigo; but in general the dried herb is used by the dyers in a state of decoction.

The use of weld in dyeing is for giving a yellow colour to cotton, woollen, mohair, silk, and linen. Blue cloths are dipped in a decoction of it, which renders them green; and the yel-
low colour of the paint called Dutch pink is obtained from weld.

WHEAT. There are a few of the largest and healthiest plants, and leave them to ripen. The seed is easily separated.

The chief disease of weld is the mildew, to which it is very liable when young, and this is one reason that it is often sown with other crops.

WELL (Sax). A term sometimes applied to a chimney or vent-hole left in a rick or mow of hay, or other similar materials, to prevent its overheating.

WHEAT (Triticum). This is undoubtedly the most important genus of the order Gramineae, for wheat is that species of grain which is more generally cultivated than any other, and, from the universal demand and high price it obtains, best repays the European farmer’s toil and outlay.

The flour of wheat is the most nutritious and palatable of all the cereal grains used as the food of man. Linnaeus comprehended all the different varieties of wheat known in his day under six species; but modern botanists enumerate about 30 species, and some hundreds of sub-varieties brought into existence by continued cultivation. It has been well observed that for mere practical purposes it is sufficient to have some general classes, namely, white and red, and the varieties distinguished by their spikelets, as the smooth or bearded, the woolly-chaffed or the hairy-chaffed. There are some varieties characterized, also, as spring or winter (Lammas) wheats, though these are frequently apt to lose their distinguishing characters, and to accommodate their habits to the season in which they are sown.

“It is to be presumed,” says Colonel le Conteur, “from the passage ‘In the sweat of thy face shalt thou eat bread,’ (Gen. iii. 19), that wheat was coeval with the creation; and that upwards of a thousand years before the Christian era, some improvement in its culture and some knowledge of a superior variety had been attained, by the circumstance of its being stated that ‘Judah traded in wheat of Moab,”’ (Ezek. xxi. 7.)

Columella, who wrote about the time of our Lord, makes some interesting remarks on wheat:

“The chief and the most profitable corns for men,” he observes, “are common wheat and bearded wheat. We have known several kinds of wheat; but of these we must chiefly sow what is called the red wheat, because it excels by a greater bulk and brightness.

“The white wheat must be placed in the second rank, of which the best sort in bread is deficient in weight.

“The trimestrian shall be the third, which husbandmen are most apt to make use of; for when, by reason of great rains or any other cause, the early sowing has been omitted, they have recourse to this for relief; it is a kind of white wheat.” Pliny says that “this is the most delicious and the daintiest of any sort of wheat, exceeding white, but without much substance or strength, only proper for moist places, such as those of Italy, and some parts of Gaul; that it ripens equally, and that there is no sort of corn that suffers delay less, because it is so tender that such ears of it that are ripe presently shed their grains; but in the stalk it is less in danger than any other corn, for it holds its ear always upright, and does not contain the dews which occasion blasting and mildew.” (This description of Pliny’s seems to accord with the spring wheat of the present day, which, be it remembered, came to us from Spain.)

“The other sorts of wheat are altogether superfluous,” continues Pliny, “unless any man has a mind to indulge a manifold variety, and a vainglorious fancy. But, of bearded wheat, we have commonly seen four sorts in use; namely, that which is called clusian, of a shining bright white colour; a bearded wheat, which is called veneculum; one sort of it is of a fiery red colour, and another sort of it is white, but they are both heavier than the clusian. The trimestrian, or that of 3 months’ growth, which is called halicastrum; and this is the chief, both for its weight and goodness.

But these sorts, both of ordinary common wheat and of bearded wheat, must, for these reasons, be kept by husbandmen; because it rarely happens that any land is so situated that we can content ourselves with one sort of seed, some of it being too early ripening, expectation, to be wet or dry. But common wheat thrives best in a dry place, and bearded wheat is less affected by moisture.”

Hence it appears that Romans were aware of the propriety of selecting their wheat, and that it was then believed that winter or beardless wheat was best suited to dry uplands, and bearded wheat to low or moist lands. In addition to the winter wheats, some of which he states to be bearded, he distinctly alludes to the trimestrian or spring wheat, of which I shall speak hereafter. In the edition of Gerard’s Herbal, printed in London in 1660, only 5 kinds of wheat are enumerated; and, although this was the leading botanical work of the day, these are most indistinctly described.

Modern writers generally are equally vague: they merely designate a number of varieties; but no attempt appears to have been made to classify them correctly, or to ascertain their relative values by comparison.

In Sinclair’s Hortus Gramineus Wolmerensis, 42 of the cultivated varieties are enumerated as winter or spring wheats, according to the arrangement of Linneus, which this illustrious writer has merely given as a sort of botanical classification.

The Maison Rustique for 1835, enumerates 39 varieties; and, although a short notice is given of them, it is by no means sufficient, as their farinaceous qualities are not explained. Mr. Paxton, in his Botanical Dictionary, enumerates 25 distinct species, besides several varieties.

A classification of wheat is much required, pointing out the relative value of varieties, in their quantity of meal, the weight of bran and pollards, with the weight of straw of each, and their adaptation to soils. That this is a desideratum no one, I imagine, will deny; but that it requires time, attention, and effort, to make such discoveries, will also be conceded, when it is stated that I already possess up-

1116
Variees of Wheat, with the most destructive Enemies.
WHEAT.

wards of 150 varieties or sub-varieties. (Le Couteur on Wheat.)

The most popular description of the different species of wheat which admit of cultivation for their seed is that given by Professor Low, in his work on the Elements of Agriculture, and I shall therefore avail myself of his scientific description.

Specific character.—The calyx of wheat consists of 2 valves or glumes, enclosing several florets. In each of these florets there are 2 valves, forming the corolla, and enclosing the seed, and the corolla encloses the perfect seed, and sometimes the seed is not perfect. Each calyx, with the florets which it encloses, is termed a spikelet. The part to which the spikelets are attached is termed the rachis or shank, and the spikelets placed one above the other, on each side of the rachis, form the ear or head. The rachis is jointed, and the spaces between the joints are termed the internodes.

Species.—1. Spring or summer wheat (T. aestivum). Pl. 2, a, has awns both on the calyx and corolla. Each spikelet has usually 5 florets, of which 2 form the corolla, and the grain is too tender to bear the frosts of the winter, but as quick in progress from its first shoot to ripeness as barley, oats, or any other spring corn. It requires a shorter period to complete its vegetation than any of the other kinds. Summer wheat is the prevailing species of warmer countries, and is cultivated in many parts of Europe. It is much used in France, where it is called blé de Mars, from the season in which it is usually sown, and in some provinces blé de trémos, from the time it takes between seedtime and harvest. In Spanish it is called trigo de marzo; in Portuguese trigo trémos; and in German Sommerseizen, all which names mark distinctly the difference between this and winter corn. It does not appear from the older books on husbandry, that it was at any period much cultivated in England; the more modern ones are, in general, silent on the subject of it; they mention, indeed, under the name of spring wheat, every kind of winter wheat which will ripen when sown after turnips in February. This is probably the reason why the real spring wheat has been so little known; agriculturists in general conceiving themselves to be actually in the habit of sowing spring wheat, when, in reality, they were substituting winter wheat in its place, have been little inclined to inquire into the properties of the true spring wheat when they had an opportunity of so doing.

Its grains are, for the most part, small, and the produce of the straw is less than that of some other species, when cultivated under the same circumstances. Professor Low says, that “the trials which have been made with it in this country have shown it to be inferior in productiveness and quality to the better kinds of winter wheat. The advantage which it possesses is the earlier period of its ripening, on which account it may be sown so late, even in this climate, as has been heretofore been the case.” Board of Agriculture being desirous of bringing spring wheat into general cultivation, in 1805 offered large premiums to those who should, in the spring of that year, sow the greatest quantity of land with spring wheat. In one of the communications made to the Board, Sir Joseph Banks states that “in the countries best acquainted with its culture, spring wheat is preferred to all other corn for raising a crop of seeds. This is owing to the small quantity of leaf it bears, less, perhaps, than any other corn, and to the short duration of the leaf, which fades and falls down almost as soon as it has attained its full size. “In cases where red wheat has been damaged by the wire-worm, a mischief which sometimes occurs to hard winters in Great Britain, spring wheat appears to hold out an easy and simple remedy. In the first week of May the ravages of the worm have somewhat abated; if then the seed of spring wheat is at that time dibbled, or only raked with a garden rake, into the naked spots left by the worm, though it will not attain the growth at which the worm begins to prey upon it till he has changed his state for that of a winged beetle, it will certainly be ripe as soon as the winter wheat, and may be threshed out and sold with it; or, if it is preferred, may be reaped separately, and the Lincolnshire sort, have longer beards or awns than the rivet or cone wheat, will point it out to the reapers in such a manner that no great error can happen in separating it from the Lammass.” (Com. to Board of Agr. vol. v p. 181.) To the Miller this mixture of grain can be of no consequence; but it would be scarcely safe to employ the produce as seed.

From the analysis of Sir H. Davy it may be inferred that bread made of the flour of spring wheat is more nutritious than that made of winter wheat, because the former contains a larger proportion of gluten or half-animallized matter. He found that

2. Winter, or lammas wheat (T. Lycburnum), Pl. 2, b, is distinguished from the last by its appearance, being much more vigorous in the stem, more erect and thick in the ear, by having no awns upon the calyx, and only short awns upon the corolla, near the summit of the spike. But the awns not being a good botanical character, many botanists have conceived the species to be the same. The characters, however, of either kind being permanent and remaining under given circumstances unchanged for an unknown period, they may be regarded as species. The winter wheat has usually 5 or 6 florets, of which 2 are barren.

Winter wheat is that which is the most important with relation to its cultivation in Northern Europe. It is, in England, generally sown in autumn, or previously to the winter months, and ripens its seed in the following summer; but it is an annual plant, and may be sown in spring.

5 B 1117
“Slight varieties of this species are exceedingly common in different localities, and are probably attributable to some peculiarities in the mode of culture. The common varieties of winter wheat are distinguished from each other according to the colour of the tunic enveloping the grain, and the difference observable in their chaff. The colours are usually divided into white and red, the latter of these including many different shades of brown. Red wheat is commonly said to be more hardy than white; it is therefore thought better suited for cultivation in bleak and upland districts. The plant is, however, not so productive as the white, and the flour which it yields is seldom of so desirable a quality.” (Baxter’s Lib. of Agr. p. 640.)

3. Compact wheat (T. compactum) is allied to the two last-named species, and may be merely a variety of them. In it the internodia of the rachis are very short. It is partially produced in different parts of Europe. “I have received specimens of it,” says Professor Low, “from France and Sweden, and I have been unable to observe any change of characters. Whether, however, the characters which distinguish it are sufficiently permanent to entitle it to be regarded as a species, has not been determined. In the mean time, following the authority of Host (Icones et Des. Gram. Aust.), I have placed it amongst the species.”

4. Egyptian, or many-spiked wheat (T. compositum), Pl. 2, 6, is distinguished from the others by its branched or compound spike, which no other species tends, under any circumstance, to produce. Its seeds are numerous, and the produce abundant. It requires a good climate and a fertile soil, for in unfavourable situations the branches of the spike are not developed, and then it assumes the appearance of ordinary wheat. It is cultivated in Egypt and the east, as it is in the south of Europe and different parts of Italy. It was known in Germany about 240 years ago, and in France it is said to have been cultivated for about 80 years, having been brought from the east under the name of wheat of Smyrna. In England it has been partially cultivated as the subject of experiment. It is uncommonly fruitful, and the straw is very strong and tough, whence it has received the name of reed wheat.

The grains, however, do not yield so large a proportion of flour or meal as any of the other species and their varieties, and the flour is scarcely superior to that obtained from the finest barley. Egyptian wheat will bear great degrees of heat and drought without harm, so that it is found to yield abundantly in situations where other kinds would be greatly injured, if not destroyed; a circumstance which points it out as admirably adapted to the arid lands wherein it is chiefly cultivated. It would be more cultivated in England, if its form did not cause it to hold the heat at harvest-time, and hence it is very liable to be said.

5. Turgid wheat (T. turgidum), Pl. 2, d. In this species the corolla is awned, but not the calyx; the spikes are covered with soft hairs, and in some varieties change to a dark colour, and the awns drop off as the seeds become ripe, in which respect it differs from summer wheat. It is known in different localities under the several names of gray wheat, duck’s bill wheat, gray pollard, rivet, pole rivet, cone, pendulum, &c. This species grows very tall, with a thick and rigid stem. The spikes are large and heavy, and nod to one side as the grain increases in weight. The kinds or minor varieties are distinguished by the farmer from their qualities of earlier or later ripening, and greater or less productivity. One of the most esteemed of these is cone wheat, so named from the conical form of its spike. The turgid wheats are productive in corn and straw, but the grain is coarse and hard, and the flour much browner and of an inferior quality. They are chiefly suited to the inferior clays, upon which in England they are extensively cultivated. They are valued under such circumstances for their productivity in grain and their large growth of straw; but being inferior to the winter wheats in the quality of their produce, the cultivation of them is not likely to increase.

6. Dark-spiked wheat (T. strigatum) is allied to the last species, if it is not rather to be regarded as a variety of it. It has merely been made the subject of experiment, but not of extended cultivation. It is not superior in productivity to the turgid wheats in common use.

7. Barley-like wheat (T. hordeiforme), so named from its peculiar form, resembling that of barley, seems, like that last described, to be derived from Africa. The florets are awned, and the calyx and corolla become dark as the seeds ripen. But it resembles the class to be next referred to, termed spelt-wheat.

8. Far (T. zoe) is one of the class of spelt-wheats. It is distinguished by the distance of its spikelets from one another. The straw is rigid; the calyx and corolla adhere closely to the seed, and the spikelets again so closely to the rachis, that they cannot be separated from the rachis without breaking it. This wheat is cultivated in some parts of Europe on inferior soils.

9. Spelt-wheat (T. spelta), Pl. 2, f, is distinguished like the last by its spikelets being firmly attached to the rachis, and by its rigid calyx and corolla closely enveloping the seed. Spelt is much cultivated in the south of Europe. It is grown extensively in the southern provinces of France, in Switzerland, Italy, in several parts of Germany, and in Aragon, Catalonia, and other parts of Spain, as well as in the north of Africa, and at the Cape of Good Hope. Spelt could be raised in England with facility, and it is probable on soils low in the scale of fertility. It has been cultivated in Scotland, 600 feet above the level of the sea. It is said that spelt-wheat is better adapted than any of the more delicate kinds for culture in Australia, and probably it will be found the more preferable sort in all the more southern wheat-growing countries.

There are two distinct varieties of spelt, distinguished as the awned and the awnless; the latter is perhaps the most naked of all the cerealia. The grains of this are large, but the ear contains only a small number of them, as
a portion of the flowers prove barren. It is generally not a hybrid, but a spring-sown crop; grows strongly, and its stalks are nearly solid. Bread made of its flour is said to be of a dry quality. It is well known in commerce that the incomparable Nuremberg and Frankfort starch and flour are solely obtained from spelt-wheat. The grain cannot be divested of its husks by thrashing, and therefore requires to be passed through a mill. It should however be sown or drilled with the husks on.

10. One-grained wheat, or St. Peter's corn (T. monococum), Pl. 2, 5, is readily distinguished from all the other wheats by its general appearance. Its spikelet consists of three or four florets, one of which only is for the most part fertile, and hence its name of one-grained wheat. The fertile floret has a long awn. The stem of this species of wheat is slender and rigid; and, from being both hard and fine, the straw is excellent for thatching. It is allied to the spelt, with which it was classed by some of the older botanical writers. This species is principally cultivated in the mountains of Switzerland and other elevated regions of Europe, and in barren soils. In consequence of its containing less gluten than common sorts, it answers better for being baked into gruel and for being baked into bread. The four-sided form of the ripe ear is so regular, that it has the appearance of being carved in ivory. It has never formed an object of cultivation in this country, and does not appear to possess properties to entitle it to be introduced.

11. Polish wheat (T. polonicum), Pl. 2, c. This species has long awns, and is distinguished from all the others by its long and leafy calyx and corolla. It is cultivated in Germany, in Poland, and in Spain. It was brought into notice, and partially cultivated, in some of the counties of England, in the latter part of the seventeenth century; and it is said to have been valued on account of its productive power of flour. But, although it may be possessed of this quality, its florets are often infertile, and it does not merit a more extended culture in this country. Unless sown sparingly, it is apt to lodge, in consequence of which the quality of the corn is impaired.

Varieties. — The minor varieties of any species of wheat are not permanent in their character, though, under given conditions, they will remain unchanged for an indefinite period. Under other circumstances, however, they degenerate; and hence particular kinds that were once valued have now ceased to be so. The best advice that can be given, therefore, in the choice of varieties and sub-varieties, is to select those which the practice and experience of the principal farmers of the neighbourhood have stamped as the best. Colonel Le Couten, one of the best authorities on the culture of wheat, has given us the result of his experiments and great experience, upon four of the best pure and improved varieties of wheat lately introduced into England. (Journ. Roy. Eng. Agr. Sor, vol. I. p. 113.)

1. White downy.—This excellent variety is believed to be the same that is so well described by Boys in his General View of the Agri-
culture of Kent, as the "Hoary White," or "Velvet-eared," and by him to have been much prized by the millers, but then entirely lost. The seed after being washed and steeped was sown in drills 7 inches apart, at the rate of two bushels or a little more to the acre. The wheat was carefully hand-hoed in the month of May, which caused it to suffer greatly. The preceding crop was potatoes. This wheat will withstand the most severe weather. The season 1837 to 1838 was a very trying one, both as to wetness and severity of cold, the thermometer having fallen to 18° below freezing; but the crops of this wheat raised by my neighbours were perfectly sensibl to it, and of great produce. This wheat is not remarkable for its early maturity, though it cannot be called a tardy variety. It is not subject to degenerate, and if attention is paid to sowing the seed pure, and annually, or even occasionally, varying the manure intended for it, it is possible that it may never degenerate. The only objection to it is the huskiness or velvety ear, which in damp weather is retentive of moisture; and in snappy seasons the grain is more apt to sprout than the smooth-chaffed varieties. It is not much affected with dust-bread; and when pickled and limed, has never been found with smut-balls. It is little liable to be shed, even when over-ripe, and will resist very heavy gales without being laid or broken.

2. Jersey Dwarf.—The seed is described as having been raised from a single ear, originating from seed procured from Dantzic, selected from the finest "high mixed." It is, however, suspected to be identical with some excellent sorts, called in Sussex, Kent, and some parts of Surrey, the "Chittums;" in other parts "Peggleshams;" in Berkshire, "Trump;" in Essex, "Hardcastle;" in some counties, "Old Suffolk;" in Scotland, "Hunter's White;" and assuming several other names. This wheat is not quite so hardy as the "hoary," it is, nevertheless, considered sufficiently so to succeed throughout the kingdom, excepting the northern parts of Scotland. In rich soils it tillers amazingly, and produces a longer straw than the hoary, nor is it so liable to sprout in a moist climate from being smooth-chaffed: in very severe, moist, and stormy weather, it will be laid sooner than the hoary.

It ripens a week earlier at least than the variety last described, and should be reaped while the grain can be marked by pressure from the thumb-nail, as it is rather liable to be shed if overripe, and to the disadvantage which the hoary is peculiarly free from, as it is firm to the ear. In the dry season this wheat will afford a beautiful, clean, white straw, fit for bonnet-making, or any purpose of thatching: it is firm and tenacious. In wet seasons it is rather subject to rust, which, under such circumstances, almost all wheat suffers from.

3. Whittington Wheat.—The seed was obtained from Mr. Whittington himself, and was a very fine, pure sample. The grain is large, fowl, and plump, rather of a whistling-red cast, and a little thick-skinned. The seed was washed, pickled, drained, and limed, then sown in drills seven inches apart, about three bushels to the acre. When the seed is large, it is con-
sidered prudent to add half a bushel or more to the acre. I consider this to be a very hardy wheat, affording much herbage and straw, very fit for being eaten down by sheep in the spring when sown early in the fall. The Whittington is rather a late wheat, ripening a week or ten days later than the Jersey Danzig before described, though it was in bloom on the same day. From the purity of the seed, and the uniform appearance of the crop, it does not appear likely to degenerate, nor does it seem more liable to disease than other wheats. The straw is brittle, and many ears break off. I am of opinion, from what I have witnessed, that the value of this description of wheat is much overrated: the millers dislike it, and in certain situations it is apt to blight.

4. *Fellwene Talweco.*—This admirable variety is invaluable where it is adapted to the soil and climate. The seed being large, a greater quantity of it should be allowed than usual. This wheat has succeeded in the north of Scotland, and is sufficiently hardy to withstand the winter in its grassy state, but it is otherwise more valuable as a spring crop: without doubt it may be sown as late as the first week in February in all the milder parts of England, with a prospect of reaping quite as good an average crop from it as from any other wheat, but with a certainty of obtaining more flour than from most. There is no tendency to degenerate observable in this wheat, as far as the experience of five or six years goes; nor, from its early habits, is it at all likely to become intermixed by fecundation from other varieties, though sown about the same period, as it will, in such cases, flower a fortnight or three weeks before them. It is not more liable to disease than ordinary white wheats, and affords a very fine, clear, white straw: it is, indeed, one of the Italian bonnet-making varieties. There is, however, one disadvantage in it, which is, that the ear is so heavy that it is apt to break down, though not break off, when swept by a gale about the period of ripening; but it has a countervailing good quality, of ripening the grain equally well though bent down; as is the case with spring wheats, which ripen their seed well though quite laid, which with winter wheats is doubtful. Another peculiarity is the tenacity of the chaff to the ear, more remaining on it after passing through the thrashing-machine than any other variety I am acquainted with.

The following sorts I have also grown experimentally, but, not having raised them in quantities sufficient to warrant a positive opinion, which probably might only tend to mislead, they are merely named.

The “golden drop” is one of the best red wheats, affording great produce in corn and straw, and a larger quantity of flour than some white wheats.

“Hickling’s prolific red” is a productive variety, but rather coarse. The properties of this wheat are, straw long, stout at the bottom, and tapering at the head; head short, thick, close, and heavy; kernels four in the row across the ear, and red in colour, with the chaff white; in sample the wheat is short, plump, thin-skinned, and looks as if it would flour well: colour dark orange-red.

Brown’s “ten-rowed chevalier,” or prolific, is well named, where it suits the soil and climate: it is, when pure, a very fine variety.

“Gale’s Hampshire” is a very enormously productive sort of bearded wheat. “Essex red,” a very good variety. “The duck’s-bill” wheat is very productive, but shedding greatly, and not very farinaceous.

In order to present the particular points of comparison between the four principal varieties above-described, the results are appended in a tabular form:

N.B.—In the estimate of profit, in the last column, the calculation is not made with relation to the respective values of the wheats as to their productiveness in flour, which it might be, but according to the ordinary marketable value of good wheat; the straw is valued as intended for manure.

The following is an excellent account of an experiment on the relative values of several varieties of wheat by Mr. John Morton, which I have extracted from the first volume of the *JournaL of the Eng. Agr. Soc.* p. 39. It is from practical and carefully carried out experiments, such as these, that we shall be able to arrive at the proportionate value of different species and new varieties of wheat, and from which we may be enabled to select the good and reject the bad kinds.

The profits of farming, whether the land be pasture or arable, and the tenant be a feeder of stock or a tiller of the ground, may be increased in two ways. The stock-farmer knows very well that the return he obtains from his cattle depends, not only on the kind of food given to them, and the manner in which it is supplied, but also on the feeding qualities of the breed to which they belong; and he increases his chance of profit as much when, on purchasing from the breeder, he selects with
judgment, as when he adopts an improved mode of feeding. The intelligent farmer of arable land, again, expects a greater crop, the more he has been able to improve the texture of the soil, and the better the nature and state of the manure which it contains. He expects it, because he knows that it depends on the nature of the food given to the plants, and the manner in which they are provided with a constant supply of it. The crop does not, however, depend only on this; for as two beasts, fed in exactly the same manner, may not be equally profitable, owing to a difference between them regarding the quantity and quality of the meat they afford, so two different kinds of wheat, though sown on land precisely similar, and in equally good condition, may give unequal returns, owing to a difference between them regarding the quantity and quality of the flour they afford. Hence the importance, too often overlooked by farmers, not only of preparing the land for the crop in a good and sufficient manner, but also of selecting that kind of seed which experience has pointed out as being most valuable and productive. It was with a view to the more orderly acre, the difference in the value, hardiness, and other properties of several of the most commonly planted wheats, but also of effecting an improvement in the best of them that the following experiment was commenced, on the 1st of November, 1837. To insure accuracy in the results, it was necessary that the seeds of each variety should be planted so as to have them all at equal distances. To effect this, two boards were used, each 6 inches wide, 9 feet long, and ½ inch thick. Along the centre of each board was a row of holes, 3 inches apart and 1 inch in diameter. A dibble was made to fit into the holes, having a shoulder at the distance of 2½ inches from the point.

When the board was placed on the ground, and the dibble put through each hole in succession, a series of holes was thus made, 2 inches deep, and 3 inches apart from centre to centre.

After this had been done through the first board, the second, which was touching it, and parallel to it, was served in the same way; and then the first was taken up, and placed on the other side of the second. By proceeding thus, the whole ground was finished, and then one grain of wheat was dropped into each hole. The rows were thus exactly 6 inches apart, and the grains in the rows were 3 inches from one another. The regularity with which the planting was performed was thus mathematically accurate. The ground planted lies on the lower edge of the great oolite formation, and the soil is a stone brash, about 10 inches in thickness. Crops of potatoes had been taken off it for a succession of eight years; and it had been manured every alternate year with a compost of equal bulks of stable-dung and earth, at the rate of above 4 tons to the acre. All that was done on the surface was dug in, and the corn was ploughed in, the third year. There were 4 rows of each of these, however, was not taken into account, because their roots had a much greater extent of ground for their growth than the others, whose roots touched one another all round. The end plants of each row were also rejected for the same reason. Sixty-six feet in length of ground were thus taken up, and three rows of each variety occupied in width 1½ foot: the ground occupied by each variety was thus 99 square feet, the 440th part of an acre.

Although the tabular form in which this experiment is detailed explains itself by the headings of each column, yet it is considered necessary to give a somewhat fuller account of it. The seed from which the first ten varieties were raised was carefully selected from specimens of each obtained in the ear. The others were from samples, and here, also, the greatest
care was taken that the seed from which each was raised should be the best and plumpest that could be obtained.

The first five columns need no explanation beyond what is given at the head of each; the sixth shows the number of grains lost from casualties. If the frost had been the only agent in the destruction of so many of the seeds, this column might have been considered as a very accurate index of the relative hardiness of each variety. This, however, is not the case; for the havoc which the birds made must also be taken into account. It was thought at the time that more injury was sustained from the latter cause by those varieties planted on the 21st than by any of the others; but this does not appear to have been the case, for, if the great loss sustained by these had been wholly owing to the havoc committed by the birds, it is evident that the varieties marked Nos. 12 and 15 would not have been so slightly injured, while Nos. 11, 13, 14, and 16 suffered so severely. The figures in this column may, therefore, be said to afford only an indication of the relative ability of each variety to withstand the effects of a severe and changeable winter, such as that during which the experiment was made.

The number of plants of each variety which came to perfection is placed opposite the name of each in the seventh column. This was ascertained by pulling each as they respectively ripened, and counting the plants of each before proceeding to the others. In this way, by a simple subtraction, the numbers contained in the sixth column also were ascertained.

When all the plants of any variety had been pulled, the number of ears also belonging to that was counted, and the results are placed in the eighth column.

By dividing these by 99, the number of square feet which each variety occupied, we obtain the number of ears in each square foot; and this is placed opposite the name of each wheat, in the ninth column.

The average number of ears to each root, ascertained by dividing the number of ears by that of the roots, is placed in the tenth column. This column shows the degree in which each species possesses the important property of spreading and shooting out stems, or, as it is technically termed, of *tillering*; and it will be seen that they vary in this respect greatly.

After having been pulled and dried, the wheat was carefully rubbed out; and, after the light and imperfect grains had been separated, the weight of the remainder was taken, and placed opposite each variety in the eleventh column.

The thirteenth column contains the number of bushels per acre raised from each variety. As the quantity produced was so small, there was some difficulty in obtaining the particulars which this column contains.

The mode adopted was this: The average weight of several of the varieties was ascertained, by weighing 8 pints of each, to be at the rate of 64 lbs. per bushel, some being rather more and others less. The number of bushels were then obtained from the weight of wheat per acre, by dividing it by 64.

The weight of straw, which is placed in the fifteenth and sixteenth columns, was ascertain-
WHEAT.

was kept, an extract from which is given here, as it refers to an insect which was observed after the blossoming of the plants, and to which the destruction of many of the seeds was owing.

Observations of this kind might be easily and generally made, and they would be useful as information regarding the nature and habits of the insects which attack wheat; and answers to the how, when, and where, on the subject, which would thus be obtained, afford the only guide to the invention of means for their destruction.

1838. Extract from Journal.

July 5th.—All the wheat is in blossom, except Nos. 13 and 15.

14th.—Very rainy and windy weather. Whether will this be found to injure or improve the quality of the grain?

16th.—Since the rain of the 14th, an orange-coloured substance, like rust, has been observed in the seed-vessels of some of the ears, as if the rain had got in and rotted the pollen. A very small fly has been observed about the ears in the evening. Many of the ears are filling rapidly; some are already full, and others are only in blossom.

19th.—In the ears of wheat, which were before-mentioned as having abortive grains, owing, as was thought, to the pollen having been rotted by the rain, I now find small orange-coloured grubs, about the tenth of an inch long, doubtless the offspring of the small fly observed about a week ago.

Aug. 4th.—All these grubs have disappeared.

27th.—Nos. 4, 10, and 11, are ripe and pulled.

28th.—Nos. 3, 5, and 6, are ripe and pulled.

29th.—Nos. 7, 8, and 9, are ripe and pulled.

30th.—Nos. 2, 12, and 16, are ripe and pulled.

Sept. 1st.—Nos. 1 and 14 are ripe and pulled.

2d.—Nos. 13 and 15 are ripe and pulled.

The account of this experiment is thus finished, and there now remains but to state what will have already occurred to the reader, especially if he be a practical man, that it is not one nor many experiments, if conducted on a small scale, which will accurately determine the point this tends to ascertain.

Soil.—Although wheat can be cultivated on any soil, yet, in the northern districts, clays, and marls are considered to be the best wheat soils, and the larger the proportion of subsoil in the soil, the heavier will be the grain, and the more productive the crop.

Sandy soils (says a modern writer) are unfavourable to the growth of wheat, for they are deficient in that degree of firmness which is necessary to support the roots of the plants. It is therefore a crop which should never be sown on such land; or if grown, it should only be upon one ploughing of a clover ley, and then afterwards folded by a flock of sheep.

(Brit. Husbandry, vol. ii. p. 140.)

Very fine descriptions of wheat are grown on gravelly, chalky, and flinty soils, which have a dry subsoil.

In England the cultivation of wheat varies in different districts, and according to the nature of the soil. Upon heavy clays, the course of cropping is commonly a twelvemonth's fallow, with from four to six ploughings, &c., and a dressing of manure or lime, or both. On this description of land, wheat also very commonly follows beans, which have been carefully cleaned; and, thirdly, is sown extensively upon clover-leys. On lighter soils, a crop of turnips or rape sown in May, and fed off by sheep early in the autumn, is frequently substituted with advantage instead of a year's naked fallow. And, again, in districts, in which I strongly condemn, is still followed in several parts of England, of sowing dressed or folded rye-grass leys with wheat. (See Rotation of Crops.) On soils adapted for turnips, and where the drill and horse-hoe are employed, a course I much approve from the ley's return, from a small expenditure, consists of: 1st, turnips; 2d, oats or barley; 3d, clover; 4th, beans or peas; and then, 5th, wheat.

The quantity of seed varies considerably; and, although I have witnessed large crops grown from one bushel of seed drilled per acre, the rows at foot intervals, yet the general practice is to plant at from two to three bushels per acre. The time of sowing is from September to March; the winter varieties should be in the ground by the end of November, and the spring varieties as early as the season will admit. For the diseases of wheat, see Fly in Wheat, MildeW, and Rust. And I may observe that, although subject to several diseases, yet upon the whole it is the hardest of the cereal grains, and flourishes under a greater variety of seasons and climate.

Sowing.—Wheat is either sown broadcast, or by the drill or dibble. Drilling is the most preferable mode. When it is sown in drills, the usual distance between the rows is from 9 to 12 inches; but it is conceived that the larger intervals are the better, and that they may in most cases be even more than 12 inches. The best period of sowing, it has been said, is from about the middle to the end of September. The early part of October, however, is well suited to the sowing of wheat, and it may be continued till the middle of November.

The proportion of seed that is necessary must depend upon and be regulated by a variety of different circumstances, but in general from two to three bushels, according to the state of the soil, the nature of the climate, and the period in which it is put into the ground, may be the most suitable proportion for soils of a medium state of fertility, under the broadcast method of husbandry; but where the drill or dibble system of culture is practised, a considerably less quantity may be sufficient for the purpose. See Seed.

In the case of summer-fallow the quantity of seed need not exceed two bushels to the acre. When the sowing takes place in spring, the quantity may be extended to three bushels, rather less than more.

The cultivation of wheat is very rapid by
WHEAT.

either of the following methods: 1. By selecting the grains of superior ears and dibbling them in a seedling bed, 4 inches apart every way. 2. By dividing and transplanting the roots.

The same weight of Rostock and Dantzic flour from wheat grown in the Baltic, made only 23 pounds of bread, very light and good, but not so white by many shades or well-flavoured as that made from the two first varieties of home growth.

These experiments having been made in my own presence, may be relied on. The dough was worked in the French mode, not pushed down, turned and worked with closed hands, but drawn up into long strings, and repeatedly lifted, in order to expose it to the action of the air as much as possible, which tends greatly to improve the bread, by rendering it more light and easy of digestion. See Bread.

The superiority of the hoary variety of wheat, which furnished three pounds more bread on a baking of 18 pounds of flour, or an increase of one-sixth over the Dantzic and Rostock, which was also a very fine sample of flour, is thus clearly established. (Le Couer in Wheat, p. 44.)

Securing the crop.—I have already briefly adverted under the head Reaping to the advantages to be derived from harvesting the grain before it is fully ripe, but have reserved to this place some further experiments and details corroborative of the benefit and profit resulting therefrom, by Mr. John Hannah of North Deighton, near Wetherby. This gentleman remarks,—

“Having selected a field of ‘old square-headed red wheat’ for the experiments, on August 4, 1840, I cut a sheaf. At this time it was quite green, i.e. both straw and ears were in full vigour, and full of sap. Though the grain appeared perfectly formed, the chaff still adhered so firmly to it that it was scarcely possible to separate them by friction in the hands. When separated it was large and plump, but so full of milk, that the slightest pressure reduced the whole to a juicy consistency or pulp.

“This sheaf stood in the field for a fortnight, when it was housed. On the same day, August 18, I cut another. The wheat was, of course, yet ‘green,’ speaking positively, or ‘not ripe,’ if we speak negatively,—being what farmers commonly term ‘true.’ This is the straw, though appearing at a distance green, when examined closely, was of a hue fast approximating to yellow; while, for about a foot upwards from the ground, it was quite yellow. The ears, too, were more open, the chaff tinged with various shades of yellow and green, and the grain itself, when separated, soft and pulpy, but not near so full of fluid as before. The judgment of the farmer will, however, best tell him the conditions of the wheat, both at this and at the preceding cutting, when I say, that in another fortnight the whole field was ripe.

At the end of this fortnight, (September 1,) I housed the sheaf cut on August 18, and which had remained exposed to the weather in the interval, and cut a third. This I have said was ‘ripe;’ but by the term I don’t mean that degree of ripeness when the straw breaks, the ears curl, and the grain shakes out; but that condition in which it is customary to commence reaping it,—when the straw, from the roots to the ear, is uniformly yellow, and has lost all symptoms of vivid health.

“On the 14th of September the third sheaf was taken from the field and carefully preserved, along with the other two, till the 1st of November, when, out of each sheaf, I selected 100 ears, and put each parcel into a separate bag. The straw from each of these parcels of ears was preserved carefully.

“The ears in one bag (No. 1,) or that cut very green) were now thrashed, the chaff carefully separated, and the gross weight of the corn yielded ascertained by an extremely accurate balance. The weights of a fixed measure of a certain number of grains were next found. To avoid error, this was repeated several times.

“No. 2 (cut raw) and No. 3 (ripe) underwent the same process: for the results of which see the following table—

Comparative Weights of Wheat reaped at different periods.

</tbody>
</table>

“As this table is merely comparative (the weights used being in parts, and decimal parts of the same, for the convenience of minute experiments), it may not be unnecessary to give the following table of the absolute weights of each sample in ounces, drachms, scruples, and grains Troy:

| No. 4. | 4 0 0 0 | 3 7 1 3 | 0 1 0 2 |
| No. 5. | 5 4 0 6 | 3 7 2 0 | 0 1 0 15 |
| No. 6. | 5 5 9 7 | 5 5 9 7 | 5 5 9 7 |

“The straw belonging to each sample was now weighed (all the parcels having previously been made of the same length, commencing from the bottom of the ear), when the following was the result:

Comparative Weights of 100 Straws of an equal length, belonging to the samples Nos. 1, 2, 3.

| No. 1. (green)     | 500 | 475 | 450 |
| No. 2. (raw)       |     |     |     |
| No. 3. (ripe)      |     |     |     |

“The next thing to be ascertained was the quality of the produce, or the comparative worth of each description. Believing in the old saying, that

‘The proper value of a thing is just as much as it will bring,’

on the 8th of November I attended market, and asked the opinion of an extensive corn-grower as to the values of the respective samples, according to the prices of the day. His opinion was,

| No. 1. | 50s. per quarter. |
| No. 2. | 64s. 6d. do.      |
| No. 3. | 62s. 6d. do.      |
Putting the same samples into the hands of an extensive corn-factor and miller, his opinion of its value, and what he would give to buy, was for

No. 1. 6 lb. 6d. per quarter.
No. 2. 6 lb. 6d. do.
No. 3. 6 lb. 6d. do.

Adding these values respectively together, and taking the mean price of each (by which we shall obtain as near an approximation to the truth as possible), we have:

No. 1. 6 lb. 6d. per quarter.
No. 2. 6 lb. 6d. do.
No. 3. 6 lb. 6d. do.

"The loss or gain on these samples, by reaping at different periods, will be best seen from the following

Table of the relative Weights and Value of Wheat cut August 4, August 18, and September 1; that cut last (or ripe) being taken as the standard, and unity assumed as its value in each column.

"According to this table, it is evident that the wheat reaped a fortnight before it was ripe has the advantage of the ripe in every point:
1st. In weight of gross produce \(\frac{3}{2} \text{ lb.}\) or \(13\frac{1}{3}\) per cent.
2d. In weight of equal measures \(\frac{2}{3}\) or nearly \(\frac{1}{3}\) per cent.
3d. In weight of equal number of grains \(\frac{1}{2}\) or nearly \(\frac{1}{3}\) per cent.
4th. In quality and value \(\frac{1}{2}\) or above \(\frac{1}{2}\) per cent.
5th. In weight of straw \(\frac{1}{2}\), or above \(5\) per cent.

On the other hand, that reaped a month before it was ripe, has an advantage of \(\frac{2}{3}\) per cent. in weight of straw, compared with the ripe, but in every other point has the disadvantage:

1st. In weight of gross produce \(\frac{3}{2} \text{ lb.}\) or \(11\frac{1}{2}\) per cent.
2d. In weight of equal measures \(\frac{2}{3}\) or rather more than \(\frac{1}{3}\) per cent.
3d. In weight of equal number of grains \(\frac{1}{2}\) or better than \(13\frac{1}{3}\) per cent.
4th. In quality and value \(\frac{1}{2}\) rather more than \(\frac{1}{3}\) per cent.

"It may be here necessary to mention that the sample No. 3 (ripe) was very bold, but rather course, feeling rough in the hand; while No. 2 (raw) was quite as bold, but very fine and thin in the skin. No. 3 (green) was also a good and clear sample, but much smaller than either of the others. This will account for the apparently anomalous fact of there being scarcely any difference in the marketable value of the green compared with the ripe, while there is a difference of \(13\) per cent. in favour of the ripe in weight of equal numbers of grains; for the sample being dry and good, the buyer lost little by this inferiority in the size of grain, as the weights of equal measures were the same,

—-the difference of \(\frac{1}{2}\) lb. of corn for \(\frac{1}{2}\) lb. in the sack.

"Before venturing to draw any deductions from these experiments, let us put their results in a still more practical point of view.

Suppose we have \(3\) acres of wheat, 1 of which, reaped when ripe, yields us \(30\) bushels of corn and \(1\) ton of straw; what will be the gross value of the same? And what the value of the other \(2\) acres, according to the data furnished by the foregoing experiments, supposing each acre to be exactly equal in crop, and the one reaped a fortnight and the other a month before the ripe.

"Before answering this, we must fix a value for the straw—say \(2\) lb. per stone, which, taking into account that used by the farmer himself—and many cannot sell any—is as much as it is actually worth. Whence we have, for the acre of ripe,

\[ \text{L.} \quad \text{each.} \]

\[ \begin{array}{ccc}
\text{30 bushels of wheat, at 6 lb. 6d. per quarter} & & \\
\text{(the price of sample No. 3.)} & & \\
\text{1 ton of straw, at 2 lb. per stone} & & \\
\end{array} \]

\[ \text{Gross produce} \quad \text{£12} \quad \frac{17}{2} \]

"Let us next take the acre cut 'raw'. Before we can come to its value, we must first resolve the question, How much, in measure, will the acre produce us, supposing it to produce 30 bushels, if cut when ripe?

"In solving this, as we must assume each crop to be exactly equal if cut at the same time, it is obvious that, if we would determine the difference caused by reaping at an earlier period, we cannot found our calculations upon the gross weight of the two samples (Nos. 2 and 3): for, although there is no doubt but that this weight was materially affected by the condition of the wheat at the time of reaping (indeed, the difference in the weight of equal numbers of grains proves the fact), it is possible that, in selecting the 100 ears from the sheaf, I might take out of one sheaf ears with a greater number of grains in them than those taken out of the other. This, then, would affect the total or gross weight; and, therefore, it cannot be taken into account in the present case, where both acres are supposed to have an equal number of grains.

"To the weights of equal measures, and of equal numbers of grains, both the result of many careful trials, this objection cannot be urged; and they are amply sufficient to enable us to tell the produce of an acre of 'raw,' when that of the 'ripe' is 30 bushels. Thus, in the first table, we have,

\[ \begin{array}{ccc}
\text{Weight of equal Measures} & \text{Number of Grains} \\
\text{No. 2 (raw)} & 500 & 23 \frac{1}{2} \\
\text{No. 3. (ripe)} & 570 & 22 \frac{1}{2} \\
\end{array} \]

Now put \(n\) = this measure, and \(m\) = the number of grains weighed of each sort; then

\[ \frac{22 \frac{1}{2}}{22 \frac{1}{2}} : \frac{570}{500} : \frac{22 \frac{1}{2}}{22 \frac{1}{2}} = \text{the weight of one grain} \]

of No. 3, whence

\[ \frac{22 \frac{1}{2}}{22 \frac{1}{2}} : \frac{570}{500} : \frac{22 \frac{1}{2}}{22 \frac{1}{2}} \]

\(n\) = the number of grains of No. 3 in the measure \(m\).

Again, similarly, \(n\) = weight of one grain of No. 2, and

1125
WHEAT.

$\frac{23\ 25}{m} = \frac{1}{508} = \frac{508n}{22\ 75} = \text{the number of grains of No. 2 in the measure } m$.  
And $m = \frac{570n}{22\ 75} = \frac{22\ 75m}{570n} = \text{the space occupied by one grain of No. 3 (ripe)}$; and  
$m = \frac{570n}{22\ 75} = \frac{22\ 75m}{570n} = \text{the space occupied by one grain of No. 2 (raw)}$.  
Now, as there are the same number of grains upon each acre, and as the acre of ripe yields 30 bushels, we have  
$23\ 75m = 22\ 25m = \frac{22\ 75m}{30} = 30 \text{ bushels} = 30 \times 130737133 \text{ bushels, the produce of one acre cut a fortnight before the ripe.}$  
Again, by reference to the second table, we have 1 and 1, as the relative weights of the straw No. 3 and No. 2; whence, as No. 3 is supposed to produce one ton,  
1: $1\frac{1}{2} = \frac{160 \text{ stones}}{168 \frac{1}{4} \text{ stones}}$, the weight upon the acre reaped when raw. And for the whole produce of the acre, we have  
$$\text{13} \begin{array}{l}
\text{L.} \\
\text{d.}
\end{array} \begin{array}{c}
\text{r.} \\
\text{d.}
\end{array}$$

Adopting the same course for the produce of the acre cut first, i.e. a month before the ripe, and which corresponds with sample No. 1, we get  
$56\frac{1}{4}n = \text{the number of grains of the green in the measure } m$; whence $19\ 725m = \text{the space occupied by one grain of green}$.  
But (vide above), $22\ 75m = \text{space by one grain of the ripe}$; whence $\frac{22\ 75m}{570n} = \frac{30 \text{ bushels}}{56\frac{1}{4}}n = 26\ 1356 \text{ bushels}$, the produce of the acre cut a month before the ripe. And (vide "Table of relative weights," &c.)  
1: $1\frac{1}{2} = \frac{160 \text{ stones}}{168\frac{1}{4} \text{ stones}}$, the produce of the same; whence we have  
$$\text{11} \begin{array}{l}
\text{L.} \\
\text{d.}
\end{array} \begin{array}{c}
\text{r.} \\
\text{d.}
\end{array}$$

The total products of the three acres stand thus:

Showing a loss of 11. 5s. 5d., or about 10 per cent., by cutting very green; and a gain of 10s. per acre, or nearly 4 per cent., by reaping in a raw state, or a fortnight before it was ripe.  
"From the above details, it would appear that it is the farmer's interest to cut his wheat before it becomes thoroughly ripe. Many, no doubt, will be disposed to doubt deductions of such importance, drawn from such limited experiments. This objection the writer anticipates, because it is a natural one, which he felt himself, when he considered the most important conclusions which resulted; when, however, he retraced, step by step, his investigations, without any variation in that result, he could no longer refuse to believe it true till he proved it untrue. He is aware that there are other points of consideration in this subject—that there are peculiarities in the nature of land, of seed, or of season, and that there is, as in all man's investigations, a possibility of error; any of which circumstances might materially affect the result of experiments upon so limited a scale as the present one; and for this reason he will, if all be well, give the subject a trial in the ensuing harvest, on a much more comprehensive scale. That the results of these experiments will be corroborative in the main points, he has no doubt, and for this cause he feels no hesitation in laying the preceding 'details' before the agricultural world; moreover, as he has in no case given a deduction without the grounds upon which it rested, the degree of 'acception' which the reader may give it rests with himself. The most skeptical, he, however, flatters himself, will think it 'worthy of being tested, if of nothing more."

"In testing, however, the conclusion which the foregoing experiments warrant, there are some other advantages which strengthen that conclusion, which must not be forgotten. That they have not been considered in the preceding pages, is not because they are of no import, but, on the contrary, because they are of such consequence, that the writer could not assign them an adequate momentary value. And had he attempted to do so, he would have at once made the details of his experiments valueless by mixing the real results of practice with the imaginary ones of opinion. Before the subject, however, can be thoroughly sifted, they must be considered. The circumstances are these:—independently of the 4 per cent. gain (according to the foregoing experiments) by reaping our wheat a fortnight before it is ripe, we have  
"1st, Straw of a better quality.  
"2d, A better chance of securing the crop; and  
"3d, A saving in securing it."

"1st, 'Straw of a better quality.' This is easily demonstrated, both for the purpose of food and manure.  
"As an article of food, the value of any vegetable depends upon the gross quantity, or upon the combination of certain substances termed soluble, from their entering into union with water. This rule applies particularly to the grasses which are used for the purpose of feeding stock. The substances generally found in these grasses are saccharine matter or sugar, mucilage or starch, and gluten or albumen, and bitter extract and saline matters. Of these the sugar is, no doubt, the most, and the extractive matter the least, nutritive; the latter having been found, by experiment, to come away in the dung of the animal consuming it, while the other matters were absorbed by the body.  
"Now, wheat is a species of grass, and the value of the straw, as an article of food, depends upon the quantity of nutritive matter contained in it. This nutritive matter must be very small in straw, as now generally used,' the practical farmer will say, 'for straw per se is but poor food, and scarcely able to sustain life.'
WHEAT.

This is true; 'from 400 grains of dry barley-straw,' says Sir H. Davy, 'I obtained 8 grains of matter soluble in water, which had a brown colour, and tasted like mucilage. From 400 grains of wheaten straw I obtained 5 grains of a similar substance.' With this paucity of nutritive matter in the straw before us, how can we account for the fact that, in the sap of wheat, the straw, and in all succulent plants, there is naturally a great proportion of mucilaginous and saccharine matter? The answer is this: in all grasses and succulent plants, the greatest proportion of this is present before the flower is dead ripe. So in wheat, when we allow the straw to remain till thoroughly ripe, a portion of the sugar is converted, by the action of light, heat, &c., into mucilage, and a great proportion of the nutritive powers of the grass absorbed by the atmosphere, or lost in some manner; for, as Mr. Sinclair observes in his Report of Experiments of Grasses, *there is a great difference between straws or leaves that have been dried after they were cut in a succulent state, and those which are dried (if I may so express it) by Nature while growing. The former retain all their nutritive powers, but the latter, if completely dry, very little, if any.*

As a manure, too, the straw cut 'rake' is equally valuable. It is, as it were, an agricultural axiom, that the better the food of an animal is, the better the manure from it; the manure from a stock consuming this straw, containing a fair proportion of nutritive matter, must be more valuable than that from stock consuming the ripe with scarcely any in it.

"But a great proportion of the farmer's straw is converted into manure without undergoing the process of mastication and digestion. For this purpose the unripe straw is equally preferable, as all maturé vegetables are manures without preparation: the soluble and nutritive extract which it contains being the principal agents in forming vegetable manure; as they not only combine to render the process of decomposition the more rapid, by breaking down the woody fibres, &c., in the manure heap, but are also, in their pure and separate states, stimulants to vegetation.

"It may be urged, that the increased value of the straw is more in favour of that cut very green (No. 1) than that cut a fortnight later (No. 2). This is true; but to produce this increase of value, if we cut our wheat so early as No. 1, we have a destruction of the grain to such an extent as to diminish the measured produce above 12 per cent.; while, by reaping with No. 2, we are, so far from injuring either sample or measure, actually improving both, and at the same time gaining above 5 per cent. in the weight, and at least as much in the quality of the straw. For the increase of weight in the latter is not produced by a greater produce, but by the presence of a greater portion of those soluble substances which are alike necessary to animal and vegetable life—are alike the nutritive part of food and the quickening principle of manure.

"2d. We come now to the second advantage, the 'better chance of securing the crop.'

"This is self-evident. We gain a fortnight at the commencement of harvest. If the weather be good, we can secure a great portion of our wheat before we should scarcely have begun upon the old system. If not, we can wait; so, under any circumstances, our chances of securing the grain must be greater. Moreover, if we take a retrospect of the harvests for a number of years, we shall find that nearly all the early harvests have been what we term 'good' ones, i.e. good as regards weather and the condition in which the grain was secured. When the peculiarities of our climate, its general fickleness, and its still greater liability to change as the autumn advances, are considered, this will explain how the sugar in this straw is absorbed.

"If we look, too, at the later harvests, we shall. I venture to say, find, that in nine cases out of ten, the grain which was first cut was secured in the best condition. As an example of this, the crop of 1839 will suffice. The crops were late, the beginning of reaping the same, and the result was, that in the North of England full 75 per cent. of the whole wheat crop was damaged. And full 75 per cent. of that which was undamaged, I will also venture to say, was that which was cut the first. In Yorkshire this was especially seen; for the earliest wheat was the greatest damaged. In this village (North Deighton) not a sheaf was in stack till the day before, and on some farms, the very day on which the rainy weather set in.

"The frequent recurrence of such years as this, will teach the value of even a fortnight, better than any thing that can be said here. And that they will recur is beyond a doubt. What has happened once may happen again, but what has frequently happened (as this sort of harvest has), with the same causes in operation, we are warranted in saying will happen again, and often.

"3d. The saving in securing the crop is a double one. In the first place, there is less waste in moving or reaping, and no danger of 'shaking' or 'necking' in strong winds. In the second place, there is an absolute economy in the expense of reaping the crop, which may be thus illustrated.

"The busy period of harvest with the farmer generally extends over four or five weeks. In this month a certain portion of his work is done by his own hands, i.e. by the regular labourers and servants of the farm; therefore, by beginning a fortnight sooner, and extending the season of harvest over six weeks instead of four, it is evident that these regular servants would cut a much greater proportion of his crop—in fact, one-half more. By this he is rendered less dependent on those extraneous 'helps' or 'takers' who, in the seasons of hurry and anxiety, fix their own terms.

"To assign a value for these advantages is, as has been said before, for the farmer himself; and it will not be an insignificant one. For if beginning harvest a fortnight earlier enables him to save a crop from spoiling once in a lifetime,—if the improved quality of his straw as food for his stock allows him to plough out an acre more, or to pasture another acre of clover with feeding-stock, instead of mowing it for his lean stock, every grain saved, every extra bushel
of corn produced, and every extra head of stock fed, is a benefit to the whole community as well as to the farmer himself—so much added to the gross produce and wealth of the country: there being, in fact, an increased return without an increased outlay." (Quart. Journ. of Agr. vol. xii. p. 24.)

In a recent obliging communication, with reference to this important subject, made to me (March 1842), by Mr. John Hannam, he observes in reference to the experiments above detailed, "At the time I wrote you last I stated that the bulk of the wheat reaped by me during the present harvest was unbrashed. I could therefore only give one idea of the quality of the raw and the ripe by public opinion from a sample sheaf. Since then the various cuttings (for I made several) have been thrashed and ground. The result of which was, 3½ bushels of the ripe gave 10 st. 11 lbs. of good flour, 1 st. 9 lbs. of seconds (technically termed 'sharps'), and 2 st. 5 lbs. of bran; 3½ bushels of raw gave 12 st. 6 lbs. of flour, 12 lbs. of sharps, and 2 st. 1 lb. of bran. From which it appears that the raw cut wheat gave 6½ lbs. of flour to the bushel more than the ripe gave, while the latter gave 3½ lbs. more sharps and 1½ lbs. more bran than the former per bushel of grain, which is the result of the effect of early reaping upon the vegetative powers of the seed I have not answered, because I can give no answer but what depends more upon opinion than fact. I have never seen a practical trial made of wheat, as seed, in the various conditions necessary to warrant a final and definite conclusion. An American writer, commenting upon my experiments, while he coincides with my conclusions as incontrovertible, says that it is 'equally indisputable' that the ripe wheat is preferable for seed. For all this, I am not disposed to assent blindly to any such doctrine, because I have seen early cut wheat used with perfect success as seed many times."

The editor of the Cultivator, in noticing these facts, remarks:—"A farmer friend of ours, growing wheat extensively, found last season that one of his fields of wheat, then in a very raw or green state, was badly struck with rust. He determined to cut it at once, and did so, amid the laugh or pity of his neighbours, who thought him little better than crazy. The adjoining fields suffered little from rust, and stood till fully ripe; yet, at thrashing, the wheat first cut gave the finest wheat and the best yield." Mr. Hannam mentions a similar instance, in which it was remarked of a farmer who was cutting his wheat earnestly, that he "had cut grass, and stacked muck;" when threshed it yielded four bushels per acre more than it had been estimated at, and was sold for the highest price in the market. In this country, the same reason, arising from bad weather or a late harvest, does not exist for early cutting, as in England; but there are others which render the subject of little less interest here than there; and the agricultural public of both countries are certainly much indebted to Mr. Hannam for the skill and perseverance with which he has pursued these investigations in all their parts.

The editor of the Cultivator proceeds to notice the experiments reported by Mr. Hannam, and in so doing exhibits the results in a manner calculated to be more striking than the statements recently presented in detail. It appears, says the editor, that J. Hannam, Esq., a farmer of Yorkshire, England, made an experiment in cutting wheat by reaping at five different times from the same crop, with the following results as to the time of cutting and value of the produce of an acre, which he sets down at 28 bushels:

<table>

</tbody>
</table>

"It thus appears," says Mr. Hannam, "that No. 3 (cut two weeks before it was fully ripe) is superior to all other varieties; giving more per bushel than No. 5 (cut when fully ripe) by 4½ lbs. of flour, and gain of about 15 per cent. as to the flour of equal measure of grain, and fibres of wheat of No. 3 makes 80 lbs. of flour; while 100 lbs. of No. 5 yields 72 lbs.; showing an average of 8 per cent. in favour of grain cut raw. In grinding, it was found that No. 5 ground the worst—worse than No. 1. In No. 5 were a greater quantity of flinty particles, which would not pass the bolt, than in any of the others. The bran from No. 5 was coarse and heavy, while that from No. 3 was 'thin as a bee's wing.'"

Mr. Hannam extended his experiments to some length, and sums up the advantages of cutting wheat two weeks before it is fully ripe, as follows: first, there is a gain of 15 per cent. of flour upon equal measures; second, a gain in the weight of straw of 14 per cent.; third, a gain of about 163 in the value of every quarter of wheat; and, fourth, a gain of about 583 upon every acre producing 28 bushels. These calculations are founded upon the price of wheat in England, at the time the experiments were made. The flour produced from No. 3 was of a far better quality than that produced from the grain cut at any other times.

Producer.—The fair produce of wheat (as is well known to the skill of Husbandry) varies so much upon different kinds of land, and is so much governed by climate and mode of cultivation, that it is difficult to form any accurate estimate of the amount or average quality in ordinary seasons and under the common course of management; it may, however, be fairly calculated at 3 quarters, or, perhaps, 28 bushels per imperial acre. To produce the latter quantity, circumstances must, however, be favourable, and anything beyond that may be considered large, though on some land 4 to 5 quarters are not unusual. The weight may average 60 lbs. per bushel. The straw is generally reckoned to be about double the weight of the grain; an acre producing three quarters of wheat of the
ordinary quality may therefore be presumed to yield about 26 cwt.

The use to which the grain is applied is almost exclusively that of food in various preparations, and chiefly in that of bread, though a considerable quantity—but generally of an inferior or damaged kind—is employed in the manufacture of starch. This preference is due, not only to the superiority of its nutritive properties, but also to their peculiar nature; for "more water is consolidated in bread made from barley, and still more in that from oats; but the gluten in wheat being in a much larger quantity than in any other grain, seems to form a combination with the starch and water which renders it more digestible than any other." (Letters on Agric. p. 121.)

Since the Western States have become thickly settled, and so much of their rich lands been brought under tillage, especially since the completion of numerous canals and rail-roads have opened ready markets in the commercial cities, they have poured into these such vast quantities of wheat as have reduced the price and tended greatly to lessen the profits of husbandry in the old Atlantic States. At present, more than a third of the whole wheat crop in the Union is produced west of the mountains, and the proportion is every year rapidly increasing. By reference to the tabular statements of crops (art. Agriculturix) it appears that Ohio stands at the head of the wheat-growing states; her product in 1839 having been estimated at over 16,500,000 bushels. Pennsylvania stands next, having furnished that year upwards of 13,000,000 bushels. The produce of New York is estimated at over 12,000,000; and of Virginia, 10,000,000 for the same time. These four large states raised upwards of 52,000,000 of the total amount of 84,828,272 bushels produced that year in the whole United States.

The aggregate of the wheat crop of the United States for 1842, has been estimated at 102,317,540 bushels. (Ellsworth’s Report to Congress.) The Governor of Ohio, in his message, computes the wheat crop of that state in 1842, at no less than 24,000,000 bushels, of which, he thinks, 14,000,000 may be allowed for exportation, after deducting 10,000,000 for domestic consumption. Some idea of the rapidity with which the wheat crop increases in the Western States, may be formed from the fact, that, in 1840, the amount of wheat shipped from Chicago to Buffalo amounted to only 20,000 bushels, whilst, in the following year, 1841, it amounted in the same period to no less than 200,000 bushels.

The United States present almost boundless facilities over an immense extent of fertile territory for raising wheat. But, great as the aggregate crop at present appears from the preceding statements, it scarcely exceeds that of the comparatively insignificant limits comprehended by the United Kingdom of Great Britain. Notwithstanding her immense domestic product of wheat, England is compelled to import annually many millions of bushels from other countries, for only a small portion of which is she indebted to the American farmers, who have for so long a period worn their cloths and tilled their ground with implements of British manufacture. In 1841, when the imports of foreign wheat into the kingdom amounted to 21,604,940 bushels, the proportion received from her great customer the United States, only amounted to 2,528,600 bushels.

In June, 1840, Lord Palmerston, the British prime minister, caused letters to be addressed to the British consuls in various parts of Northern and Southern Europe, from which wheat is extensively exported. These letters contained certain queries relating to points connected with the grain-growing countries and their markets. A great many highly interesting facts were elicited in the answers to these circulars, many of which have been condensed in the following tabular form.

Other facts elicited by these inquiries with respect to other countries competing with the agricultural interests of the United States, may be interesting. Among these are the following:

It appears that in the grain-growing districts in Europe, the soil continuous to seaports has already been extensively tilled, and cannot be pushed further without the aid of artificial minerals, while the bad roads from the interior shut them out from a competition with this and other countries more favourably situated.

Thus in Russia: The corn districts are too
remote from the seaports for the grain to be ready, in season, for exportation; the rapid increase of manufactures has withdrawn from tillage, &c.

In Poland, there is a deficiency of manure, and scarcity of hands, and want of skill in cultivation.

From Odessa, the report is that the crops are precocious, on account of drought; tillage is defective, and improvement difficult; distances great; no roads; the rivers unnavigable; the landholders impoverished, and no improvements to be expected.

It may also be gratifying to some to compare the transportation of flour, &c., from Poland (one of the greatest grain-growing districts) and the United States to England.

From Poland to Dantzic, the grain is chiefly brought from the interior in flatboats of the rudest construction, similar to those in use on the western waters of the United States, at an expense of 25 cents per bushel, open to the weather, &c. During the voyage the wheat sprouts, and forms a thick mat or covering for the bulk. On reaching Dantzic, the boat is broken up and sold, the wheat taken out and dried in the fields, then stored in the warehouses at an expense of 6 cents per bushel. From Dantzic to England the freight, &c., not including the duty, is nearly 6d. — equal to about 15 cents per bushel; making in all about 46 cents per bushel. From Illinois to Liverpool the whole freight would be 14s. 6d. per quarter, or 1s. 6d. — equal to 28 cents per bushel; being about 8 cents in favour of Illinois. There are costs and charges also, in both cases, which would probably be in favour of our export.

In this connection, it may be interesting to compare a detailed estimate of the exports of wheat from Illinois to England, both by New Orleans and Canada.

Illinois wheat, via New Orleans to Liverpool.

| Wheat, 4½ bushels, at 50 cents, is | $2.37 |
| Grinding and barreling (with oil) | 50 |
| Freight to New Orleans | 62 |
| Freight to Liverpool | 68 |
| 415 |

which is a little less than 90 cents per bushel. Charges would be alike in both cases.

View the matter in another point of light. Suppose the wheat or flour of the Western States carried through Canada, and, after the 6th July, to pay 3s. on an imperial quarter, viz., (8 bushels), which is about 8½ cents per bushel: Foreign wheat would have to pay, at the present sliding rule, about 60 cents per bushel.

The United States, therefore, could succeed with the greatest competitor; but that competitor could not supply 1,500,000 bushels,—less than the surplus of some of the smaller states of this Union produce; and, indeed, all Europe could not supply England with more than 18,000,000 bushels, under the most favourable circumstances,—about three-fourths as much as the state of Ohio now furnishes.

It may be remarked, too, that the crops on the continent are far more precarious than those of the United States; and hence the continental governments find it necessary, and are careful to reserve large granaries, to guard against such a misfortune as a failure of the usual harvest. Exportation thence is also forbidden in certain cases, but in the United States no such prohibition exists.

While, therefore, we may look with confidence to advantages in our favour in the British market, we must remember that competition against almost unpaid labour, and cannot expect a great profit on our culture, unless the very cheapest mode of production is studied. Labour (as we have before remarked) must doubtless fall very considerably in agricultural districts, or else farmers and planters cannot hire. (Ellsworth's Report.)

With regard to the different kinds of wheat cultivated in the United States, some are best adapted to one latitude and soil, some to another. The fine varieties which succeed so well in England and other parts of Northern Europe, very often fail in the United States, and the most common difficulty with them arises from the circumstance of their tardy habit of maturing, which exposes them to rust and mildew. Seeds from the southern parts of Europe and shores of the Mediterranean, are those which seem best adapted to the climate of the United States, since these mature very early. A fine red variety, now commonly known as the Mediterranean wheat, is being very extensively cultivated. It seems to have improved under culture in the United States in the essential qualities for making flour, since the millers, who at first objected to it and would only purchase at a reduced price now pay the same as for other red wheat. This wheat has been already mentioned as resisting the attacks of that great American scourge of wheat crops, the Hessian fly.

For the following valuable table, showing the exports of flour from the United States, during a long series of years, with the prices per barrel, we are indebted to Hunt's Merchant's Magazine.

Exports of Flour from the United States, and Price, from 1795 to 1843.

</table>

From these tables it appears that, during the period 1795 to 1810, which embraced the European wars, and when the population of the United States averaged 5,000,000, the exports
of flour averaged nearly 1,000,000 barrels per annum, at near $10 per barrel, or an export of 1 barrel to every 5 inhabitants. During the non-intercourse, from 1807 to 1811, the price fell very low; and in 1812 the export was resumed, and was so large that the rate again rose very high, so high as to check the export. Under the high successive tariffs of 1824-28-33, the export of flour declined, and with that decline prices fell; until after 1834, when debt and state stocks were exported in return for foreign goods, instead of the legitimate export of produce, and the rage of speculation, by checking agriculture, produced actual scarcity, which again brought up prices. The revulsion drove people to work, and the large crops of 1839, assisted by a scarcity in England, caused a great export, which, with the 1,000,000 barrels sent forward in 1841, raised the value of the whole crop $1.50 per barrel, or 25 per cent. in that year. The surplus of those two years may be estimated at 2,500,000 barrels. According to the census, there were produced in 1839, in round numbers, 8,000,000 barrels of flour, and the product of 1840 was estimated at 12,000,000 barrels, worth $60,000,000. The export of one-sixth part, or 2,000,000 barrels, raised the price to $6.50 in 1811, or the value of the crop to $78,000,000; making a difference, in favour of the farmer, equal to $18,000,000 or 30 per cent. (Hunt's Mag.)

The average price of wheat may be estimated pretty correctly from that of flour, by adopting the miller's rule of computing the price of a bushel of wheat weighing 60 lbs. at one-fifth the price of a barrel of flour. See Bread, Flour, Fly in Wheat, Grain, Grain Flour, &c.

Previously to 1822, the monthly returns of the importation and consumption of foreign and colonial corn were collected together, in annual periods, commencing on 1 January, and terminating on 31 December. From 1823, downwards, they have been made up, like the other accounts of this department, in periods, commencing on 1st January in each year, and terminating on 31st January, in the year succeeding. This circumstance is necessary to be noted, inasmuch as it explains why the aggregate imports and consumption of the several years, from 1823 to 1825 inclusive, as exhibited in the present statement, will be found to differ, to a small extent, from the quantities shown in other accounts, which have been compiled, not, as in this case, from special monthly returns of the corn trade, but from the ordinary records of the general commerce of the country.

Statement of the Septennial Prices of each Kind of Grain, as prepared for the Purposes of the Tithe Commission, in each Year, from 1835 to 1841.

WHEAT, COW (Melampyrum, from melas, black; and pyros, wheat). A genus of branched, spreading, annual, nearly smooth herbage, growing to the height of twelve or eighteen inches. The seeds, which resemble grains of wheat in shape and colour, turn black in drying. There are, in England, four indigenous species of cow-wheat, namely:

1. Crested cow-wheat (M. cristatum), which grows in woods and thickets, and sometimes in corn-fields, flowering in July. Flower rather small, not quite closed, variegated with cream colour and light purple; the palate yellow. The seed-vessel is a crescent-shaped capsule, containing two large seeds in each cell.

2. Purple cow-wheat (M. arvense). This species grows in corn-fields on a light soil, and flowers in July. Stem 1 ft. high, purplish, nearly quadrangular; the branches more upright than in the foregoing. Leaves lanceolate, rough-edged. Spikes long, many-flowered. Bracts loosely spreading, deeply pectinated or pinnatifid, the upper ones entirely, and the lower ones partially, coloured of a delicate purplish rose colour. The flowers are large and scentless. The seeds are two or three in each capsule, but one is often abortive. This is one of the most beautiful of English wild plants. It will grow from fresh seeds in a dry garden, and is well worthy of cultivation.

3. Common yellow cow-wheat (M. pratense). Pl. 7, q. This is a very common species in woods and bushy places, especially on clay or loamy soil. It flowers in July and August. Stem smooth, with several wide-spreading branches. Leaves bright green, lanceolate. Flowers axillary, solitary, opposite, turned in pairs to one side. The capsules have a curved point. Cows are reported to be fond of this plant; and Linnaeus says the beat, and yellowest butter is made where it abounds.

4. Wood cow-wheat (M. sylvaticum). This species grows in alpine woods, especially in forests of fir. It agrees with the last in general habit, but is rather smaller, especially the flowers, and the capsule is less pointed.

Two or three species of cow-wheat are found in the United States.

WHEAT-GRASS (Triticum). Of this genus, to which belongs our cultivated wheat, there are five species indigenous to England.

1. Sea rushy wheat-grass (T. junceum). which is frequent on the sandy sea-coast, is a perennial, and flowers in July. The root, with its widely creeping, numerous woolly fibres, is well calculated for binding the loose sand, which purpose it serves in common with Elymus arenarius, Arundo arenaria, &c. The whole plant is glaucous and rigid, like those grasses. Stem 12 or 18 inches high, simple, inclining, smooth, even and polished, tinged with a bright violet hue below, striated above. Leaves involute, sharp-pointed.

2. Creeping wheat-grass, or couch-grass (T. repens). Pl. 10, a. This is a common pest everywhere, in waste as well as cultivated land. The long-jointed, creeping root-stock, or...
rhizome, strikes so deeply and widely as to be very difficult of extirpation. It is, in fact, an underground stem, vivacious, and consequently shooting up stems and leaves at every joint. The stem above ground is slender, 2 feet high, and leafy. Leaves linear, flat, of a dull, somewhat glaucous green, most numerous on the lower part of the stems. But the plant is so well known that it requires no description. Poking out the roots after the plough is doubtless the best mode of extirpating this noxious weed; but the process must not be discontinued while a particle of the root-stock is suspected to remain in the soil, as the least portion will grow, and the land being so much broken and loosened by the operation, gives double encouragement for the rapid growth of the plant. It does not thrive well when combined with other grasses, but is naturally more common in hedges. The root-stock contains a large proportion of nutritive matter; it is esteemed abroad for feeding horses. At Naples the root-stocks are collected in large quantities for this purpose, and brought to market. The nutritive matter from the leaves contains an excess of bitter extractive and saline matters. Dogs eat the leaves, and also those of the Holcus avena- cenis, to excite vomiting; hence it is sometimes called dog's grass, and in other places bears the name of quitch or quickum. See Cow-Rye.

3. Fibrous-rooted, or bearded wheat-grass (T. caninun). This differs essentially from the common couch-grass last described, in having the root fibrous, without a rhizome. It grows in woods and shady hedges on a chalky or limestone soil. The stems are 2 feet high, very smooth. Leaves nearly upright, lanceo- late, taper-pointed, thin, flat, bright green, rough on both sides. As this grass yields a large supply of early spring herbage, and produces a sufficiency of seeds, which vegetate quickly on all soils except such as are tenacious or retentive of moisture, it might be cultivated to advantage as a source of an article of food instead of rye-grass. But for soils of the best quality it does not, as yet, uphold a sufficient stand of the spike being objectionable, and the produce of the latter-math very inconsiderable.

4. Crested wheat-grass (T. cristatum), a native of Scotland. The roots of this species consist of several long, strong woolly fibres, suited to a sandy soil. The culms are ascending, 12 or 18 inches high, simple, rigid, slender, leafy; hairy at the top. This grass seems well adapted, from its comparative merits, for cultivation on light heath soils; the produce of early herbage in the spring being superior to most of the alpine grasses, or those which affect sandy dry soils. The latter-math is productive, and very nutritious. It flowers about the second week of July, and the seed is ripe about the end of August.

5. Dwarf sea wheat-grass (T. loliaceum). This is an annual species, growing on the sandy sea-coast, flowering in June and July. The root is formed of many long downy fibres. Stem rigid and wiry, branched from the bottom, generally 2 or 3 inches high, but various in luxuriance, leafy, very smooth, and polished, erect or decumbent. Leaves linear, acute, nearly smooth, involute when dry.
use. At the same time the proprietors and drivers of carriages seem to be convinced, by experience, that a narrow-wheeled cart is more easily and speedily drawn by the same number of horses than a broad-wheeled one of the same burden; probably because they are much lighter, and have less friction on the axle.

WHEE'LO-PLUGH. See Plough.

WHEY. A provincial term applied to the serious part of the milk, from which the curd has been separated.

Whew, when new and of a pale green colour, forms an agreeable beverage, and with oatmeal makes an excellent gruel or porridge. Left till it gets sour, it undergoes the vinous fermentation as readily as buttermilk. Among the Tartars and Scythians a spirituous liquor is prepared from milk which has undergone fermentation.

Whew is divided into two sorts, green and white; the former escaping readily from the curd, while the latter is freed from it by means of pressure. There are different methods of extracting the whey. In some dairies the whole whey, when taken from the cheese-tub, is put into a great or other vessels, where it remains for about 24 hours; when it is creamed, and the whey is applied to the use of calves and pigs, which are said to thrive as well on it after the cream has been taken from it as before. The cream, when skimmed off the whey, is put into a brass pan and boiled, and afterwards set in pans or jars, where it remains till a sufficient quantity for churning is procured, which in large dairies happens generally once, but sometimes twice, in the week. In Ayrshire whey is given to horses. See Dale and Milk.

WHEY BUTTER, as its name implies, is butter made from the whey which is taken from the curd, after the milk is coagulated for the manufacture of cheese. It is chiefly made in those counties where cheese is manufactured, and where it forms no inconsiderable part of the profits of the dairy. In the county of Derby, more butter is said to be made from whey than from the cream of milk, or from milk churned altogether. A similar preparation in the United States goes under the names of cottage cheese, schmeer case, &c.

WHIN, or GORSE. See Furze.

WHISKY. A spirit obtained by distillation from corn, sugar, or molasses, though generally from the former. Whisky is the “national spirit,” if we may so term it, of Scotland and Ireland; but that distilled in the former is generally reckoned superior to that of the latter.

WHITE CROPS. A term used in England to designate crops of grain, such as wheat, barley, oats, &c.

WHITE-ROT (Hydrocotele; from hydor, water, and eziele, a cavity; in reference to the plants growing in moist situations, and the leaves being hollowed like cups). One species only is indigenous, the common white-rot or marsh penny-wort (H. vulgaris), which grows very frequent on moist heaths, boggy commons, and the margins of little clear rivulets. It is perennial in habit, flowering in May or June. The roots are fibrous; stems creeping to the extent of 2 or 3 feet, slender, smooth, often subdivided, quite prostrate. Leaves solitary or aggregate, on upright, simple foot-stalks, 2 or 3 inches high; orbicular, peltate, smooth, cloven at the base. Umbels very small, of diminutive white or reddish, nearly sessile flowers. Fruit somewhat wrinkled, compressed. This herb is acrid, and, probably, like others of the umbelliferous tribe growing in wet places, poisonous. But whether it causes the rot in sheep, and, indeed, whether these animals ever touch it, is doubtful. Too moist a pasture is known to produce that disease, and there the Hydrocotele is generally to be found. See Rot.

WHITE-THORN. See Hawthorn.

WHITE-TOP (Agrostis alba). See Herb’s and Yellow-Top.

WHITLOW-GRASS (Draba, from drabe, acrid, biting; alluding to the taste of the leaves). Some of the species of this genus are very pretty, being well adapted for ornamenting rock-work or growing in pots among other alpine plants. A mixture of loam and peat suits them best; and they increase with facility, either by dividing at the root or by seed. There are in England five native species: the common whitlow-grass (D. verna); the yellow alpine whitlow-grass (D. aizoides); the simple-haired whitlow-grass (D. hirta); the twisted-podded whitlow-grass (D. incana); and the speedwell-leaved whitlow-grass (D. muralis). The leaves are undivided; the flowers either white or yellow.

WHORLLEBERRY (Vaccaaria). A genus of shrubs mostly of very humble growth, with simple, alternate, evergreen, or deciduous leaves. Flowers stalked, solitary or aggregate, reddish or white, very elegant. Berries blue, black, or red, acid and eatable. The genus is chiefly American, and the foliage turns red in decay. All the species are well worth cultivating, some of them for the sake of their fruit, some for curiosity, and others for ornament. The different kinds of whortleberry and bilberry succeed well in peat soil or very sandy loam. Some of them grow best in moist situations, and others in dry. They may be raised from root suckers, creeping roots, trailing rooting stems, or from seeds. There are four indigenous species, namely—

1. In England the black whortleberry or bilberry (V. myrtillus), a shrub growing on stony heaths, and in woods where the soil is sandy, chiefly in mountainous countries, abundantly flowering in May. The stem is bushy, from 1 to 2 feet high, with irregular, smooth, green, leafy, angular branches. Leaves stalked, ovate, serrated, about an inch long, bright green, smooth, thin, delicate, and reiny; deciduous. Flowers on simple, axillary, solitary, drooping stalks. Corolla ovate, bright red, with a waxy transparency. Berries bluish-black, of 5 cells, acid, but not agreeable nor wholesome except when dressed. They are, nevertheless, eaten raw in some countries with boiled cream and sugar. The leaves contain a good deal of tannic acid, and have been substituted for those of Vino urui, as an astringent medicine, but are very inferior to them.

1. Bog whortleberry or great bilberry (V. 1140
WHORTLEBERRY. WILLOW.

uliginosum), grows on boggy, mountainous heaths, and is common in the Highlands of Scotland. It flowers in May. Tallier than the preceding, with round branches. Leaves obovate, entire, smooth, deciduous. Flowers several together, flesh-coloured. Berries large, bluish-black, less acid, and less wholesome than the former.

3. Red whortleberry, or cowberry (V. vitis idea). This species grows on dry, stony, turfy heaths, or in mountainous woods, in many parts of Scotland, Wales, and the north of England. It is plentiful in Derbyshire. It is an evergreen, flowering in June. The roots are creeping; stems erect, 3 or 4 inches high, with a few irregular, downy, leafy, downward branches at the summit. Berries globose, deep red, astringent, and acid, with much bitterness, which they lose by immersion for some hours in water before they are made into pies, rob, or jelly. In the latter state this fruit is excellent for sore throats, as well as for eating with venison or other roast meat, as is practised generally in Sweden. The leaves of this species are often mistaken for those of Uva ursi. They contain much astringent matter, and are little inferior to Uva ursi as a medicine.

4. Marsh whortleberry, or cranberry (V. oxycoccus). This species grows in clear, watery, turfy bogs, among mosses. The roots are creeping, with many long fibres. Stems slender, wiry, trailing, and creeping, with numerous leafy branches. Leaves ovate, entire, smooth, revolute, acute, perennial. Flowers very elegant, drooping, on simple red stalks, several together at the end of each branch. Berries spotted in an early state, finally deep red, very acid, highly grateful to most people in tarts or other preparations with sugar; though in Sweden they serve only for the acid liquor to boil sugar plate in, to eat away the minute external particles of the copper alloy.

Mr. Nuttall enumerates twenty-three species of whortleberry, or huckleberry, natives of the United States, 17 of which are deciduous, and 8 evergreens. The following is his enumeration:

1. Leaves deciduous.

1. Vaccinium stamineum. Berries large, partly pyriform, and green when ripe; bitter and scarcely edible. 2. album. 3. arborum. The largest species of the genus in North America; branches divaricate; flowers partly as in V. stamineum; berries rather dry but sweet, with a granular pulp, dry, downy, naked, or nearly so; berries perfectly black in appearance, conspicuously crowned by the persistent calyx. 5. frondosum. Berries and under side of the leaves glaucous; fruit large and rarely copious; agreeable, but quickly deliquescent, and subject to be infested by the larva of insects. 6. populin. 7. resinosum. Flowers reddish, angular. Fruit not much esteemed. 8. coriaceum. Fruit subacid, and agreeable, as well as that of the following.

9. angustatum. 10. virgatum. 11. fuscatum. 12. galeæus. 13. luzularium. 14. tendulum, sometimes called sugar-huckleberries, small and rather too saccharine, but a very agreeable fruit, brought in great quantities to the Philadelpia market. 15. uliginosum. The European whortleberry. 16. myrsilloides. 17. sciponum.

2. Leaves semipervirent.

18. Vitis idea. Berries scarlet, farinaceous, and insipid. A small subsalpine species, indigenous also to the north of Europe. 19. myrsifoenum. 20. crassifolium. A variety probably of the following. 21. nitidum. Branches procumbent and repent. From Virginia to Georgia. 22. myrsinites, 23. laxifolium. 24. ovatum. 25. obtusum. These two last are indigenous to the northwest coast.

Vaccinium is a North American genus, with the exception of 3 species in Europe, 1 in Jamaica, and the island of Tahiti, in the Pacific, indigenous to Madeira and Cappadocia, and 3 in Japan.

The species first named by Mr. Nuttall, is what is commonly called in the Middle States squaw huckleberry and deerberry, the stems of which are low. The 5th species, or leafy vaccinium, is commonly called blue huckleberry, and blue-tangles. The stems grow from 2 to 5 feet high. The large and dark blue berries of this species are a very agreeable fruit. The 7th species, or resinous vaccinium, is commonly known in the Middle States by the appellation of black huckleberry; the fruit of this has larger seeds than the species last described, and, though pleasant, is not so much esteemed. The 8th species, or corymbose vaccinium, is what is known in the Middle States as the swamp, or tall huckleberry, a stout shrub, growing from 5 to 10 feet high, yielding abundantly large berries, one-third of an inch in diameter, purplish-black when ripe. Some other species, especially the V. fuscatum, and V. amœnum, are confounded with this by some naturalists. The 14th species is also called the Pennsylvania vaccinium, and commonly the sugar-huckleberry. The stem of this is from 1 to 2 feet high, and much branched. The berries are much sweeter, and correspond with a little silvery powder or bloom when mature. The product is very abundant and the fruit sweet and pleasant.

In Kent county, Delaware, a new species or variety of whortleberry has been recently discovered, the fruit of which is of a beautiful rich white colour with a yellowish tinge. The flavour is extremely pleasant, and free from the least harshness or astringency. They are of course exempt from the objection to the common kinds, that of staining the teeth and lips.

In the valley of the Columbia river a new species of bushberry has been discovered, called Parthenocissus.

WIKES. A provincial term in England, signifying temporary boundaries or marks, set up to divide swath, to be mown, such as boughs in the common fields, or meadows. Also boughs set upon haycocks for tithes, &c.

WILD OATS. A name given to the tall oat-like soft grass (Holcus arenacus). A noxious weed in arable lands. See Holcus.

WILD PEAR TREE. See JUNE BERRY.

WILLOW (Salix; from sal, near, and lus, water (Celtic); in allusion to the place of its growth). Vigorous and rapid in growth, it has the rapidity of its growth). An extensive genus of well-known useful and ornamental trees
and shrubs. They all delight to grow in swampy places, and are increased by cuttings, though some of the more rare alpine kinds root with difficulty. There is no tribe of trees of such various magnitude as the willows, from the large white willow to the minute *Salix herbacea*, six of which may be placed between two leaves of a duodecima, roots, stems, leaves, and flowers. Many of the species of willow, under the names of osier and sallow, are extensively grown for the manufacture of basket-rods; the best sorts for which are the great round-leaved sallow (*S. caprea*) and the common osier (*S. viminalis*). The branches of some of the species, as stakes, poles, handles to rakes, hoes, and similar articles of a great variety of economical purposes. Loudon (Arb. Brit.) says, "In the north of Europe the bark of *S. alba* is used for tanning leather, and for dyeing yarn of a common cinnamon colour; and the leaves and young shoots are given to cattle in a green state, or dried like the twigs of the birch, and laid up for winter fodder." The bark, however, is less valuable than that of the twig of the other species. The leaves of the least willow (*S. herbacea*), soaked in water, are employed in Scotland for tanning leather. (Paxton's Bot. Dict.) The arrangement of the species of willows is a matter of controversy; *S. alba* and *S. caprea* are held by the followers of Linné as an allied unity; while *S. herbacea*, *S. viminalis*, and the rest are considered by others as distinct genera. Among the numerous species of willows there are only a few which are cultivated for farm purposes: of these we shall enumerate and describe the following:—

1. The long-leaved triandrous willow (*S. triandra*). This tree is very common in wet woods, hedges, and osier grounds. It is of an upright form, rising naturally, when not injured, to the height of 30 feet; towards autumn casting the bark of its trunk and larger branches in broad, solid portions, cracking angularly asunder, like the plane tree. The young branches, in contrast to those of the English willow, are more smooth, leafy, brownish, somewhat brittle at their joint of insertion. Leaves linear-oblong, serrated, smooth, rather unequally sloping at the base. The narrower-leaved willows generally come under the denomination of osiers, of which this is one of the most valuable. It is cultivated for white basket-work, producing rods 8 or 9 feet long, tough and pliant, even when stripped of their bark, and very durable. They are cut down every year. There are several varieties of this species; one, called the French willow, is cultivated in Sussex and the eastern counties of England; it is more slender in form, and only about 12 or 15 feet high.

2. Bedford willow (*S. Russelliana*). When this tree was first recommended for cultivation, by the name of the Leicestershire, or Dishley willow, it was regarded with scorn as "only the crack willow" (*S. fragilis*), a sort notoriously useless. This ignorance and prejudice are now removed, and this willow is found the most profitable for cultivation of any species of the genus, for the value of its timber as well as bark, the rapidity of its growth, and the handsome aspect of the tree. This species of willow was first brought into notice by the late Duke of Bedford, who engaged an able chemist, Mr. Biggin, to make experiments upon it. It was found to contain in its bark more of the tanning principle than any other tree of England, except the oak. The bark also contains the largest quantity of salicina, a salt which has been found useful as a substitute for the quinia and cinchona in agues, and which is much less liable to excite irritation in the stomach than the salts of the cinchona. It is of great importance that the distinctions between this willow and the crack willow (*S. fragilis*) should be clearly pointed out, on account of the wide difference in their qualities and value. This tree is more handsome than the crack willow, and in its mode of growth, as well as altogether of a lighter or brighter hue. The branches are long, straight, and slender, not angular in their insertion, like *S. fragilis*; and the trees, when stripped of their leaves, may always be distinguished by these marks. They are polished, very tough, flexible, round, and smooth. Leaves lanceolate, tapering at each end, serrated throughout, and very smooth. Those of *S. fragilis* are ovate-lanceolate; the foot-stalk, also, is longer than the scale, whilst in *S. fragilis* it is so short that the leaf is nearly sessile. In both it is glandular or leafy.

3. Bitter purple willow (*S. purpurea*). This is a shrub growing in low meadows about the banks of rivers and ditches, but not common. The trunk is 3 or 4 feet high, with long, slender, very smooth branches, spreading widely, and, if not supported, trailing on the ground, of a rich and shining purple, with a somewhat glaucous hue. Leaves partly opposite, obovate-lanceolate, serrated, very smooth, narrow at the base. This is a very valuable osier for fine basket-work, but more especially for plaiting into law, close fences, to keep out hares and rabbits; the leaves and bark being intensely bitter, those animals will not touch either. The twigs, moreover, are so long, tough, and flexible, that they may be put into any shape, and kept very close to the ground, as they always retain their horizontal mode of growth. Such a fence is scarcely inferior to one made of wire, and is, perhaps, more durable, as continually producing young shoots, to supply the place of those that decay. It is important to distinguish this useful and elegant willow from that to be next described. The bark contains much salicina.

4. The rose willow (*S. helix*) grows in marshes, osier holts, and about the banks of rivulets. It is a tree of humble growth, erect, about 10 feet high; the lower part, together with a lighter hue than the last. The branches not trailing, but upright, smooth, and polished, of a pale yellowish or purplish ash colour, tough, and pliable, less slender and elongated than the foregoing species, though useful for the coarser sorts of basket-work. Leaves partly opposite, oblong-lanceolate, pointed, slightly serrated, very smooth, linear towards the base. Their colour a light, rather glaucous green, turning blackish in drying. The leaves and twigs are less bitter than the former, and the greater size of the trunk, as well as branches, renders this species fit for several purposes which that is not. It also
WILLOW.

makes a better figure in plantations, and the roots give more solidity to the banks of rivers or ditches.

5. Common white willow (S. alba). This is a tall tree, whose bark is thick, full of cracks, useful for tanning; and, as yielding much salicin, good also for the cure of agues, though inferior in quality to that of the true Bedford, or Huntingdon willow. The bark is called coriander salicinum, and anglicanum by some writers. The branches are numerous, spreading widely, silky when young. Leaves all alternate, elliptic-lanceolate, pointed, serrated, silky on both sides; the lowest ramifications glandular. There is a variety which is very superior in the value of the wood and bark, and the rapid growth as well as handsome aspect of the tree, to the original species. See Osier and Sallow.

The willow genus contains more than 130 species, chiefly distributed over the northern parts of Europe and America. Many of the species are alpine. Only 4 have as yet been found indigenous to South America, whilst in North America botanists enumerate upwards of 25 indigenous kinds. Some of these are mere shrubs.

The black willow (S. nigra) is the most common of the American willows, and the most analogous to that of Europe. It is less multiplied in the Northern and Southern than in the Middle and especially in the Western States. It is found on the banks of the great rivers, such as the Susquehanna and the Ohio, and is called black willow, or simply willow, in America.

The common black willow is rarely more than 30 or 35 feet high and 12 or 15 inches in diameter. It divides at a small height into several divergent but not pendent limbs, and forms a spacious summit. The leaves are long, narrow, finely dentilculated, of a light green, and destitute of stipulae. In the uniformity of its colouring the foliage of this species differs from that of the European willow, the lower surface of which is glaucous.

Upon the trunk the bark is grayish and finely chapt; upon the roots it is of a dark brown, whence may have been derived the specific name of the tree. The roots allow an intense bitter decoction, which is considered in the country as a purifier of the blood, and as a preventive and a remedy for intermittent fevers.

The wood is white and soft, and the branches are easily broken from the tree. Neither the wood nor the twigs are applied to any useful purpose. (Michaux.)

Michaux describes two other species of American willow. One, from being found on the shores of Lake Champlain, he calls Champlain willow (S. aegostigma). It grows 20 to 25 feet high, with 7 or 8 inches diameter, and very much branches. The black willow, except that the leaves are longer and narrower. The other is the shining willow (S. lucida), so called on account of the brilliancy of its foliage. This Michaux found only in the Middle and Northern States. It is found in moist but open grounds, and is more common on the edges of the salt meadows than in the interior of the forests; it is also seen on the islands, not covered with woods, in the rivers, and near the shores of the lakes.

This species is easily distinguished by the superior size of its leaves, which are oval-acuminate, dentilculated, and sometimes 4 inches in length.

The shining willow attains the height of 18 or 20 feet; but its ordinary elevation is 9 or 10 feet. Basketry is made of its twigs differently to those of the European willow, which are preferable, cannot be obtained; but it possesses no property that recommends it to attention.

Many species of willow are found in the United States and in Canada, the greater part of which are susceptible of no useful employment. The three species described are distinguished only by their superior height; but even these are generally inferior to the European willow in size and in the properties of their wood. In the Northern and Middle States, particularly in Pennsylvania and in some townships in the lower part of New Jersey, great numbers of the European willow have been planted, of which light baskets are fabricated for the market of Philadelphia. This tree furnishes the charcoal for the manufacture of gunpowder. (Michaux.)

The common yellow willow is the S. vitellina of botanists. It is also frequently called golden willow, and by some egg-yolk willow. The French call it Le Saule. This, says Dr. Darlington, was early introduced here as a shade tree, and has become partially naturalized in many places. I think I have never seen any but the pustilloj; a variety with paler bark (perhaps the S. alba of the Florists) will not long be met with.

The handsomest S. labychaste, or weeping willow, is more generally preferred as an ornamental shade tree, and the pustilloj plant of that species is extensively propagated about houses, but it can hardly be said to be naturalized.

WILLOW-HERB (Epilobium, from epi, upon, and lobos, a lobe; the flowers have the appearance of being seated on the top of the pod). Many of the species of this genus are very ornamental, as E. angustifolium; while a few others, such as E. montanum, are mere weeds. They are all grown with in any ordinary soil, and are either increased by seeds or by dividing the roots. The indigenous species are nine, namely, the rosebay willow-herb (E. angustifolium), the great hairy willow-herb (E. hirtinum), the small-flowered hoary willow-herb (E. parviflorum), the broad smooth-leaved willow-herb (E. montanum), pale smooth-leaved willow-herb (E. roseum), square-stalked willow-herb (E. tetragnum), round-stalked marsh willow-herb (E. palustrum), chickweed-leaved willow-herb (E. alismifolium), and the alpine willow-herb (E. alpinum). These are all perennial herbs, with simple, generally toothed, leaves; flowers mostly purple, in terminal leafy clusters or spikes, without scent. The most common of these are—

1. The rose-bay willow-herb (E. angustifolium), which grows wild in meadows and moist shady places, chiefly in the north of England. The root is creeping, fibrous, with numerous buds, stems from three to six feet high, erect, roundish, leafy, smooth, reddish, seldom branch-
WINE.

ed. Leaves scattered, numerous, nearly sessile, linear-lanceolate, acute, various in breadth, velvety, smooth. Flowers crimson, inodorous, very handsome, numerous, in long terminal upright clusters. This is a very ornamental flower and produces a dish of flowers which are very common, but too rapidly; thriving, like many mountain plants, even in the smoky air of London. There is a white variety. 2. The great hairy willow-herb (E. hirsutum). This species is very common in England in all watery places, ditches, and the margins of rivers; among reeds, coarse grasses, and willows. It has an extensively creeping root. The whole herbage is downy, soft, and clammy, exhaling a peculiar but tranitory acidulous scent, justly compared to the flavour of boiled codlings and cream. Stems four feet or more in height, round, leafy, copiously branched, and bushy. Leaves half, clasping the stem, ovate-lanceolate, hairy.

WINDROW. A term signifying in England the green parts, or borders of a field, dug up, in order to carry the earth on other land to mend it; so called because it is laid in rows, and exposed to the wind. It is also applied to a row of peats or a line of hay exposed to dry, and also to turfs cut up in paring and burning.

WINE (Vinum, Lat.; vin, Fr.; vino, Ital. and Span.; vinho, Portu.; wein, Germ.; wijn, Dutch; vin, Swed.; vin, Dan.; vino, Russ.) A well-known agreeable, and, when moderately used, wholesome liquor, prepared from the juice of the grape, and that of some other fruits. The invention of wine is involved in the obscurity of the earliest ages. The sacred writers, however, lend us to believe that it must have been known before the deluge; for we are informed that the patriarch Noah, immediately after that overwhelming event, "began to be a husbandman; and he planted a vineyard; and he drank of the wine, and was drunken" (Genesis, ch. ix. v. 20, 21), a sufficient reason for supposing that it was a fermented liquor, and not merely the simple juice of the grape. It is, indeed, natural to imagine, that in those countries where the vine is a native, the spontaneous fermentation of the juice of the fruit, when it was expressed, either purposely or accidentally, and not immediately used and consumed by the fowl, would do well on them, if boiled. These seeds would very much infest samples of fen corn, whether wheat, oats, or barley. As a weed in fen soils, this plant is the most ramping and cumbersome of any weed that grows.

WIND. See Weather.

WIND-FLOWER. One of the names of the marsh gentian. See Gentian.

WIND, in HORSES. See Broken Wind and Roaming.

WINDMILL. A well-known contrivance for grinding corn or raising water, which is put in motion by the action of the wind upon its sails or vanes. They are of two kinds, vertical and horizontal, but the former is generally preferred. Since the extensive introduction of improved horse power, hand, and steam machinery, windmills are becoming much less common throughout the country; and from depending entirely upon the caprice of the weather, they are only suited to elevated or exposed situations, where they will catch every passing breeze; and are much less useful than water-mills, which can generally be kept at work continuously, or for a much longer period. A set of arms and sails might be advantageously used in some situations for pumping up water from a well into a trough or cistern for cattle, or for the purposes of irrigation.

In the West Indies, a simple apparatus of this kind is employed for grinding the rice which is flailed in the farm-yard. The velocity of the sails of a windmill, in a moderate wind, was calculated by Mr. Ferguson to be thirty miles an hour.

WIND-PLANT. Wood or Grove Anemone (A. nemorosa). An American plant, with a perennial root, found in the moist woodlands and thickets of the Middle States, flowering in April and May. Flowers white, often tinged with purple.

WILLOW-LICE. See Aphidians.

WILLOW-WEEED. In England, a name applied in the fens to the snake-weed, or pale-flowered persicaria (Polygonum lapathifolium), an annual plant, which grows very freely on all loose and deep soils, and on marshy lands, though it be scarcely known to any of the cultivators of clay, and it is as rarely to be seen on any sort of turnip land. This plant grows commonly from 18 inches to 2 feet; its stalks are tender and succulent, pale, spotted, or redish; the joints much swollen. The plant branches most when it has free growth, and produces a great number of crowded spikes of seeds. The leaves resemble those of the willow, but are charged with dark spots in the middle. The seeds are very bright and heavy, highly nutritious, and therefore very grateful to birds, especially partridges. Those who keep decoys for catching wild ducks will buy the seeds in abundance from the fowl. Pigs will do well on them, if boiled. These seeds would very much infest samples of fen corn, whether wheat, oats, or barley. As a weed in fen soils, this plant is the most ramping and cumbersome of any weed that grows.

WINE. See Weather.

WIND-FLOWER. One of the names of the marsh gentian. See Gentian.

WIND, in HORSES. See Broken Wind and Roaming.
Moselle and St. John, probably an Italian sweet wine, were added to the imports. But for a considerable period the foreign wines were not drunk in their genuine form, but were mixed with honey, sugar, orange juice, and even opium. Chaucer, in the *Knight's Tale*, speaks of

"A clarete (clarete) made of certain wine, With narcotic and ophe of Thebes fine."

These mixed wines received different names, according to the nature of the wine employed. When made with Burgundy or Bordeaux, the mixture was called Bishop; when with old Rhenish, its name was Cardinard; and when with Tokay, it was dignified with the title of Pope. In the reign of Edward II. the taste for sweet wines prevailed; and consequently we find the wines which Alsace then furnished, which were chiefly sweet, were much used. In the time of Elizabeth, the profusion and diversity of wines displayed on the tables even of the citizens of the metropolis, and the inhabitants of the southern provinces, almost exceeded belief. Harrison, in his account of the mode of living in England in that reign, states, that there were upwards of eighty-six different wines in use; "whereof," he adds, "Vernage, Cote-piquem, Raspin, Muscadell, Romnie, Bastard, Tire, Oscie, Caprique, Clarece, and Malmesbury, are not least of all, accustomed of, because of their strength and value." (Hollishead's *Chron.* p. 167.) Sack, with which all familiar who have read the works of our immortal dramatist, was a dry Spanish wine; but sugar was often added to it, with the view, as Venner informs us, to lessen the hot and penetrative quality of the wine. In truth, the best sack (for there were several kinds in use) was that of the growth of Xerez, or in other words sherry. In *Pasquill's* *Palinode*, published in 1619, this is stated in the following lines:

"gim me sacke, old sacke, boys, 
To make the mouses merry; 
The life and health, and the joy of earth, 
Is a cup of old sturdy."

The Spanish wines still retained the first place on English tables, at the commencement of the seventeenth century. After this they declined, the preference was, however, given to the Canary wines, more of which, Howell (Familiar Letters, part ii. 60) informs us, "was brought into England than to all the world besides." Champagne appears to have been unknown in Britain until a present from Louis XIV. of two hundred hogsheads of wine, consisting of Champagne, Burgundy, and Hermitage, was sent to the king of England; but it was long after this time unknown to those not connected with the court, and, therefore, it was regarded, as Venner terms it, "a regal wine." Even at this period, however, although much wine was drunk, yet few persons kept a stock of it in private cellars; the chief consumption was in taverns. The war with France in 1689 introduced the use of the wines of Portugal, particularly the red wine, or port, as a substitute for the growths of Bordeaux; and the celebrated Methuen treaty, which obliged us to receive the wines of Portugal in exchange for our woollen manufactures, and at one-third less rate of the duty levied on French wines, confirmed the taste of Englishmen for this strong and intoxicating beverage, a taste which is again happily, as respects health and longevity, on the decline.

From the foregoing sketch it is evident that the English taste in wine has varied considerably at different periods. For five or six centuries, the light wines of France and the banks of the Rhine were in the vogue; but sweet wines, the Mediterranean and the Archipelago, were in high estimation. Then came the dry Spanish wines; and at the close of the seventeenth century the red growths of the Bordelais were in most frequent demand; which, however, owing to the wars with France, were given up, and the rough wines of Portugal substituted for them. But, as we have already said, the use of these is now on the decline, and our growing intercourse with the continent has revived the taste for light wines. (Henderson's *History of Wine*.)

As far as concerns what is denominated home-made wines, there is in England scarcely any, if we except the gooseberry (intended to imitate Champagne) and raisin wine, that merit any notice. Indeed, it is an incontrovertible fact, that grapes ripened on walls and trellises are in general unfit for the manufacture of wine; and, in England, those cultivated under glass are too valuable for the dessert and other purposes, in their recent state, to be employed for making wine. Still, however, to make home-made wine forms one of the occupations of the wife of a farmer, and tolerable wines are made with a mixture of raisins and grapes cultivated in the open air, in favourable seasons. The principles of wine-making are the same, whatever kind of fruit is employed: in knowing, therefore, the manufacture of grape-wine, it is easy to modify the process, so as to render it applicable to every other description of wine. The juice of the grape, when chemically analyzed, is found to consist of a considerable portion of sugar and water, mucilage, tannic acid, bitartrate of potassa, tartrate of lime, phosphate of magnesia, chloride of sodium, sulphate of potassa, and a mucilaginous substance. The fermentative process productive of the wine depends. Thénard, a distinguished French chemist, assures us that this substance excites the vinous fermentation by abstracting a portion of oxygen from the sugar, by means of its carbon, forming carbonic acid gas, whilst its hydrogen and the remaining oxygen and carbon of the sugar are converted into alcohol, the basis and exciting principle of all wines. When the must, or expressed juice of the grape, is exposed to a temperature of 65° Fahr., this chemical change or fermentation commences; an intestine motion takes place in the liquor; bubbles are evolved, which buoy up the grosser matter, increasing the bulk of the mass, and forming a scum upon the surface. An augmentation of temperature now takes place; the must loses its saccharine taste; it acquires a deeper colour than before, and a vinous flavour, which increases with the advancement of the process. After a few days, the fermentation gradually subsides, the mass returns to its original bulk, the scum sinks to

144

5 p 2

1145
the bottom of the vessel, the liquor becomes transparent, and it is now wine. The constitution of the must is liable to be greatly influenced by the quality, the variety, the climate, and the culture of the grapes, as well as the nature of the seasons. In a cold year, owing to the deficiency of the saccharine matter, the wine is weak, harsh, and acescent; in wet seasons it is devoid of a competent quantity of spirit: high winds and fog are also injurious.

In England, the mode of training the vine has been adopted; and the advantage of making the fruit into wine. In the best wine countries, it is never allowed to grow more than 3 or 4 feet high; and it is found that the bunches nearest to the soil, if they do not touch it, are always the richest. It is a mistake to suppose that sweet wines are the most susceptible of decomposition; on the contrary, they can be kept for almost an indefinite length of time without undergoing any deleterious change. All wines continue to suffer a certain degree of fermentation after they are racked off and put into casks; and as long as the saccharine matter is supplied to maintain this slow fermentation, the wine becomes stronger, when that is exhausted, the acetous fermentation begins, and the wine is converted into vinegar.

Admitting, however, the goodness of the fruit, and the wine to be made consequently expected to be excellent, many circumstances may destroy that hope, for the process does not proceed in the regular manner above described, unless certain rules be strictly observed: these are the following: 1. The grapes should be well and equally bruised or trodden; for the juice that first flows contains little uncesaricin matter, and consequently does not ferment freely. That substance is contained chiefly in the insoluble organized parts and the skin, which also contains the greatest part of the acid, the resinous extractive, and the colouring principle. 2. The fermentation should be conducted at a temperature of 60° to 65° Fahr., below which it languishes, and above which it proceeds too violently. When it progresses too slowly, that evil may be remedied by the addition of a little boiling must. 3. The contact of air is essential in the commencement; and this affords another reason for the good bruising of the fruit, as much air is absorbed in that stage of the process. But after the fermentation is established, the air should be excluded, for the sake of preserving the aroma; and to secure this, the French chemist, Chapital, who paid much attention to the manufacture of wines, recommends the vats to be covered with boards and linen cloths. 4. The greater the bulk of material, the more perfect the wine. 5. When the wine is perfected and racked off, it should be sulphured by burning sulphur-matches within the casks intended to contain it, in order to restrain, within a certain degree, the further fermentation.

When good wine is actually produced, much of the advantage expected from the possession of it depends on the future management and preservation of it; for every wine contains within itself the sources of both improvement and decline. The chief points to be attended to are guarding against vicissitudes of tempera-

WINE.
WINE.

In noticing, therefore, the dietetic properties of wine, we must take society as we find it, not as it ought to be constituted. The stimulating operation of wine is exerted on the nerves of the stomach, and the secreting powers of that organ are influenced by these; and thus a beneficial effect results when the digestive powers are depressed. This, in a great degree, depends on the alcohol contained in the wine; yet it is a fact, that the same quantity of brandy diluted with water, to the strength of wine, will cause intoxication more speedily than when it is taken in the form of wine, especially if the wine contains no uncombined alcohol. The stimulating power of wine, however, depends on the quantity of alcohol in its composition; but this power is much greater in those wines that contain adventitious and imperfectly combined spirits. On this account, Port-wine is more apt to derange the stomach, and to cause intoxication, than Sherry of the same strength; and Claret or Rhenish less than either. But besides the evils arising from wines containing uncombined brandy, those wines that contain much acid are usually deleterious to persons of sedentary habits, or who have weak stomachs. Indeed, the daily use of the best wine can only be supported with impunity by those who take much exercise in the open air. But, if we admit that wine is a necessary article of life for the healthy, there can be only one opinion respecting the superiority of the better kinds of Bordeaux. Whatever wine is taken, it should not be conjoined with other sorts, as nothing impairs digestion more than mingling several sorts of wines.

Such are the general effects of the moderate use of wine; its abuse is so well known, both in reference to mind and body, that it is unnecessary to make a single remark, in this place, upon the subject, except to caution those who feel no immediate injurious effects from a pint of Port, or indeed of any wine, daily, not to rely too confidently upon their apparent powers of resisting its evil influence; for a foundation may be slowly formed for maladies, that, when they appear, are always difficult of cure, and often altogether irremediable.

With respect to the comparative value in reference to the wholesomeness of different wines, a few remarks may be necessary, before concluding this article. Among the brisk wines, Champagne is the least noxious, even when it is drunk to excess, the excitement is of shorter duration, and the subsequent exhaustion is less. It is said to be hurtful to the gouty; but gout is almost unknown in the province where it is made; and more of the evil said to be caused by Champagne is due to the variety and the nature of the dishes, and the period of the day at which they are eaten, than to the wine itself. The red wines of Burgundy are strong, heating, and consequently intoxicating, and they should only be taken in very small quantities. The Bordeaux wines, as we have already stated, are the safest for daily use. They certainly do not excite inebriety so rapidly as most other wines. The wines of Oporto abound in astringent matter, and in uncombined brandy. They are unfit for weak stomachs; they tend to cause sleep rather than to elevate the spirits, and they are the most pernicious as daily beverage. The Spanish wines, especially Sherries, are less objectionable, but they should never be drunk without dilution with water, unless for medicinal purposes. The same opinion may be hazarded with respect to Madeira; and perhaps no wine is more suited to the hypochondriac, if hypochondriasis be absent. The best light wines of the Rhine and the Moselle are, of all others, the most wholesome. They contain little alcohol, and that little is wholly combined. They prove, in many instances, refrigerant, and have a tendency, from the nature of the acid which they contain, the tartaric, to diminish obesity. Lastly, all sweet wines are apt to disorder the stomach; and when used freely they intoxicate as readily, and cause as deleterious subsequent effects as the stronger wines. But, after all, we must revert to the opinion, that wine is an unnecessary article of diet for all who are healthy and robust; and must truly be regarded, beyond certain limits, either as a medicine or a poison. (Henderson's History of Ancient and Modern Wines; Macaulay on Winemaking.) See Alcohol and Vine.

Account of the Quantity of Foreign Wine retained in England for Home Consumption, in Wine Galloins, from 1789 to 1836.

WINNOWING-MACHINE. A contrivance employed for separating, by an artificial current of air, the chaff from the grain, after it has been threshed out of the straw. Various are the accounts (remarks Mr. J. A. Ransome in his Treatise on the Implements of Agriculture) given of the introduction of this machine, and many the claimants for the credit of having been the first maker of this piece of mechan-
ism in England or Scotland. All, however, agree that the idea, design, or model was originally furnished from Holland, earlier, however, than the date of any of these by at least a period of twenty years. We learn from the papers of Robert Somerville of Haddington, that in 1710, pursuant to articles of agreement between himself and Fletcher, laird of Soutlan, James Meikle (father to Meikle of thrashing-machine memory) visited Holland for the purpose of learning "the perfect art of sheeling barley," in order to the introduction of the barleys-mill. The same authority, 1805, states, "that on Meikle's return he made the first fan-ners which were seen in Britain,* and that these were in use only a few years before that date at the Soutlan barley-mills. That the machine was not made public till many years afterwards may be attributed to a clause in the above-mentioned agreement, by which Meikle was bound, on leaving Soutlan's service, "not to profit any more by this mill, nor communicate the arts he had learned to any other." In 1737, through the medium of Rogers of Cavers and others, it was brought into more general use; and in 1768, A. and R. Meikle obtained a patent for a machine of this kind. Although a very considerable advantage over the plan of dressing by hand, these still appear to have been but little understood; the corn having to be passed through them twice or thrice, in order to be perfectly separated. And in 1798, R. Douglas, in his Agricultural Survey of Roxburgh-shire, remarking upon these defects, mentions an improvement invented by one Moodie of Lilliesleaf, "in which he had happily combined some properties of other fans, so that the grain at one operation could be both separated from the chaff and lighter seeds, and completely riddled of all sorts of refuse."

Other patents had been taken out which do not appear to have involved much real improvement; in 1801, J. Cooch of Northampton patented the machine which has since been known by his name, and has obtained deserved commendation, being in use and approved beyond most at the present day. This machine dresses all kinds of seeds, and its work is performed in a perfect manner: its principle involved more mechanical combinations than were at that time generally understood by the class for whose use it was intended; and this, together with its then cost, retarded its more general adoption.

In 1812, John Elmy obtained a patent for improvements in winnowing-machines, and produced a very efficient implement; the arrangement of its various parts were simple, and greater effect was obtained from the blast. Comparing this with the drawings and description of one we find in the Edinburgh Journal of Agriculture, and with that described by Professor Low, we have little doubt of their general identity with this, the model upon which the machines in general use are now made.

In 1839, T. F. Sailer obtained a patent for a machine for winnowing and dressing corn and seeds, which at the R. A. S. E. meeting at Cambridge was exhibited, and obtained the silver medal.

In this invention are combined the princi-
WINTER CHICKWEED. See Chickweed, European.

WINTER-CRESS (Barbarea, on account of its being formerly called the herb of St. Barbara). There are, in England, two indigenous species; 1. The bitter winter-cress, or yellow rocket (B. vulgaris), a perennial, which is common in rather moist waste ground, about hedges, or in marshy meadows. The root is tapering, somewhat woody; stem about 2 feet high, simple or branched, leafy, stout, angular, and furrowed. Lower leaves lyrate, the terminal lobe roundish; upper obovate, toothed, strongly ribbed, of a fine texture, quite smooth. Flowers bright yellow, in round-headed corymbose clusters. Pod quadrangular, about an inch long. The whole herb is nauseous bit- ter, and in some degree mucilaginous. A double-flowered variety, with innumerable petals produced in long succession, and turning white as they fade, is frequent in gardens. 2. Early winter-cress (B. proecea). This biennial species is found in watery, grassy places, or on the banks of ditches, from 3 to 6 ridged, seldom more than 1½ or 2 feet high, smooth, a little branched, tinged at the bottom with a violet tone. Lower leaves lyrate; upper deeply pinnatifid, with linear, oblong, entire segments; flowers fewer,

smaller, and paler than those of B. vulgaris. Pods thrice as long as in that species, exactly square, smooth. This species propagates itself abundantly by seed, but the root is not perennial. It may be eaten like water-cresses, with which it agrees in flavour, except being rather more pungent.

WINTER-GREEN (Pyrola, from the leaves being similar to those of the pear tree). A genus of very pretty plants, rather difficult to cultivate. A shaded peat border appears to suit them best, and they are readily increased by divisions of roots or seeds. The whole genus is astringent and tonic. There are, in England, five native species, all perennials, as follows—1. Round-leaved winter-green (Pyrola rotundifolia). 2. Intermediate winter-green (P. media). 3. Lesser winter-green (P. minor). 4. Serrate winter-green (P. secunda); and, 5. Single-flowered winter-green (P. uniflora). They all inhabit alpine wooded localities; the flowers are white or reddish, often highly fragrant. P. uniflora is one of the most curious and elegant of British flowers.

WINTER-GREEN, American (Pyrola umbellata), Pipsissewa. The Chimonaphila umbellata of Nuttall. This plant is very abundant in cool situations in the United States. It has a long creeping root, and ascending stem 3 to 6 inches long, leafy at the top. The leaves are of a deep green and very glossy, possessing a peculiar flavour, some bitterness, and a moderate degree of astringency. Under the Indian name of Pipsisseua, this plant has been long noted as a popular medicine. It has doubtless some virtues, but its properties are very often misapplied in its empirical use. The Spotted Winter-Green (Pyrola maculata), is also a common plant in the United States, erroneously called Pipsissiwa by Pursh. Its properties are similar to those of the first-named species, though weaker. Five or six additional species of the Pyrola genus are found in the United States.

WINTER-PROUD. A term provincially applied to wheat which in winter puts on a more green and luxuriant appearance than it is able to support in the following summer; or in which the ramifications become too numerous to be kept up, or brought to maturity, from the previous over-exertion of the soil. In these cases the crops decline during the spring and summer, and at harvest yield imperfectly, and running much below other crops which had a more backward appearance in the winter.

WINTER-WEED. A name given, in Norfolk and other parts, to the ivy-leaved speedwell (Veronica hederifolia). See Speedwell.

WIRE-WORM (Elater segesis). These are larve of that tribe of insects named Elaterides, or click-beetles, which are readily known by having the sternum produced behind into a strong spine fitted to enter a groove in the abdomen situated between the intermediate pair of legs. By bringing these parts suddenly into contact, the insects are enabled to spring to some height, and thus throw off their natural position, when they happen to fall on their backs, which they frequently do, when dropping from plants to the ground. A special provision of this kind is rendered
WIRE-WORM.

necessary, in consequence of the shortness and weakness of their legs. The wire-worms have a long, slender, and cylindrical body, covered by a hard crust, which has obtained for them the above name. They are composed of twelve segments fitting closely to each other, and are provided with six conical scaly feet, placed in pairs on the three segments next the head. The latter is furnished with short antennae, palpi, and two strong mandibles or jaws.

Upwards of sixty different species of these insects occur in Britain, and it is probable that a considerable proportion of them feed upon the most valuable cultivated plants. The same species of larva does not appear to confine itself to one kind of food, but attacks indiscriminately the roots of grain and other grasses, as well as esculent roots, such as turnips, carrots, radishes, &c. But it is at the same time deserving of notice, that as a strong similarity prevails among larvæ specifically distinct, it is probable that different kinds may often have been confounded, and a more correct knowledge may prove them to be more restricted in their choice of food than is at present supposed; this, at least, is rendered not unlikely by what is ascribed to them in the old writers. We are as yet acquainted with the metamorphoses and habits of a very small number of these insects; and it is, therefore, highly desirable that whenever a destructive species of wire-worm prevails, it should be traced to the perfect condition. This, however, is attended with considerable difficulty, owing to the length of time they continue in the larva state, extending, in many instances, to several years.

This insect occurs in considerable plenty throughout the country in grass fields and pasture lands, and is usually found creeping among the herbage, or lying at the sides of streams; it is scarcely ever observed on the wing. The extent of the injury they sometimes occasion may be estimated from the fact, that a single worm has been observed to bite from 8 to 20 plants in a very short time; and they are occasionally so abundant, that from 4 to 8 have been turned up by the spade in a space of 4 square feet. The depredations of the wire-worm in England being principally confined to wheat sown upon clover leys, old pastures recently broken up, pea and bean stubbles, &c., we may suppose the general average of the injury to amount to about a twentieth part of what it was, even upon this description of lands. This may be deemed a very fair and moderate calculation.

When the fields lie fallow, these insects continue to feed on the grass and other weeds, which are frequently allowed to overrun the surface; whereas, if the soil were kept clean, they would either die for want of food, or be compelled to remove to some other place. As these larvæ invariably live beneath the surface of the soil, every plan suggested for their destruction must be founded on this consideration.

Without advertting to this fact, many superficial applications, such as strewing the surface with quicklime, soot, &c., have been tried without effect. The most obvious remedy is to saturate the soil with some fluid which has been previously ascertained to destroy the insects without injurious the plants; that is, if the latter be of a kind which it is necessary to preserve, as will usually be the case. In a fallow field, this precaution need not be observed, as a double benefit would ensue from the destruction of both insects and weeds. More carefully conducted experiments, and on a more extensive scale, than any that have yet been undertaken, will be necessary to show what kind of liquid is best adapted for this purpose. Probably, different substances will be found most useful in different situations, according to the nature of the soil and the chemical ingredients which enter into its composition.

The latter consideration should be particularly attended to in all experiments on the subject, as most likely to suggest the most appropriate remedy; and it might even happen that the fluid employed to destroy the insects might be so managed as to produce a most beneficial change in the chemical qualities of the soil. If a strong saline solution, for example, should be found to kill the insects, as it is very likely to do, there are few soils which would not derive benefit from such an application. Of course, many substances prove specifically fatal to these insects, and among these the classic would have to be selected for cheapness and ease of application. Beckrander, a Swedish observer, who has investigated their habits, found that they lived among-

He suggests that such of these plants as proved most specifically fatal should be mixed with the manure. He also considers it of great advantage to cause children to follow the plough, and pick up all that happen to be turned up. He states that in this way he has seen 351 wire-worms collected in a field not exceeding 600 feet by 56.

Sir Joseph Banks suggested a very simple plan for alluring the wire-worms from the plants, and collecting them that they might be destroyed. This consisted merely in burying slices of potato, stuck upon skewers, near the seeds sown. As the larva are very fond of this root, they leave the young plants and fix upon it. These slices require to be examined every day, and the wire-worms collected upon them destroyed. Mr. Tallant affirms that he has frequently freed fields entirely from wire-worms by sowing a crop of white mustard-seed. The experiment he has tried so frequently, and in circumstances so well calculated to demonstrate its effects, that he is perfectly satisfied that the remedy is efficient. “Encouraged,” he observes, “by the results of my former trials, I sowed a whole field of 42 acres, which had never repaid me for 19 years, in consequence of nearly every crop being destroyed by the wire-worm; and I am warranted in stating that not a single wire-worm could be found that following winter. The field was sown by wheat throughout, which was reaped last harvest, was superior to any I had grown for 21 years. I am, therefore, under a strong persua-
sion that the wire-worm may be successfully repelled and eradicated by carefully destroying all weeds and roots, drilling white mustard-seed, and keeping the ground clear by hoeing." (Jr. Brit. Farm. Mag. 1831.)

Nature herself has taken means to check their superabundant increase by making them the prey of a small ichneumon, which searches out their retreats, and deposits its eggs in their bodies, which are consumed by the parasitic larvae as soon as hatched." (Mr. Duncan, Quart. Journ. of Agr. vol. viii. pp. 96, 316.) (See Is- 
sers.) Under the head BEETLE, at page 174, the habits and effects of wire-worms have been described as materially differing in structure and habits from those of Europe.

WISP. A term applied to a small bunch of hay or straw, when used in rubbing down horses or cattle.

WITHY. A name sometimes given to the flexible boughs of willows and osiers.

WOAD, DYER'S (*Isatis tinctoria*). This is a biennial plant, growing wild in cultivated fields and about borders in England, but rare. As the ancient Britons are reported to have painted their bodies with the blue colour obtained from this plant, which is still used in dyeing, the use of it was most probably an original prior to the introduction of England; though what occurs now and then about cultivated fields is supposed to have escaped from the crops occasionally raised, chiefly in the middle part of the island. The naturalized plants are less perfectly smooth, and far less luxuriant than the cultivated ones. This plant has a tapering and fibrous root. The stem rises 2 or 5 feet high, wand-like, slightly glaucous, leafy, panicked at the top. Panicle of many compound racemose branches, beset with diminished lanceolate leaves, all of a yellow hue as well as the stalks. Flowers numerous, small, bright yellow.

Woad has been cultivated in France from time immemorial. In England its culture is mostly confined to Lincolnshire, where it is a common practice to take rich flat tracts near rivers, at a high price, for the purpose of growing it for 2 or 4 years. Those who engage in this sort of culture form a sort of colony, and move from place to place as they complete their engagements. It is sometimes, however, grown by stationary farmers. The leaves are the parts of the plant used, and it is considered as a severe crop.

There is a variety of woad, called the Dalmatian, described by Miller, and also a wild sort, but only the common is cultivated in England.

The soil for woad should be deep and perfectly fresh, such as those of the rich, mellow, loamy, and deep vegetable kind. Where this culture is carried to a considerable degree of perfection, as in Lincolnshire, the deep, rich, putrid, alluvial soils on the flat tracts extending upon the borders of the large rivers, are chiefly employed for the growth of this sort of crop; and it has been shown by repeated trials that it answers most perfectly when they are broken up for it immediately from a state of seed and is a wire-worm have been described as rising to the height of 8 or 10 inches; but in other circumstances a sudden twist. In favourable seasons, the plant will often rise to the height of 8 or 10 inches; but in other circumstances they seldom attain more than 4 or 5; and where the lands are well ma-
naged in the culture of the plants, they will often afford two or three gatherings, but the best cultivator's seldom take more than two, which are sometimes mixed together in the manufacturing of them. It is necessary that the after croppings, when they are taken, are constantly kept separate from the others, as they would injure the whole if blended together, and considerably diminish the value of the root-dye. It is said that the best method, where a third cropping is either wholly or partially made, is to keep it separate, forming it into an inferior kind of woad.

The produce is mostly from about a ton to a ton and a half of green leaves. The price varies considerably; but for woad of the prime quality it is often from 25l. to 30l. the ton, and for that of an inferior quality 6l. or 7l., and sometimes much more.

To prepare it for the dyer, it is bruised by machinery to press out the watery part; it is afterwards formed into bales and fermented, re-ground, and fermented in vats. Then, as the water is evaporated into cakes in the manner of indigo, the haulm is burned for manure or spread over the straw-yard, to be fermented along with straw-dung.

The use of woad in dyeing is as a basis for the black and other colours.

To save seed, leave some of the plants undenuded of their leaves the second year, and when it is ripe in July or August, treat it like turmip-seed.

The only diseases to which the woad is liable are the mildews and rust; when young it is often attacked by the fly, and obtained to be ravaged, and this even on winter-ploughed grasslands more than once. (London.)

**WOLFP'S-BANE (Aconitum).** A genus of ornamental, tall, tree-flowering, very hardy plants, succeeding well under the shade of trees; increased by division or by seeds. All the species are to be dreaded, being of a poisonous quality, highly narcotic, and acid. Theaconite has, however, become of great service as a narcotic in many very troublesome disorders. One species, the common Wolf's-bane or monk's hood (A. napellus), is a native of Great Britain, but wild in this country in watery places. It is perennial in habit. Root fleshy, tapering; stem erect, simple, leafy, clothed with minute, close hairs, and terminating in a solitary, simple, upright, spike-like panicle of large, dark-blue, helmeted flowers, without scent. The nectaries are full of honey, and form the spur of the flower. Leaves deeply five-cleft, cut, with linear segments, furrowed above, and of a deep green, but pale beneath. See Aconite.

**WOOD.** The fibrous or ligneous substance of which the branches, trunks, and roots of trees are principally composed. In vascular trunks, the hardest wood is always in the centre. See BARK, LIGNER, LIGNIN, TIMBER, TREES, &c.

**WOODBINE.** See HONEYSUCKLE.

**WOOD-RUSH (Luzula) from the German Luzule, or glow-worm grass of Bavuin.)** These plants are nearly related to Juncus, from which they are at once distinguished by their flat leaves. They possess little beauty, and are of the easiest culture. There are seven indigenous species, all of which are described in Smith's Eng. Flor. vol. ii. p. 177.

**WOODSIA.** (named in honour of Joseph Woods, F. L. S., an excellent practical British botanist, who first illustrated our native species of Rose.) A genus of small ferns, of which two species only have hitherto been discovered. W. Rosei, the rounded-leaved Woodsia (W. hyperborea). These ferns grow best in peat and loam mixed, and are increased by division, or by seed. Their roots are fibrous; fronds tufted, erect, stalked, pinnate, pinnatifid, clothed with simple hairs, or narrow-pointed scales. (Smith's Eng. Flor. vol. iv. p. 322.)

**WOOD-SORREL (Oxalis, from oxys, acid; the leaves have an acid taste).** Most of the plants of this genus deserve cultivating on account of their very pretty blossoms, which are produced in great abundance. The hardy species should be planted in a shady border, where they will grow and flower very freely. These seeds of the hardy annual species may be sown in the open border in spring. There are in England two wild native species,—1. The common wood-sorrel (O. acetosella), which grows abundantly in groves and shady places. Stalks radical, single-flowered. Leaves ternate, inversely heart-shaped, hairy; root of many scaly joints. Leaves of a delicate bright green, often purplish at the back, drooping at night, on long, hairy, radical, purplish foot-stalks. Flowers solitary, drooping, bell-shaped, either white or purplish, always streaked with fine branching purple veines, which when ripe, the blackish shining seeds are projected to a distance on the slightest touch or motion, by their elastic tunic, which remain contracted and wrinkled in the capsule. This herb is powerfully and most agreeably acid, making a refreshing and wholesome conserve with fine sugar; its flavour resembling green tea. Few of our wild flowers are more elegant.

2. Yellow procumbent wood-sorrel (O. corniculata). This species is annual, growing in shady, rather moist waste ground. The root is fibrous, and it has become almost a weed in gardens. Stems branched or simple. Flower stalks in smallumbs of yellow flowers.

Several species of oxalis have been found in the United States, among which are the following, enumeratt by Nuttall. 1. O. acetosella. 2. violacea. This species appears often to flower late in the autumn, and is then destitute of leaves. 3. O. floribunda. 4. Corniculata. 5. Strica. 6. Dilatata. These two last are scarcely distinct species.

This genus of more than 100 species is, with a few exceptions in Europe and America, peculiarly indigenous to the Cape of Good Hope. The leaves of all the species are more or less sensitive and nictitans. (Pavon's Bot. Dict.; Smith's Eng. Flor, vol. ii. p. 322.) See SORREL.

**WOOD-WASP.** See SAW-FLY.

**WOOD-WAXEN.** See GREENWEED.

**WOOL (Germ. wolle; Dutch, wol; Rus. volna).** The soft, hairy, or downy substance which forms the covering of sheep, and is found in smaller proportion on many other animals. It is an article which has continued
from the earliest period down to the present day to be of primary importance, having always formed the principal part of the clothing of mankind in most temperate regions. Authors have seemed to imagine that the production of wool was confined to the sheep; practical men, however, know that there is a numerous list of animals, on whom, at some season of the year at least, wool is found.

M. Chevreul, who long devoted himself to the examination of wool, has proved that wool contains three or four different substances. The following is the result of an examination of 100 parts of a merino fleece:

A consideration of the most important properties of wool cannot be better introduced than in the words of one to whom the agriculturist, whatever his sentiment out of bushes, may chiefly occupy his attention, is much indebted.

"Fine and coarse," says Arthur Young, "are but vague and general descriptions of wool; all fine fleeces have some coarse wool, and all coarse fleeces some fine. I shall endeavour, for the information of my readers, to distinguish the various qualities of wool in the order in which they are esteemed and preferred by the manufacturer. First, fineness with close ground, that is, thick-matted ground. Second, fineness. Third, straight-haired, when broken by drawing. Fourth, elasticity, rising after compression in the hand. Fifth, staple not too long. Sixth, colour. Seventh, what coarse is in it to be very coarse. Eighth, tenacity. Ninth, not much pitch-mark; but this is no other disadvantage than the loss of weight in scouring. The bad or disagreeable properties are,—thin, grounded, topsy, curly-haired, and, if in a sorted state, little that is very fine, a tender staple, no elasticity, many dead white hairs, very yokly. Those who buy wool for combing and other light goods that do not want milling, wish to find length of staple, fineness of hair, whiteness, tenacity, firmness, elasticity, and not too many pitch-marks. (Annals of Agriculture, vol. xviii. p. 322.) The fineness of the wool differs greatly in the different parts of the sheep. That running down the side of the neck, and covering the shoulders, the ribs, and the back, is the finest; the next covers the superior parts of the legs and the thighs, and extends up to nearly the haunch and the tail, and a still inferior portion runs along the upper part of the neck, the throat, the breast, the belly, and the lower part of the legs. There is considerable variation in this respect in different breeds, and in individuals of the same breed; and although a fleece, taken generally, may be said to be adapted to a particular use, yet a portion of it may be employed in the manufacture of a much more valuable article; and at the same time, a greater quantity will be thrown aside as not sufficiently fine for the originally intended purpose. The influence of temperature on the growth of wool is very considerable. Sheep in a hot climate will yield a comparatively coarse wool, and those in a cold climate will carry a finer, but, at the same time, a closer and a warmer fleece. The natural instinct of the sheep would seem to teach the wool-grower the advantage of attending to the influence of temperature on him. He is evidently impatient of heat. In the open district, and where no shelter is near, he climbs to the highest parts of his walk, that if the rays of the sun must still fall on him, he may nevertheless be cooled by the breeze; but if shelter is near, of whatever kind, every shaded spot is crowded with sheep. Pasture has a very great influence on the fineness of the fleece. The staple of the wool, like every other part of the sheep, must increase in length or in bulk, when the animal has a superabundance of nutrition; and, on the other hand, the secretion which forms the wool must decrease, like every other, when sufficient nourishment is not afforded. Connected with fineness is truth of staple—as equal a growth as possible over the animal—a freedom from the shaggy portions, and trifling portions, here and there, which are occasionally observed. These portions are very objectionable. These portions are always coarse and comparatively worthless, and they indicate an irregular and unhealthy action of the secretion of wool, which will probably weaken or render the fibre diseased in other parts. Soundness and elasticity are also very important properties in wool.

If the pile is sound, there are few qualities in wool of so much consequence as softness. Fashion has done much in effecting this. Softness of the pile is evidently connected with the presence and quantity of yolk. There is no doubt that this substance is designed, not only to nourish the hair, but to give it richness and pliability. Bad management, neglect, exposure, starvation, impair the pliability of the woolly fibre, but chiefly so because they arrest the secretion of the yolk, or change its properties. The colour of the fleece is of minor, and yet of no trifling importance. The alteration of the colour was the first recorded improvement of the sheep; and its purity, its perfect whiteness, should never be lost sight of by the sheepmaster of the present day. To a certain extent, the fleece is frequently stained with the colour of the soil on which the animal grows. In some parts of Gloucestershire the wool acquires an orange colour; in Hertfordshire and Warwickshire it is of a brownish red; and in the fens of Lincoln and Cambridge it has a dark blue tint.

In some districts, and particularly in the west of England, the farmer needlessly uses a considerable quantity of ocher or ruddle, either in the composition of his salving mixture, or to gratify a foolish fancy. The tar gives consistence to the oil or butter, and although it is often with considerable difficulty washed away, yet while it remains on the fleece, it gives a permanent odour. The salting process, however, can be offered in favour of the ruddle. See Salting. It is not necessary (nor, indeed, would our space permit it) to go into the construction of wool, as seen through the microscope. We shall pass on, therefore, to point out the differ-
The old and apparently simple division of wool was into long and short, or, according to the purposes to which it was devoted, "comb- ing" and "clothing wool:" but there was considerable difficulty in arranging some fleeces which were of intermediate length, and convertible to either purpose. A third subdivision, that of "middle wool," has recently been added. These are again divided into subordinate classes, according to the fineness of the fibre. "In sorting woods," says Mr. McCulloch, "there are frequently eight or ten different species in a single fleece; and if the best wool of one fleece be not equal to the finest sort, it is thrown to a 2d, 3d, or 4th, or to a still lower sort, of an equal degree of fineness with it. The best English short native fleeces, such as the fine Norfolk and Southdown, are generally divided by the wool-sorter into the following sorts, all varying in fineness from each other:—viz. 1. Prime; 2. Choice; 3. Super; 4. Head; 5. Downrights; 6. Seconds; 7. Fine Abb; 8. Coarse Abb; 9. Livery; 10. Short coarse, or breech wool. The relative value of each varies, according to the greater demand for coarse, fine, or middle cloths." (Youatt on Sheep; Botswell's Observations on Wool; Lucock on Wool; Anderson on Wool.) See Alpaca, Fleece, Lamb-skins, and Sheep.

An interesting view of the foreign wool trade and the check upon this effected through the protection received from Congress, is exhibited in the following account derived from the columns of the New York Journal of Commerce, (for Sept. 1843.)

In a communication to the Middlebury People's Press, dated 10th July last, and signed by the Hon. William Slade, late a member of Congress from Vermont, some interesting facts are stated as to the operation of the new Tariff upon the importation of wool from foreign countries. By information received from the Register of the Treasury, it appears that during the 1st half of the present fiscal year, which commenced on the 1st of October last, about a month after the new Tariff went into operation, there was imported into the United States, of wool costing 7 cts. a lb. or under, only 881,688 lbs. and of wool costing over 7 cts. a lb., only 175,962 lbs. Making a total of only 1,037,650 lbs. of all descriptions of wool in 6 months! This is a most extraordinary falling off, compared with the importations of previous years, as will be seen from the following schedule:

Making, on an average of 7 years, something over 9,000,000 lbs. per annum, thirds of which, at the place whence imported, cost less than 8 cts. a lb. The new Tariff makes the minimum 7 cts. per lb. instead of 8 cents, and levies a duty of 5 per cent. on wool not above that minimum, whereas under the old Tariff such wool was duty free. But these changes are so slight, that they are not at all sufficient to account for the immense decrease in the amount imported. Let such should be the inference of the wool-growers, Mr. Slade tells them that through the efforts of the Vermont delegation in Congress, the word "coarse" was inserted in connection with cheap wool, so that now, in order to be admitted at the low duty of 5 per cent. (which cannot exceed 3½ mills per lb.), wool must not only have been bought at 7 cts. a lb. or under, but must also be coarse: and he adds, "I have no doubt that with a careful and thorough execution of the coarse wool provision, according to its true intent and meaning, the reduction [in the quantity of wool imported] would have been still greater." To illustrate this point, he states the following particulars:

"It appears from the Custom House returns that 1,101 sheep, of the aggregate value of $10,565—averaging $9 60 each, and therefore presumably had been merino sheep—were exported from the United States to Buenos Ayres in the years 1837 and 1838. The quantity of wool, the product of the crossings of these merino with the native South American sheep, imported into the United States at and below the value of 8 cts., cannot, of course, be ascertained. The importations from that country of wool costing 8 cts. and under, were greatly increased in the succeeding years; embracing, as is well known, much fine wool, and therefore presumed to have been the product of the crossings referred to. That increase will appear by the following statement of the importations of wool costing 8 cts. and under, from Buenos Ayres, during the years 1833, 1840, and 1841, compared with the previous 3 years.

<table>

<td>596,105</td>
<td>8,576,795</td>
</tr>
</tbody>
</table>

"The French blockade of Buenos Ayres in 1839 and 1840 diminished the exports of those years, and consequently swelled those of 1841 when the blockade was raised. The annual average of the 3 years was 3,373,800 lbs. That of the preceding 3 years was 2,243,781 lbs.; making an excess of the average of the last 3, over that of the first 3 years, of 1,079,816 lbs.—an increase of about 47 per cent.

"It was the extraordinary quantity of fine wool thus cheapened in the market of Buenos Ayres, and thrown, in large quantities, upon our own, that suggested the necessity of the introduction of the word `coarse' into the clause in question. Its intended effect was, to subject to the higher duty all wool not coarse, though costing less than 7 cts."

This higher duty, which applies to all wool costing over 7 cts. a lb. and, according to Mr. Slade, did not apply to all wool but coarse whatever may be its cost, is 3 cts. a lb. and 30 per cent. ad valorem. Hence the duty on wool costing 10 cts. at the place whence imported, is 6 cts. a lb.; and on wool costing 20 cts., 9
WOOLLEN RAGS.

WORK. See Labour.

WORLIDGE, or WOOLRIDGE, JOHN. An early English agricultural writer. But little more is known of his history, than that he was a gentleman who was a great lover of rural affairs and gardening. He was perhaps the first to have written in detail and at length on their subject. He had been acquainted with the following:—1. Systema Agricultura: The Mystery of Husbandry discovered and laid open, 1669—77—81, 1687, folio, 1716, 8vo. 2. Tretise on Husbandry, 1675, folio. 3. Systema Horticultura; or, The Art of Gardening, 1677. 4. Vivarium Britannicum, 1678—91, 8vo. 5. The most easy way of making Cyder, 1678. 6. Apiarium, 1691, 12mo.

The Systema Agricultura was the most bulky folio volume on agriculture that had yet appeared, and its comprehensive themes are all set forth in its first page. The authors of those days seemed to consider it essential that their readers should have, in the title-page of a book, a complete summary of its inviting contents. Woolridge was evidently of this opinion, for his title-page announces that this was the "Systema Agricultura, or the Mystery of Husbandry discovered; treating of the several new and most advantageous ways of tilling, planting, sowing, manuring, ordering, improving, of all sorts of gardens, orchards, meadows, pastures, corn-lands, woods, and coppers; as also of fruits, corn-grain, pulse, new hays, cattle, fowl, beasts, bees, silk-worms, and fish, with an account of the several instruments and engines used in the profession; to which is added, Kalendarium Rusticum, or the husbandman's monthly directions; also the prognosticks of dearth, scarcity, plenty, sickness, heat, cold, frost, snows, suns, rain, hail, thunder, &c.; and Dictionary Rusticum, or the interpretation of rustick terms; the whole work being of great use and advantage to all that delight in that most noble practice." It is dedicated to the gentry and yeomanry of England, and opens with a preface laudatory of agriculture.

Notwithstanding, however, the ill aspect of this heavy title-page, the book contains more useful and more enlightened observations on many points of husbandry than any which had preceded it. He was a warm friend to the enclosure of commons and other waste land, and he suggests the use of those lands to have been carried into effect in 1665, at Wilton, the erection of water-works for the purpose of flooding meadows, an improvement of which I think not nearly so much has been made as is possible in this land of steam and steam-engines. He was evidently well acquainted with the management of water-meeds, and his directions with relation to them are practical and sensible. He advises that sandy meadows should be chalked, and ashes applied to sour rushy grasses. When speaking of several new species of hay or grass, he enumerates clover-grass, trefoyle, St. Poy, La Lucrea, ray-grass, &c. He also recommends the ploughing or digging of land, and on all occasions seemed alive to any improvement in the implements of agriculture. After giving an account, at some length, of the rude and clumsy contrivance of Gabriel Plate, for a dibbling-machine, he elaborately and earnestly advocates the use of a drill, an engraving of one of which, primitive enough, it is true, in its appearance, he gives in his work. "To remove," he says, "all manner of errors or inconveniences that can be found in setting or hoeing of corn, I shall here give you a plain and perfect description of an easy and feasible instrument that shall divine the way and course, and guide you, what of kind soever, at what distance, and in what proportion you please." The farmer may be curious to know the construction of this drill of a century and a half since. It had a coulter, a pipe, a hopper, wheels, and axletrees. He was the first English author, I believe, who suggested the use of the manure-drill, for, when speaking of the drill, he says (p. 52), "By the use of this instrument also, you may cover your grain or pulse with any rich compost you shall prepare for that purpose, either with pigeon's dung, dry or granulated, or with burnt straw, or any substance made dispersable, which may drop after the corn, and prove an excellent improvement; for we find experimentally, that pigeon's dung, sown by the hand on wheat or barley, mightily advantageth it by the common way of husbandry; much more might we, therefore, expect this way, where the dung, or such like substance, is all in the same furrow with the corn, where, in the other vulgar way, a great part thereof comes not near it. It may either be done by having another hopper, on the same frame, behind that for the corn, wherein the compost may be put and made to drop successively after the corn, or it may be sown"
with another instrument to follow the former, which is the better way, and may both disperse the soil, and cover both soil and seed.”

Woolridge was evidently an observer who was able and willing to think for himself. He advocated change of seed “from dry, hungry, barren land, to rich and fat land; also from land inclining to the south, to land inclining towards the north, and the contrary,” all of which, he well adds (and the reader must remember that Woolridge was writing when chemistry existed only in name), “are manifest signs that there is something therein each seed delight, which if we did understand but we might properly apply it, and gain riches and honours to ourselves; but because we are ignorant thereof, and are content to remain, we must make use of such soils, dung, composts, and other preparations and ways of advancement of the growth of vegetables as are already discovered and made use of.” (p. 57.)

He extols the use of steeps for seed-corn, mentions with approbation for this purpose nitre, common salt, as well as urine, and gives a recipe for “two kinds of liquid manure with sheep-dung (1 bushel) and common salt (1 lb.), and common salt (1 lb.), boiled together for ten minutes in water (20 quarts), and this he commends very highly as a steep; and I am inclined to believe that something of this kind of rich liquor, more especially if the seed was afterwards dried by being sprinkled with some of the very fine manure powders at present proposed, such as the urine of the London Manure Company, the composition of M. Pottevin, the guano, gypsum powder, &c., might be used more profitably by the cultivator than at first sight he may be inclined to believe. He was in favour of paring and burning on some soils, and had the good sense to discern the advantages capable of being derived from the permanent improvement of the soil by the use of earthy manures. He devotes, therefore, a chapter to the soils and manures taken from the earth (p. 65); notices the uses, for this purpose, of chalk, lime, marl, clay, fuller’s earth.

The value of sand as a fertilizer did not escape our author’s attention. He notices the value to some soils of that of the calcareous shores of Cornwall, and of the Suffolk craig formation, and of that which he advises the farmer to lay under his farm-yards and sheep-pens.

The excrements of fowls were strongly recommended by Woolridge as a fertilizer. He describes those of pigeons and hens as “incomparable, one load is worth ten loads of other dung;” commends the use of “all marrow-bones, fish-bones, horn, or horn-shavings;” but he fell into the error with regard to those which it required a century and a quarter to remove, viz., he fancied that all the enriching qualities of the bones were to be attributed to the grease they contained, instead of to their phosphatic time. He advocated the mixture of peat, saw-dust, and tanners’ refuse back with dung-heaps,—a plan which is even now not nearly so extensively adopted as its merits deserve. Indeed, as honest John Woolridge concludes his section (p. 83), “The well-preparing of dung-mixt is a piece of husbandry not to be slighted, on which point of good or ill husbandry depends the rise and fall of the rents or values of many farms in this kingdom.”

Every account of live-stock given by the earlier agricultural writers betrays the total want of attention then paid by the farmers to the breeding of stock, or if they do mention the points to be commended in an ox or a sheep, they are precisely those which a modern breeder endeavours to avoid. For instance, the chapter of the “Society for improving the English cows for their largeness of body,” and even Woolridge, writing centuries after him, although very elaborate on most points of husbandry, treats of the farmer’s live-stock in a manner that clearly indicates that in those days, to use a Norfolk phrase, “a cow was a cow, and a sheep a sheep.” Thus all the instruction he gives the breeder with regard to the selection of a cow is, that “the best sort is the large Dutch cow, that brings two calves at one birth, and gives ordinarily two gallons of milk at one meal.” His account of sheep I will also give, without abridgment, for its facts will sound still more novel to a modern farmer:

—“There are divers sorts, some bearing much finer wool than others: as the Hertfordshire sheep about Lemster bear the finest fleece of any in England. Also they are of several kinds as to their proportion; some are very small, others larger. But the Dutch sheep are the largest of all, being much bigger than any I have seen in England, and yearly bear two or three lambs at a time. It is also reported that they sometimes bear lambs twice in the year.” This seemed to convince Woolridge, and very naturally, too, of their value, for he adds, “It may doubtless be of very good advantage to obtain of those kinds and also of Spanish sheep that bear such fine fleeces.”

The scientific modern breeder, when he smiles at this negligence and folly of a by-gone race of farmers, must remember, however, the difficulties under which they laboured, not only from lack of knowledge, but also of the means to improve at a reasonable rate their ill-shaped, large-boned, and slow-feeding race of oxen. He should recollect that they had not had the advantage of a Bakewell, a Culley, or a Collings, to labour during a lengthened period for their improvement—the days of the Southfield Club, and of the Highland Society, were yet far distant. They had not even a suspicion of what improved breeding would effect; and if they were ignorant, as they evidently were, that their breeds were inferior, we can hardly wonder that they were content to labour on, since the very first step to improvement, a belief in greater excellence being possible, was wanting.

The opinions, however, of Woolridge with regard to plantations of timber-trees were evidently more enlightened; for although he lived a century before the days of our modern extensive planters,—of such men as the Lords Athol, Devonshire, and Fife, and of Sir Henry Stuart—yet he earnestly advised the planting of the poorer soils of our island; he asked the landowners of his time, after describing to
them the profit they might derive from such foresighted enterprise, "What can be more pleasant than to have the bounds and limits of your own property preserved, and continued from age to age by the testimony of such growing and living witnesses, in the spring yielding a reviving cordial to your winter-chilled spirit, giving you an assurance of the approaching summer by their pregnant buds and musical inhabitants? In the summer, what more delectable than the curious prospect of the variety of greenness, dark shades, and retirement from the scorching sunbeams?" He well knew, too, what some of his northern friends are only now proving to be practically the case, that "woods also finely refrigerate the air in the summer's parching heats, and qualify the dry and injurious winds, both in winter, spring, and autumn." He devotes a long chapter to the profits and pleasures of fruit trees, and ridicules very quaintly the objection too commonly made to such plantations, viz., "that their fruit would be stolen." "When," he says, "the proprietor ADS 'manors will be little regarded by these fitchers, or if they do borrow a few sometimes in their pockets, or to make a few apple-pies withal, yet that is a poor discouragement to an ingenious spirit, and much like that rustick humour of one that would not improve a very good piece of ground for that purpose with fruit trees, because the parson would have the decimation of it, and so denied himself the nine parts, because the parson should not have the remainder.'"

Of the ploughs employed 150 years since, he mentions the double-wheeled or Hertfordshire plough, the turnwrest or Kentish plough, "which surpasseth for weight and clumsiness" the one-wheeled plough, the plain plough, and the trenching plough.

Woolridge gives also sundry directions for angling, bowing, bird-catching, horse-breeding, and sundry other rural affairs, and finally he winds up with a Kalendarium Rusticum. In these he gives various monthly directions, of which one specimen will suffice, of the mode of farming then commonly adopted. In May he directs the farmer "*to kill ivy, to feed down or mow rank corn; to sow barley, buckwheat, pease, hemp, and flax, clover-grass, St. Foyne, and other French grasses; to pare and burn land, and wean lambs." He every month, as if in rivalry of the almanac-makers of former generations, treated the farmer to some poetry, often of a most absurd description; thus, in the month of March, after having told them that "this month ushers in the most welcome season of the year," and that "now gentle Zephyrus fans the sweet buds, and the celestial drops water fair Flora's garden," he could not help adding some of his own poetry, telling them what must have been indeed novel information, that now

*"The lofty mountains standing on a row,
Which but of late were periwigged with snow,
Boff their old coats, and now are daily seen.
To stand on topies all in swaggering green;
Meadows and gardens are prankt up with buds,
And chirping birds now chant it in the woods."

Woolridge laboured hard, however, in spite of occasional absurdities of expression, to elevate the science of agriculture; and that it was deemed a science in the 17th century, is evident in this opening address to the farmer, when he says, "Agriculture hath been (not undeservedly) esteemed a science that principally teaches us the nature and divers properties and qualities, as well of the several soils, earths, and places, as of the several productions or creatures, whether vegetable, animal, or mineral, or that nature procured can be artificially produced from, or maintained by the earth." This he promises the husbandman he will do "after a plain and familiar method." He soon, however, begins to illustrate his "plain and familiar method," by talking of the "secret, mystical, and mechanick inducations of nature, the universal spirit, or spirit of mercury and of salt; and gives us but a mean opinion of his natural philosophy, by gravely telling us that "soon will horse-hairs receive life lying in rain-water but a few days in the heat of the sun in spring-time."

But in spite of the occasional mistakes, the book of Woolridge was perhaps the most practical, and therefore the most useful book which had yet appeared treating of agriculture and rural affairs. The very publication of such an expensive folio, of 326 pages, betray the increasing thirst for knowledge of the cultivators of those days, and the same remarks apply generally to those of Plate and of Hartlib; in truth, both agriculture and agricultural writers could hardly fail to keep pace with the rapid increase to the general stock of knowledge which the age in which they flourished received to so remarkable an extent; and this improvement was not, as my brother, Mr. George Johnson remarks (Hist. of Gard.), in only one branch of knowledge, but in the whole circle of the arts and sciences. The reformation was not confined to religion. By delivering the human mind from servile thraldom and teaching man, instead of bowing blindly to custom, merely on account of its antiquity, to have a self-dependence, it gave an impulse to improvement which no tyrant opposition of either bigotry, indulgence, or self-sufficiency could check. Such men as Bacon, Peiresc, and Evelyn arose, and whilst the first traced the path which men of science should tread, the two latter lent their talents and their wealth to sustain them in the pursuit. Bacon, it has been truly observed, was the first who taught men that they were but the servants and interpreters of nature, capable of discovering truth in no other way than by observing and imitating her operations; that facts must be collected instead of speculations formed, and that the materials for the foundations of true systems of knowledge were to be discovered, not in the books of the ancients, not in metaphysical theories, not in the fancies of men, but by careful, and laborious, and patient experiments and observations in the external world. Peiresc was a manifest man of letters; his advice, his purse were open to the votaries of every art and every science; his library was stored with the literature of every age and nation, his garden with the rarest and most useful exotics and these last he delighted to spread over in
country. When, indeed, we cast our eyes over a list of the men of science and literature of all kinds that adorned this age, especially in chemistry and in botany, the two sciences perhaps of all others the most important to agriculture, we need not be surprised to find how rapidly it was rising from being a mere art of empiricism; and when we note how rapidly the thirst for foreign researches as prevalent, we can easily perceive how improved modes of culture and new plants were acquired to agriculture. Cavendish, but especially Raleigh, by their visits for lucrum as well as fame to the Spanish settlements of America in 1580-8, led the way in a path which Lancaster and Raymond followed in 1791, and laid the foundation of that anomalous copartnership of commercial monarchs, the East India Company. Annual fleets now returned from the east and west, laden with the curiosities of both the animal and vegetable kingdoms; of these the potato, tobacco, and tea need alone be instanced; and although the views of men were not yet liberal enough to prompt them to voyages of discovery, with an unmixed desire of extending the field of science, or an enlarged wish to benefit mankind, yet new plants, in common with other hitherto strange natural products, attracted their attention, and, though at first imported as novelties, soon became by degrees to be desired and sought for as the luxuries and necessities of life. (Quart. Journ. Agr. vol. xi. p. 460.)

WORM. See CUT-WORM, EARTH-WORM, WORM-SEED, &c. WORM-SEED (Chenopodium). See GOOSEFOOT.

WORMS, INTESTINAL. A troublesome sort of vermin found in the intestines of horses and other animals. There is, perhaps, nothing so destructive to the health and appearance of the horse as worms. When they have obtained a settlement in the intestines, neither the labour of the groom nor the liberality of the master will prove of any avail towards improving the animal’s condition: for as fast as the chyle is formed from the aliment, which ought to be converted into blood, these numerous guests first sateate their craving appetites, and leave but a scanty supply for the exhausted system of the horse, so that a double allowance of corn would not preserve a healthy state; because the digestive organs cannot exert an extraordinary power for any length of time, without producing such a state of debility as to render them incapable of performing afterwards their proper office.

In these animals, the most common kinds are the following:—1. Bots, which many young horses are subject to in the spring; 2. Those that resemble earth-worms, and which, by physicians, are called luminaria; 3. Those that are of the same size as the largest spring-needles, with flat heads, called sea-apes; 4. The species of worm called rana, or tape-worm. See BOTS, FLUKE-WORM, &c.

WORMWOOD (Artemisia, so named in honour of Artemisia, wife of King Mansolus, or Diana Agrippa). There are four perennial-rooted bitter aromatic herbs included under this name, and cultivated solely for medicinal purposes:—Common wormwood (A. absinthium) is a native of almost every part of Europe, and in England is found by road-sides on heaps of rubbish, &c. It is an erect shrub, with hoary tri-pinnatisert leaves. The flowers in small, globose, nodding, racemose panicles. The same remarks apply to the drooping sea-wormwood (A. maritima), which is found on salt marshes and the sea-coast. The Roman wormwood (A. ebratti) is a native of Italy; and Santonicum or Tartarian wormwood (A. santonicum), which is a mere variety of A. maritima, of Persia and Siberia. The soil best suited to the growth of these plants is one that is dry, light, and poor, otherwise they become luxuriant, and are defective in their medicinal qualities, as well as in their power to withstand the rigour of the winter. Any situation will suit the common and the sea-wormwoods that is open and unconfined; but the exotic species require to be sheltered from the severe aspects. In a severe winter, the Tartarian wormwood loses its leaves, but the sea-wormwood seldom suffers from the want of a genial soil; the application of salt would undoubtedly be beneficial.

They are all propagated by seed, as well as slips and cuttings, the first of which may be sown in March or April, and the latter planted during June, July, and beginning of August. The seed is sown thinly broadcast, and when the plants arrive at a height of 2 or 3 inches, are weeded and thinned to 6 inches asunder; and those taken away pricked out at a similar distance, water being given if the weather is at all dry. The slips and cuttings are planted in a shady bed by about 8 inches spaced, and water given regularly every evening until they have taken root. They are all to be transplanted finally early in the following spring, by whichever mode they are raised, setting the plants at last 18 inches apart. See MUGWORT, and SOUTHERN WORM. WOUNDWORT (Stachys, from stachys, a spike, alluding to the mode of flowering). A genus of rather weedy-looking plants, hardly worth cultivating for ornament. They all succeed in common garden soil. The perennial kinds are easily increased by dividing the roots in spring or autumn. The seeds of the annual kinds should be sown in spring, in the open border. As a vulnerary these plants have no power. There are five indigenous species: the hedge woundwort (S. sylvatica); the amigious woundwort (S. amigus); the marsh woundwort (S. palustris); the downy woundwort (S. germanica); and the corn woundwort (S. arvensis). The marsh woundwort has a fetid root, creeping extensively; throwing out in autumn a number of tuberous shoots, which render it, in low, wet ground, very difficult of extirpation. This, therefore, should be attempted in summer before these knobs are produced, when the flowers are appearing.

Several species of woundwort, or hedge-nettle, are found in the United States. One, called S. sylvatica, is found on the banks of the Ohio, on the skirts of thickets, giving out the same fetid odour as the European species. The flowers are, however, paler. (Nuttall.)
**YAM.**

YAM (*Dioscorea sativa*). A climbing plant, cultivated in the East and West Indies. Its roots are very large, flattened, sometimes palmed. It is boiled or roasted like the potato, and is wholesome, palatable, and nutritious. The flour is also used for puddings and bread. The *D. alata* is equally cultivated; its root is 3 feet long, and often weighs 30 lbs. Of both kinds there are numerous varieties.

**YARD-DUNG.** See Farm-Yard Manure.

**YARD OF LAND.** A quantity of land which in some counties in England signifies 15 acres, in some 20, and in others 24, 30, and 34 acres.

**YARROW (Achillea).** A genus of showy, free-flowering plants, succeeding well in any common soil, and readily increased by dividing the roots. The species are possessed of aromatic, bitter, tonic, and stimulating qualities. In England the following are indigenous perennials:

1. Sneezewort yarrow, or goose-tongue (*A. ptarmica*), which grows in wet hedges, or about the banks of rivers, flowering in July and August. The root creeps widely, and is difficult of extirpation where the soil is moist. Stems upright, about 2 feet high; corymbose at the top. Leaves sessile, linear, pointed, equally and sharply serrated, and of a glaucous green. Flowers numerous, small, milk-white in the disk as well as in the radius, with an irregular number of ligulate florets. The whole plant has a pungent flavour, provoking a flow of saliva, and this flavour renders it acceptable, as Schreber asserts, to sheep, who delight especially in saltish food. The sneezing caused by the dried and powdered leaves is rather owing to their little, sharp, marginal prickles. Its name is derived from this property of causing sneezing.

2. Serrated yarrow (*A. serrata*). This is a much less common species, in which the root is fibrous, leaves linear, lanceolate, downy, deeply serrated. Flowers of a yellowish-white or buff color, not at the size of the foregoing. The whole herb has a powerful aromatic scent and bitter flavour, somewhat like tansy.

3. Common yarrow or milfoil (*A. milifolium*), Pl. 9, k. This species grows abundantly in English meadows and pastures. The root is creeping, with smooth, reddish, subterraneous shoots, which are warm and agreeably pungent, partaking of the flavour and salivating quality of the pellitory of Spain (*A. pyrcho*). Stems furrowed, erect, about a foot high. Leaves doubly pinnatifid, hairy; segments linear, toothed, pointed. Flowers numerous, white, occasionally reddish or purple. The whole herb is astrigent, and weakly astringent. Although considered a bad weed in pasture and arable lands, in consequence of its creeping root, Dr. Anderson and others have recommended it for cultivation; but its productive and nutrient properties are very inferior to many other plants equally adapted to light soils; 60 drachms of the leaves and stems, cut when in flower, afforded 98 grains of nutritive matter. Linnaeus says that its properties are vulnerary and styptic. An essential oil is extracted from the flowers; and an ointment made of the leaves is reckoned good against the scab in sheep. *A. moschata*, an exotic species, a native of Italy, is sudorific and acrid, and makes a wholesome food for cattle.

4. Woolly yellow milfoil, or yarrow (*A. tomentosa*). This species, which grows in many pastures in Scotland and Ireland. The root is woody, slightly creeping, with many long fibres. Stems scarcely a foot high, curved at the base, then erect. Leaves doubly pinnatifid, woolly, segments linear, crowded, acute. Flowers densely corymbose, on woolly stalks, of a bright golden yellow. The whole herb, as well as the flowers, has an aromatic scent when rubbed. It serves to decorate rock-work in gardens, but will not bear wet or shade.

**YEARLINGS.** A term applied to calves, colts, and other young stock, when they have completed their first year.

**YEAST.** The froth or scum which rises on beer during the act of fermentation. (See BREWING and FERMENTATION.) It contains a variety of components; among others, carbon, acetic and malic acids, alcohol, potassa, lime, a saccharine, mucilaginous extract, gluten, and water.

Yeast is an article of the greatest importance in domestic economy, forming a necessary ingredient in the manufacture of bread, which would otherwise become heavy and unwholesome. When put in contact with saccharine matters, at a temperature of between 50° and 60°, it causes fermentation, and changes the sugar into alcohol and carbonic acid. Yeast may be dried and yet retain its properties, but a temperature of 212° destroys it.

The yeast prepared by the Hungarians will keep for a whole twelvemonth. During the summer season they boil a quantity of wheaten bran and hops in water; the decoction is not long in fermenting, and when this has taken place they throw in a sufficient portion of bran to form the whole into a thick paste, which they work into balls, that are afterwards dried by a slow heat. When wanted for use they are broken, and boiling water is poured upon them; having stood a proper time, the fluid is decanted, and in a fit state for leavening bread. See BREAD.

"The substance called yeast or ferment, derives its name from the power it possesses of causing fermentation in sugar, or saccharine vegetable juices. It possesses," says Liebig, "all the characters of a compound of nitrogen in the state of putrefaction and eremacausis."

"Like wood in the state of eremacausis, yeast converts the oxygen of the surrounding air into carbonic acid, but it also evolves this gas from its own mass, like bodies in the state of putrefaction. (Colin.) When kept under water, it emits carbonic acid, accompanied by gas of an offensive smell (Thénaud), and is at last converted into a substance resembling old cheese. (Proust.) But when its own putrefaction is completed, it has no longer the power of inducing fermentation in other bodies. The presence of water is quite necessary for sustaining the properties of ferment, for simple pressure its power to excite fermentation is much diminished, and is completely destroyed by dry-
ing. Its action is arrested also by the temperature of boiling water, by alcohol, common salt, an excess of sugar, oxide of mercury, corrosive sublimate, pyrogallic acid, sulphurous acid, nitrate of silver, volatile oils, and, in short, by all antiseptic substances.

The insoluble part of the substance called ferment does not cause fermentation. For when the yeast from wine or beer is carefully washed with water, care being taken that it is always covered with this fluid, the residue does not produce fermentation.

"The soluble part of ferment likewise does not excite fermentation. An aqueous infusion of yeast may be mixed with a solution of sugar, and preserved in vessels from which the air is excluded, without either experiencing the slightest change. What then, we may ask, is the matter in ferment which excites fermentation, if neither the soluble nor insoluble parts possess the power? This question has been answered by Colin in the most satisfactory manner. He has shown that in reality it is the soluble part. Before it obtains this power, the decanted infusion must be allowed to cool in contact with the air, and to remain some time exposed to its action. When introduced into a solution of sugar in this state, it produces a brisk fermentation; but without a previous exposure to the air it manifests no such property.

"During the fermentation of sugar by yeast, both of these substances suffer decomposition at the same time, and disappear in consequence. But if yeast be a body which excites fermentation by being itself in a state of decomposition, all other matters in the same condition should have a similar action upon sugar; and this is in reality the case. Muscle, urine, isinglass, osmazome,* albumen, cheese, gladium, gluten, legumin, and blood, when in a state of putrefaction, have all the power of producing the putrefaction or fermentation of a solution of sugar. Yeast, which by continued washing has entirely lost the property of inducing fermentation, regains it when its putrefaction has recommenced, in consequence of its being kept in a warm situation for some time.

"If we consider the process of the fermentation of pure sugar, in a practical point of view, we meet with two facts of constant occurrence. When the quantity of ferment is too small in proportion to that of the sugar, its putrefaction will be completed before the transformation of all the sugar is effected. Some sugar here remains undecomposed, because the cause of its transformation is absent, viz., contact with a body in a state of decomposition.

"But when the quantity of ferment predominates, a certain quantity of it remains after all the sugar has fermented, its decomposition proceeding very slowly, on account of its insolubility in water. This residue of ferment is still able to induce fermentation, when introduced into a fresh solution of sugar, and retains the same power until it has passed through all the stages of its own transformation.

"Hence a certain quantity of yeast is necessary in order to effect the transformation of a certain portion of sugar, not because it acts by its quantity increasing any affinity, but because its influence depends solely on its presence, and its presence is necessary, until the last atom of sugar is decomposed.

"We have seen that ferment or yeast is a body in the state of decomposition, the atoms of which, consequently, are in a state of motion or transposition. Yeast, placed in contact with sugar, communicates to the elements of that compound the same state, in consequence of which, the constituents of the sugar arrange themselves into new and simpler forms, namely, into alcohol and carbonic acid. In these new compounds, the elements are united together by stronger affinities than they were in the sugar, and therefore under the conditions in which they were produced further decomposition is arrested.

"We know, also, that the elements of sugar assume totally different arrangements, when the substances which excite their transposition are in a different state of decomposition from the yeast just mentioned. Thus, when sugar is acted on by rennet or putrefying vegetable juices, it is not converted into alcohol and carbonic acid, but into lactic acid, mannite, and gum.

"Again, it has been shown, that yeast added to a solution of pure sugar gradually disappears, but that when added to vegetable juices which contain gluten as well as sugar, it is reproduced by the decomposition of the former substance. The yeast with which these liquids are made to ferment, has itself been originally produced from gluten.

"The conversion of gluten into yeast in these vegetable juices is dependent on the decomposition (fermentation) of sugar; for, when the sugar has completely disappeared, any gluten which may still remain in the liquid does not suffer change from contact with the newly deposited yeast, but retains all the characters of gluten.

"Yeast is a product of the decomposition of gluten; but it passes into a second stage of decomposition when in contact with water. On account of its being in this state of further change, yeast excites fermentation in a fresh solution of sugar, and if this second saccharine fluid should contain gluten, (should it be wort, for example,) yeast is again generated in consequence of the transposition of the elements of the sugar exciting a similar change in this gluten.

"After this explanation, the idea that yeast reproduces itself as seeds reproduce seeds, cannot for a moment be entertained."

* An extractive animal matter on which the peculiar flavour of broth is supposed to depend; hence its name, from the Greek for odour and broth.

YEAST.

YELOW-WOOD.
YEOMAN.

This tree grows of preference on gentle declivities, in a loose, deep, and fertile soil, and is usually accompanied by the red mulberry, coffee tree, sweet locust, black walnut, and other species whose presence evinces the richness of the land. It rarely exceeds 40 feet in height and 1 foot in diameter, and in general it does not attain seven of these dimensions. Its trunk is covered with a greenish bark, which is smooth instead of being furrowed like that of most other trees.

The leaves of the yellow-wood are 6 or 8 inches long on old trees, and of twice this size on young and thriving stocks. They are composed of two rows of leaflets, smooth, entire, nearly round, and about an inch and a half in diameter. The leaflets are 3, 4 or 5 on each side, borne by short petioles, and surmounted by an odd one, which is supported by the common footstalk. As in the buttonwood, the lower part of the footstalk contains the bud, which becomes visible in plucking the leaf.

The flowers form elegant, white, pendulous bunches, a little larger than those of the locust, but less odoriferous.

The seeds of the yellow-wood also nearly resemble those of the locust, and are contained in pods that differ only in being a little narrower. The seeds are ripe in the vicinity of Nashville about the 15th of August.

YEOMAN. A term applied to the first or highest degree of cultivators in England. The yeomen are properly freeholders, and such as cultivate their own lands. This term has been derived from various words by different authors. Dr. Johnson seems to incline to the word geman, Frisick, a villager; Fortescue derives it from geman, or yemen, Saxon for a commoner. Sir Thomas Smith's definition of a yeoman is, "a free-born Englishman who may lay out of his own free lands in yearly revenue to the sum of 40s."

YEW TREE (Taxus). A genus of ornamental evergreen trees, well adapted for wooded, as they thrive under the shade and drip of other trees; they are also very ornamental when planted to form hedges. They will grow in almost any soil, but in deep fine loams and clays. They are chiefly propagated from seeds, which should be sown as soon as ripe; but can also be increased by cuttings formed of either one or two years' wood, and planted in a shady border in the beginning of April or end of August. In England the common yew tree (T. baccata) is the only indigenous species. The trunk is straight, with a smooth deciduous bark. Leaves two-ranked, crowded, linear, flat, about an inch long, dark green. Fruit drooping, consisting of a sweet, internally glutinous, scarlet berry. The leaves are feathery and very poisonous, and prove speedily fatal to cattle accidentally tasting them when young and tender. The berries have a sweet mawkish taste, and may be eaten without danger. The wood of the yew tree, being of extremely slow growth, is hard and tough, formerly highly valuable for making bows, but now chiefly used for fine cabinet-work or inlaying. It makes handsome chairs than many exotic woods.

YOKE. A frame of wood fixed with bows over the necks of oxen, whereby they are coupled together, and harnessed to the plough, &c. It is sometimes written "yok," and is composed 1. of a thick piece of wood that passes over the neck, and is strictly called the "yoke;" 2. of a bow, which encompasses the neck; and 3. of the "wreakings," or "stitchings," that serve to connect the whole. Besides these parts, there are employed a ring, denominated the "yoke-ring," and a chain for securing the traces.

YOKE OF LAND. In England, the quantity of land which a yoke of oxen can plough in a day. Hence, in some parts of Kent, a little farm, from its only requiring a yoke of oxen to till it, is called a "yokelot."

YOLK. See Egg, and Wool.

YOUNG, ARTHUR. A celebrated agricultural writer and farmer; perhaps the most popular author on rural affairs that England or any other country has produced. His characteristics were those of the English, and energy, with a copious flow of plain and intelligible language, which the meanest capacity could readily comprehend; and although he possessed few claims to be ranked as a scientific farmer, yet he succeeded by his labours in exciting a general love of agriculture in the upper classes of his countrymen, which has, since his day, never materially subsided. And this feeling, although attended, through a want of practical information, with considerable individual loss, has yet produced great public advantages. It has been remarked, indeed, of the writer Young, that they produced more private losses and more public benefit than those of any other author. A memoir of this extraordinary man was published soon after his death by Dr. Paris, his friend and medical attendant.

His services to agriculture were important, and they would have been still more valuable if he had confined himself to the improvement of the science of agriculture, and avoided all those many political and party themes of which he was ever too ready to be the champion.

This morbid feeling he carried with him to the Booth of Agriculture; and, in consequence, both Arthur Young and the land of which he was long the chief spirit, experienced the same fate,—they obtained the support of only a section of the farmers of England, and they much too often laid themselves open to the charge of being more intent upon the advancement of the interests of their party than those of practical agriculture. Thus the very first sentence of the first volume of the Annals of Agriculture, published in 1790, is as follows:—"The parties of one country and the debility of another having at last extinguished the torch of discord," and the entire essay comprehends hardly anything else than a political survey of the state of the kingdom, and its possessions, fisheries, &c. It speaks with much zeal of the French Revolution, union with Ireland, customs, exports, tonnage, produce of the taxes, population, national debt, West Indian plantations of Great Britain; indulges in all kinds of visions; gives a statement of what the editor would do if he were made a king, &c., &c.; and hardly a page is reserved for practical
Young, Arthur.

Young, Arthur, was the descendant of a respectable family, who had resided on their estate at Bradfield Combust, near Bury St. Edmund's, in the county of Suffolk, for more than two centuries; he was born in London, on the 7th of September, 1741. His father, the Reverend Arthur Young, rector of Bradfield, had three children; John, and a daughter Elizabeth; the third was Arthur, the subject of the present memoir, who was educated at Lavenham, a school about six miles from Bradfield Hall.

Arthur Young was brought up for mercantile pursuits, in a merchant's counting-house at Lynn, where, at the age of 17, he commenced his literary career by writing a political pamphlet, entitled The Theatre of the present War in North America; and then four novels—The Fair American, Sir Charles Beaufort, Lucy Watson, and Julia Benson, or the Innocent Sufferer. In 1763 he returned from the residence of his uncle in London to his mother at Bradfield Hall, without any prospect of a pursuit, profession, or employment. His whole income, during the life of his mother, arising from a copyhold farm of 20 acres, and producing only as many pounds, she was anxious that he should reside with her; and, as the lease of her farm of 80 acres, his literary career short, she urged him to undertake its cultivation, a scheme so much in unison with his taste and wishes, that he did not long hesitate in accepting her proposal, and he embarked as a farmer. Young, eager, and totally ignorant, as he then was, of every necessary detail, it is not surprising, as he used to say, that he should have squandered large sums, under golden dreams of improvements, especially as he had a thirst for experiment, without a knowledge of what is demanded for its success. In this year (1765) he married Miss Martha Allen, of Lynn, and in the year 1767 undertook the management of the farm of 80 acres in Essex, which consisted of about 300 acres of land. Various unforeseen circumstances, and embarrassments from the want of capital, soon induced him to give 100l. to a farmer for taking the estate off his hands; and this farmer, by the advantages of capital, realized a fortune upon it. It was here, uniting the plough with the pen, that he wrote his work entitled, Political Essays on the Present State of the British Empire, but which was not published until 1772, in 1 vol. 4to. He now advertised for another farm, and the knowledge which resulted from viewing the different farms of Essex, in this occupation, and to his notice, furnished him with the materials for his tour, which he called The Six Weeks' Tour through the Southern Counties. By the advice of his Suffolk bailiff, he hired a farm of 100 acres in Hertfordshire; and, from viewing it in an uncommonly favourable season, they were both deceived in the nature of the soil. "I know not," said Young, "what epithet to give this soil; sterility falls short of the idea; a hungry, vitriolic gravel— I occupied, for 9 years, the jaws of a wolf. A nabob's fortune would sink in the attempt to raise good arable crops, upon so extensive a scale. I had increased from travelling and from practice; but all was lost when exerted upon such a spot. I hardly wonder at a losing account, after fashion had fixed me upon land, and calculated to swallow, without return, all that folly or imprudence could bestow upon it." It will be here naturally asked, why he did not go to land, decisively good? He answers the question very satisfactorily. "It was on account of the houses; for, although I saw numerous farms that would have suited well, they had wretched bovols on them."

Finding, about the year 1783, that his income was barely sufficient to meet his expenditure, he engaged to report the parliamentary debates for the Morning Post; this he continued to perform for several years; and after the hours of the week, he walked every Saturday evening to his farm, a distance of 17 miles from London, from which he as regularly returned every Monday morning. This was the most anxious and laborious part of his life: "I worked," says he, "more like a coal-heaver, though without his reward, than a man acting only from a predominant impulse." In 1774, he published Political Arithmetic, a work which met with high consideration abroad, and was immediately translated into several languages. Mr. Young has left a memorandum which states that he received for his different writings in the interval between the years 1766 and 1775, the sum of 3000l.

In 1784 he commenced the publication of his Annals of Agriculture, in which he appeared in the double capacity of editor and author, a work which he continued to the period of his blindness; it extends to 45 vols. 8vo, and presents a vast store of information upon subjects of agriculture and political economy. The plan upon which it was conducted was one which ought to have ensured for it more extensive and profitable patronage, for, instead of recording anonymous correspondence, it refused admittance to any paper that did not bear the name and address of its author; it can accordingly boast of communications from the most exalted and enlightened characters in Europe, at the head of whom stands our late most gracious sovereign, who transmitted to Mr. Young for publication an account of the farm of Mr. Duckett, the able cultivator of Petersham, which is recorded in the 7th volume of the Annals, under the signature of "Ralph Robinson." During the progress of this work he travelled (and he published a popular description of his travels over most parts of England, into Ireland, and in France.)

In 1793, animated as he always was by the spirit of adventure, he could not resist an opportunity that occurred for realizing the favourite speculation he had so long entertained—that of cultivating a large tract of waste land. He accordingly completed the purchase of 4,400 acres of waste in Yorkshire. But his fates had deuced other things for him. The Board of Agriculture was established in the August of 1793, and he was immediately appointed its secretary. An individual is rarely appointed to an official situation on account of his possessing in an eminent degree those qualifications which its duties require; but in the instance of Mr. Young this was undoubtedly the fact;
his general and profound knowledge in agriculture was the only circumstance that marked him as the most proper person to fill a situation in every respect so important and honourable. "The gratification," says he, "of being elected into so respectable a situation, in which opportunities of still giving an humble aid to the good cause of the plough could scarcely fail of offering, would not permit me to decline the appointment; although, to a person established in the country, the salary, with the residence annexed, was not that pecuniary object which has been represented; and I must have improved on bad principles indeed, if it would not, in a few years, have turned out a more profitable speculation. (The salary was 400l per annum, with a house free from all charge.) What a change in the destination of a man's life! Instead of entering, as I proposed, the solitary lord of 4,000 acres, in the keen atmosphere of lofty rocks and mountain torrents, with a little creation rising gradually around me, making the desert smile with cultivation, and grouse give way to industrious population, active and energetic, though remote and tranquil; and every instant of my existence making two blades of grass to grow where not one was found before—behold me at a desk, in the smoke, the fog, the din of Whitehall; with special and, so has been my mind employed. The die, however, is cast, and my steps may still be, metaphorically, said to be in the furrow."

At the Board Arthur Young continued to his death, zealously employed on all occasions as its secretary, in the service of agriculture—old age at last crept on; he became blind, and afflicted with the complaint which caused his death. He was attended (concludes Dr. Parls) by Mr. Wilson, Mr. Chilver, and myself; and although the incurable nature of his disease defied every hope of permanent relief, yet his sufferings were greatly palliated by the resources of art, and he died without entertaining the least suspicion of the malady under which he suffered. Pious resignation cheered him in his illness, and not a murmur of complaint was heard to escape his lips. On the 15th of April, in the year 1820, at his house in Sackville street, after taking a glass of lemonade, and expressing himself calm and easy, he expired. His remains were conveyed to Bradford, and deposited in a vault in the church-yard.

I have thus offered a brief sketch of the principal labours of Arthur Young, a man who filled a large space in the public eye for a long series of years, but whose name and talents appear to have commanded still greater notice and respect in foreign countries than in his own. That he reflected lustre on the age and the country in which he lived can be hardly denied. Of what other philosopher can it be said that at one time he entertained, under his humble roof, pupils of seven different nations, each of whom had been sent to him, for instructions in agriculture, by his respective governments? I was lately informed by his daughter, that the late Duke of Bedford breakfasted at Bradford on one of the mornings of a Newmarket race-meeting, and was met by pupils from Russia, France, America, Poland, Sicily, and Portugal. His numerous works are distinguished by vivacity of thought, quickness of imagination, bias to calculation, and fondness for political speculation; and had they been less successful, posterity might perhaps have regarded these traits of genius as fatal defects, and as pregnant sources of fallacy and disappointment.

YUCCA (commonly called Adam's needle). An American genus of plants found on the sandy sea-coasts of the Southern States and tropical regions, several of which are made to subserve valuable purposes. Nuttall gives the following description of the characters of the genus and individual species:

1. Y. filamentosus. 2. Angustifolia. Stemless; leaves glaucous, long, linear, and mucronate, margin filamentose; capsules large and dry, oblong-obovate. Habitat on the banks of the Missouri, from the confluence of the river Platte to the mountains. Flowers large and white; leaves scarcely half an inch wide.

3. Recurrens. In sandy fields, North Carolina. 4. Glaucous. Capsule internally filled with a sweetish pulp of a purple colour. This plant is called petre by the Mexican Spaniards, and used for cordage, ropes, &c., as well as for packing-cloth, and is extremely durable.

5. Albiflora. There is also a 6th species of this genus, discovered by the late Mr. John Lyons, improperly called Y. angustifolia by the gardeners around London: it is nearly allied to Y. filamentosus, but has much narrower leaves; with its specific characters I am unacquainted.

The soil and climate of East Florida are believed to be well adapted to the culture of these and many other plants, the fibres of which are converted into fabrics and cordage of great value. The general government, a few years since, granted a large tract of land in that territory to the late Dr. Perrine for the purpose of encouraging the introduction of the Sisal hemp, and other filamentous plants and tropical productions. The recent melancholy massacre of this gentleman and his family by the Indians have frustrated these attempts, for a time at least. See Hemp.

ZAPZIEGER, or SAP-SAGO, a kind of cheese made in Switzerland. See Cheese and SAP-SAGO.

THE END.
